All trademarks displayed are the trademarks of the parties noted herein. *Critical Care Transport*, *Third Edition* is an independent publication and has not been authorized, sponsored, or otherwise approved by the owners of the trademarks or service marks referenced in this product.

There may be images in this book that feature models; these models do not necessarily endorse, represent, or participate in the activities represented in the images. Any screenshots in this product are for educational and instructive purposes only. Any individuals and scenarios featured in the case studies throughout this product may be real or fictitious but are used for instructional purposes only.

The procedures and protocols in this book are based on the most current recommendations of responsible medical sources. The American Academy of Orthopaedic Surgeons and the publisher, however, make no guarantee as to, and assume no responsibility for, the correctness, sufficiency, or completeness of such information or recommendations. Other or additional safety measures may be required under particular circumstances. Clinicians should use their own independent medical judgment, in addition to open discussion with the patient, when developing patient care recommendations and treatment plans.

This textbook is intended solely as a guide to the appropriate procedures to be employed when rendering emergency care to the sick and injured. It is not intended as a statement of the standards of care required in any particular situation, because circumstances and the patient's physical condition can vary widely from one emergency to another. Nor is it intended that this

textbook shall in any way advise emergency personnel concerning legal authority to perform the activities or procedures discussed. Such local determination should be made only with the aid of legal counsel.

CONTENTS

Acknowledgments

1 Introduction and Overview of Critical Care Transport
Introduction
Critical Care Team Composition and Qualifications
Modes of Transportation
The Transport Process
State and National Standards
Reimbursement
Well-Being
Interpersonal Communication
Quality Assurance and Improvement
The History of CCT
Summary

2 Medical-Legal Issues
Introduction
General Concepts of Liability
Insurance
The Patient’s Right to Decide
Emergency Medical Treatment and Active Labor Act
Health Insurance Portability and Accountability Act
Legal Considerations During Transport Operations
Documentation
Summary

3 Patient Safety
Introduction

History of Quality as a Health Care Discipline
What Is Patient Safety?
Safety Culture
Common Health Care Errors
Why Do Health Care Errors Occur?
Handling Serious Errors
Tools to Identify Errors
Strategies to Avoid Errors
Quality in EMS Settings
Summary

4 Aircraft Fundamentals and Flight Physiology
Introduction
The Air Medical Role
The Atmosphere
Gas Laws
Medical Transport Aircraft
Primary Stressors of Flight
Factors Affecting Tolerance of the Physiologic Stressors of Flight
Hypoxia
Dysbarism and Evolved Gas Disorders
Operational Issues Related to Medical Transport
Air Medical Safety
Making the Industry Safer
Summary

5 Patient Assessment
Introduction
Scene Versus Interfacility Transports
Arrival and Planning
Primary Assessment
Secondary Assessment
Ongoing Assessment
Assembling the Assessed Information
Communications With Receiving Facilities
Summary

6 Respiratory Emergencies and Airway Management
Introduction

Anatomy and Physiology of the Respiratory System
Physiology of the Respiratory System
Patient Assessment
ABG Monitoring
Noninvasive Ventilatory and Oxygenation Monitoring
Respiratory and Ventilation Abnormalities
Basic Airway Management
Advanced Airway Management
Tracheostomy Management
Summary

7 Ventilation
Introduction
Overview of Mechanical Ventilation
Positive-Pressure Ventilators
Ventilator Modes and Parameters
Inhaled Gases
Respiratory Distress and Respiratory Failure
Ventilator Management
Management of Lung Diseases and Conditions
Patient Monitoring
Ongoing Care
Flight Considerations
Basic Ventilator Waveform Analysis
Troubleshooting and Diagnosing Ventilator Problems
Transporting the Patient With a Tracheostomy
Summary

8 Critical Care Pharmacology
Introduction
Pharmacology and Medication Information
A Practical Approach to Medication Administration
Pharmacokinetics
Pharmacodynamics
Avoiding Medication Errors
Medication Management
Specific Medications Used in Critical Care Transport
Medication Infusion Technique
Summary

9 Laboratory Analysis and Diagnostic Studies
Introduction
Principles of Analysis
Specimen Cultures
Chemistry Review
Biochemistry Review
Lab Panels
Blood Gases
Obtaining Blood Samples
Point-of-Care Testing
Urine Lab Values
Diagnostic Imaging
Summary

10 Resuscitation, Shock, and Blood Products
Introduction
Cellular Respiration
Microcirculation and the Cell: Oxygen Transport and Utilization
Shock
Classification of Shock
Sepsis
Blood Administration
Flight Considerations
Summary

11 Trauma
Introduction
Scenarios Involving Trauma Patients
Morbidity and Mortality
Overview of Trauma
Trauma Scoring Systems
Trauma Systems
Interfacility Transport Trauma Management
The Hypothermia–Acidosis–Coagulopathy Triad
Diagnostic Imaging for Trauma
Thoracic Trauma
Pneumothorax
Facial Trauma
Neck Injuries

Abdominal Trauma
Resuscitative Endovascular Balloon Occlusion of the Aorta
Hollow Versus Solid-Organ Injury
Pelvic Trauma
Extremity Trauma
Trauma to Special Populations
Flight Considerations
Summary

12 Neurologic Emergencies
Introduction
Anatomy and Physiology
Neurologic Examination
Traumatic Brain Injury
Specific Neurologic Injuries
Intracranial Pressure
Brain Herniation
Spinal Cord Injuries
Stroke
Intracerebral Hemorrhage
Subarachnoid Hemorrhage
Acute Guillain-Barré Syndrome
Seizures and Epilepsy
Transport Considerations
Summary

13 Burns
Introduction
Anatomy and Function of the Skin
Physiology of Burns
Classification of Burn Injuries
Assessment
Management
Special Situations
Summary

14 Electrophysiology, Pacemakers, and Defibrillators
Introduction
Cardiac Anatomy and Physiology

Cardiac Monitoring: 12-Lead ECG
Axis Determination
Bundle Branch Blocks and Hemiblocks
Selected ECG Findings
Cardiac Disease
Cardiac Electrophysiology
Transport Considerations
Summary

15 Hemodynamic Monitoring
Introduction
Cardiovascular Anatomy and Physiology
Arterial Lines
Central Venous Lines
Pulmonary Artery Catheters
Invasive Pressure Measurements
Heart Failure
Shock
Flight Considerations
Summary

16 Mechanical Circulatory Support
Introduction
Intra-aortic Balloon Pump
Extracorporeal Membrane Oxygenation
Microaxial Catheter Pump Systems
Implantable Left Ventricular Assist Devices
Summary

17 Gastrointestinal and Genitourinary Emergencies
Introduction
Anatomy and Physiology
Conditions Affecting the Alimentary Canal
Intestinal Obstructions
Liver Disease
Biliary Tract Obstructions
Pancreatic Disease
Urinary System Conditions
Maintenance Tubes

Metabolic Regulation of Acid–Base Status
Flight Considerations
Summary

18 Endocrine Emergencies
Introduction
Anatomy and Physiology
Diabetes
Pituitary Disorders
Adrenal Abnormalities
Thyroid Abnormalities
Lipid Disorders
Flight Considerations
Summary

19 Environmental Emergencies
Introduction
Heat Emergencies
Cold Emergencies
Drowning
Diving Injuries and Decompression Sickness
Altitude Illness
Summary

20 Infectious and Communicable Diseases
Introduction
Fundamental Principles of Infectious Disease
The Human Immune System
Pathogenicity
Epidemiology
Selected Diseases
Emerging Infectious Diseases
Strategies for the Treatment of Infectious Disease
The Post-Antibiotic Era
Bioterrorism
Exposure and Protection
Flight Considerations
Summary

21 Toxicologic Emergencies
Introduction
General Toxicologic Emergency Management
Toxic Syndromes and Medication Reaction Syndromes
Decontamination
Specific Toxicologic Emergencies
Hazardous Materials Response
Radiation Emergencies
Flight Considerations
Summary

22 Obstetric and Gynecologic Emergencies
Introduction
Anatomy and Physiology of the Female Reproductive System
Physiologic Changes During Pregnancy
Critical Care Transport of the Pregnant Patient
Fetal Assessment and Monitoring
Complications of Pregnancy
Medical Conditions During Pregnancy
Complications During Labor
Delivery
Postdelivery Complications
Gynecologic Emergencies
Gynecologic Trauma
Summary

23 Neonatal Emergencies
Introduction
Anatomy and Physiology of a Neonate
Neonatal Assessment and Stabilization
Neonatal Resuscitation
Respiratory Conditions
Cardiovascular Conditions
Gastrointestinal Conditions
Infectious Diseases/Sepsis
Hyperthermia/Hypothermia
Toxic Exposure
Trauma/Birth Injuries
Neurologic Conditions

Metabolic Conditions
The Transfer Process for a Neonate
Flight Considerations
Summary

24 Pediatric Emergencies
Introduction
Anatomy and Physiology
Growth and Development
Approach to Parents and Caregivers
Pediatric Assessment
Transport Considerations
Airway Management Devices
Respiratory Conditions
Mechanical Ventilation
Cardiac Conditions
Cardiac Anomalies
Renal Conditions
Meningitis
Trauma
Abuse and Neglect
Hypothermia During Transport
Drowning
Flight Considerations
Summary

25 Bariatric and Special Situations
Introduction
Bariatric Patients
Excited Delirium
Children With Special Health Care Needs
Summary

CHAPTER 1

Introduction and Overview of Critical Care Transport

Mike McEvoy, PhD, NRP, RN, CCRN

OBJECTIVES

After completing this chapter, you will be able to:

1. Define the terms *critical care*, *critical care transport*, *critical care patient,* and *critical care transport professional* (p 2).
2. Differentiate between interfacility and specialty care transport (p 2).
3. Describe the composition of the critical care transport team (p 3).
4. List the qualifications of members of a critical care transport team (pp 3–4).
5. Identify the modes of transportation used during critical care transports, including mobile (ground) units, rotor-wing aircraft, and fixed-wing aircraft (p 5).
6. Discuss the differences between the modes of transportation (p 5).
7. Discuss the advantages and disadvantages for each mode of transportation (pp 9–10).
8. Describe the role of dispatch in determining the mode of transportation (pp 5–7).
9. Describe the steps involved in the transport process (pp 7–9).
10. Discuss how the decision for ground transport versus air transport is made (p 9).
11. Describe the role of medical control in the critical care transport environment (pp 10–11).
12. Discuss state and national standards for critical care transport (pp 11–12).
13. Discuss reimbursement criteria and their relevance to critical care transport (p 12).
14. Identify sources of stress specific to the critical care transport professional and their signs (pp 12–14).
15. Discuss ways to ensure safety for both critical care transport professionals and their patients (p 14).
16. Discuss the importance of interpersonal communications with the patient and family members (pp 14–15).
17. Explain the process of quality assurance and improvement, and understand the importance of maintaining skills and knowledge (p 15).

18. Summarize the history of critical care transport, including both air and ground transport (pp 15–20).

Introduction

Trends in Patient Transportation

The continued evolution of health care has dramatically affected patient transportation. Notably, in recent times the emphasis on efficiency and cost containment has altered referral patterns and increased utilization of specialty centers. Payers and providers are increasingly referring patients with urgent conditions to alternative destinations such as clinics and freestanding emergency centers. Nurses, paramedics, and physicians routinely visit patients in their homes. Use of telemedicine skyrocketed during the coronavirus disease 2019 (COVID-19) pandemic, not only facilitating virtual house calls but also providing ready access to consultation by health care providers in the field or outlying facilities. Treatment of patients with costly and more complex conditions is being migrated to increasingly sophisticated specialty centers. As these facilities become more advanced, they are absorbing the workload of lower-volume specialty centers, many of which are closing because they were not designed for today's high patient volumes or cutting-edge procedures. Rural hospitals are also closing their doors, unable to cope with the regulatory burden of the 21st-century health care system.

Emergency medical services (EMS) are experiencing shifts in call types as more Americans obtain health insurance and their payers prioritize destinations for their care other than emergency departments (EDs). Closer scrutiny of costs and billing practices has also significantly curtailed ambulance and ambulette transport of patients for routine tests and procedures. At the same time, health insurance plans and accountable care organizations have a significant financial incentive to transport their insured patients back to contracted health care centers when they become injured or seriously ill outside of their home networks.

Even as emergency and routine ambulance and ambulette transports continue to decline, **critical care transport (CCT)** volumes have increased—and will continue to increase—exponentially. Moreover, the field of critical care has become increasingly complex. **Critical care** is intensive care and monitoring provided to patients with life-threatening conditions that require constant monitoring and treatment with drugs and equipment.

Despite our best intentions, health care is not always safe for the **critical care patient**. Unintentional harm and unnecessary deaths continue to occur at alarming rates. The larger the number of medications and the more complex the equipment being used, the greater the likelihood of an adverse event. Critical care units may be the riskiest patient care environments for patients. Because it lacks many of the common safety practices and technologies employed in critical care units, such as bar-coded medication administration, independent double-checks, and readily accessible intensive care physicians (to name a few), the CCT setting may have an even greater potential for errors leading to patient harm. Indeed, significant adverse events—such as hypothermia, hypotension, drug errors, procedure errors, loss of vascular access, and ventilator and oxygen system malfunctions—frequently occur during these transports.

Transports once managed exclusively by physicians and nurses now rely on emergency medical technicians (EMTs) and paramedics to conduct them. Use of specialized teams with CCT training has been shown to decrease rates of adverse events in the transport of children and neonates. A growing body of evidence indicates that specialized CCT teams can also offer more competent and safer care to critically ill adults during transport. This text provides a core curriculum for the specialized and additional education needed to aid providers in bridging the gap from their respective educational foundations to the level of **critical care transport professional (CCTP)**.

Definitions

The terms **interfacility transport (IFT)** and **specialty care transport (SCT)** are often used interchangeably when, in fact, they represent different types of CCT. IFT is the transport of a patient between two health care facilities. For health insurance billing claim purposes, definitions of facilities are typically obtained from the Centers for Medicare and Medicaid Services (CMS), because other health insurance plans in the United States often adopt CMS rules and definitions in administering their own plans. Health care “facilities,” as defined by CMS, include skilled nursing facilities and hospitals that participate in the federal Medicare program. IFT, then, may involve transport between hospitals, between clinics and hospitals, between hospitals and rehabilitation facilities, or between hospitals and long-term care facilities.

CMS defines SCT as the interfacility ground transport of a critically ill or injured patient, including provision of medically necessary supplies and services that are beyond the paramedic scope of practice. SCT is necessary, according to CMS, when a patient’s condition requires ongoing care from providers in a specialty area such as emergency or critical care nursing, emergency medicine, respiratory care, or cardiovascular care, or from a paramedic with additional training. For a service to bill CMS for SCT, three conditions must be met: (1) the patient must be critically ill or injured, (2) the transport must be interfacility, and (3) the care provided must be beyond the scope of a paramedic. Thus, merely putting a nurse aboard an ambulance does not turn that transport into SCT, nor does moving a stable ventilator-dependent patient from a skilled nursing facility to a hospital meet the definition of SCT.

Setting the CMS definitions aside, CCT is a transport level of care provided to a patient with immediate life threats from injury or illness. Unlike the CMS definition of SCT, which specifies ground transport, the definition of CCT does not designate a specific mode of transportation. CCT requires a specialized body of knowledge and skills, an environment with the proper equipment, and ability above and beyond the intensive care unit (ICU) environment to address the specific challenges encountered during transport.

This curriculum recognizes that CCT team composition varies considerably from one area to another and with respect to the resources and skills needed to transport each patient. Team members may include almost any health care provider with an expertise in caring for a particular CCT patient.

Critical Care Team Composition and Qualifications

Crew Configurations

The most common CCT crew configurations used in the United States employ various combinations of EMTs, paramedics, registered nurses (RNs), and respiratory therapists (RTs). Crew configurations depend largely on the staffing policy of the organization, state requirements, scopes of practice, and patient needs **FIGURE 1-1**. Additional crew members, including **perfusionists**, surgeons, neonatologists, or pediatric intensivists, may be required for certain patient transports.

FIGURE 1-1 The CCT team composition varies depending on staffing policies, state requirements, scopes of practice, and patient needs.

© Kevin Frayer/AP/Shutterstock.

A three-member team configuration is sometimes used, but is less common than the two-member crew because of the increased costs associated with adding a third staff member as well as the space and weight limitations of some transport vehicles. Most patients requiring CCT do not have a condition that necessitates a third team member.

Educational Qualifications

Just as crew configurations vary, so do the recommended educational qualifications for each team member. CCTPs must be able to provide care at the same, or higher, level than their non-CCT counterparts. In addition, they must be educated and proficient in the following skills:

- Advanced practice procedures, such as managing surgical airways or performing an escharotomy
- Management of chest tubes
- Blood product administration
- Intracranial pressure monitoring
- Mechanical circulatory support
- Central line management
- Invasive arterial and cardiac pressure monitoring
- Interpretation of lab test results and diagnostic imaging
- Use and troubleshooting of ventilators
- Use of a variety of invasive catheters, tubes, and drains
- Management of pacemakers
- Use of portable ultrasonography

Many of these devices and procedures may not be covered by CCTPs' formal medical education.

Because critical care medicine is a dynamic, ever-changing science, CCTPs must be lifelong learners. Most CCT programs require CCTPs to complete frequent continuing professional education classes, which exceed the requirements to maintain the state or national certification and/or licensure necessary for employment. Most CCT services hold a variety of mandatory educational and competency training days each year. Objectives of these sessions include reviewing uncommonly used advanced procedures, validating skills and competencies, simulating case-based scenarios, and disseminating cutting-edge clinical information.

Types of CCTPs

Emergency Medical Technicians

An EMT is trained at the basic life support level and frequently operates the emergency transport vehicle. This position requires completion of an EMT course and current EMT certification by the state in which the person practices. Under the current National EMS Education Standards, most EMT courses require roughly 148 hours to complete. Employers and states may mandate additional requirements. Because the EMT role involves driving the CCT team, training in the form of an emergency vehicle operator course (EVOC) is highly recommended. Like all health care providers, an EMT should maintain current certification and proficiency in cardiopulmonary resuscitation (CPR).

Paramedics

Paramedics are trained at the advanced life support level. They may be the primary CCTP, or they may work with an RN or another paramedic-level provider. This position requires completion of a paramedic course and current paramedic certification in the state in which the person is practicing. Some states require certification by the National Registry for EMTs as a Nationally Registered Paramedic (NRP) to attain state paramedic certification. Most paramedic courses meeting the current National EMS Education Standards encompass some 1,200 hours of didactic and clinical time, in addition to demonstrating competency. Beginning in 2013, paramedic program graduates seeking National Registry of EMTs certification must have graduated from a program that is approved by their state and accredited by the Commission on Accreditation of Allied Health

Education Programs (CAAHEP). Not all states require their approved paramedic programs to be accredited by the CAAHEP. Given that many CCTP programs desire paramedics with NRP certification, however, prospective CCTP candidates should verify that the paramedic program they apply to is CAAHEP accredited.

Many programs require paramedic CCTPs to have at least 5 years' experience in a busy 9-1-1 EMS system and hold specialty certifications in basic, advanced, pediatric, and neonatal life support, as well as basic and prehospital trauma life support. In addition, they should have successfully completed a sanctioned CCT course of training.

Registered Nurses

RNs are licensed health care providers. In a CCT service, RNs may be the primary CCTP, or they may work with another RN or paramedic provider. This position requires completion of a state-approved nursing program and licensure by the state in which the person is practicing. Obtaining licensure requires successful completion of the National Council Licensure Examination for Registered Nurses (NCLEX-RN), which is administered by the National Council of State Boards of Nursing.

Programs frequently require RN CCTPs to have at least 5 years' experience in a combination of the following areas: critical care, emergency nursing, and prehospital care. They should also hold specialty certifications in basic, advanced, pediatric, and neonatal life support; have completed an advanced trauma nursing course; and preferably hold an emergency, flight, ground transport, or critical care nursing specialty certification. Many CCTP programs desire or require CCTP RNs to have paramedic certification as well, since paramedics' training and scope of practice differ significantly from those of nurses.

Respiratory Therapists, Perfusionists, and Physicians

When patient needs dictate their inclusion, RTs, perfusionists, and advanced providers such as nurse practitioners or physician assistants, physicians, or surgeons may be members of the CCT team. Rarely are these providers permanent members of the CCT team; instead, they typically join the CCT crew on an as-needed basis. The institutions or practices that employ these providers credential them, verify their education and licensing, and often monitor their practice. It is important to remember that non-CCTP providers accompanying a CCT team on transport are likely clinical experts in management of a specific patient problem or technology but rarely have equivalent experience operating in the harsh and often adverse transport environment. They typically require assistance in preplanning for anticipated complications related to transport.

Modes of Transportation

Modes of transportation vary widely from agency to agency and by region of the country. The optimal transportation mode is dictated by patient acuity, distance between the sending and receiving facilities, ability of the transport service to respond, weather conditions, and the topography of the region. The standard types of **mobile intensive care units** used for CCT include ground units, rotor-wing aircraft, and fixed-wing aircraft. Commonalities among these transportation modes include availability of standard equipment, adequate room for specialty equipment and providers to deliver patient care, compliance with safety standards, electrical power, adequate lighting systems, and reliable communication systems with redundant backup.

Equipment

States have specific equipment requirements for transport vehicles, and professional organizations interested in CCT publish lists of recommended additional equipment. The additional and specialty equipment carried on a CCT vehicle must fit the mission profile of the CCT service. It is particularly important that electrical power systems such as generators or inverters are readily accessible for troubleshooting should power issues arise during transport.

Mobile Units

Mobile (ground) units, commonly referred to simply as ambulances, are typically used to transport critically ill or injured patients for distances of up to 50 miles (80 km). They may be used for greater distances when the transport is not time critical. A ground unit may also be used when a patient has contraindications to air transport. Ground units are available in a wide variety of configurations, body types, and sizes to suit the needs of the specific provider.

Rotor-Wing Aircraft

Rotor-wing aircraft, commonly called helicopters, are used to transport critically ill and injured patients in rural and difficult-to-access settings; they can travel for distances of up to 150 miles (240 km). A wide variety of helicopters are available for use, including the BK 117, Bell Model 220/230, Sikorsky S-76, AgustaWestland AW109, and Dauphin **FIGURE 1-2**. These helicopters can be single- or twin-engine models. Depending on the design, patients may be loaded from the side or the rear of the aircraft. As with ambulances, the size and type of helicopter varies by program needs and the area serviced.

Fixed-Wing Aircraft

Fixed-wing aircraft, or planes, are typically used to transport critically ill or injured patients for distances of 150 miles (240 km) or more. These aircraft are often used in combination with mobile critical care units, which transport patients to the aircraft take-off site **FIGURE 1-3**.

For further discussion of the types of aircraft used in CCT, see Chapter 4, *Aircraft Fundamentals and Flight Physiology*.

The Transport Process

Dispatch

Dispatch is the first point of contact for the CCT team. The dispatch center may reside within a hospital, in a 9-1-1 center, or at a remote, independent site. Regardless of its location, the initial triage process starts with the dispatch center's call taker. The call taker typically follows a standard question template to obtain information about the patient and their condition from the referring facility. Call-taking checklists ensure dispatchers cover all relevant information so providers can arrive fully prepared, but also so the sending facility can properly prepare the patient for transport. Pertinent information that should be obtained from the referring facility includes the following:

- Patient age
- Patient weight
- Diagnosis
- Number and type of infusions
- Most recent vital signs
- Level of consciousness
- Airway status (patent or intubated)
- Presence of mechanical ventilation
- Presence of mechanical circulatory support devices

Although this list is not all-inclusive, it does provide dispatch center personnel with adequate information for making the proper decisions. Once this information is obtained, a clinical supervisor or algorithm should be used to help select the most appropriate crew configuration and mode of transportation. Often, the attending physician and staff at the referring facility suggest a particular mode of transportation.

Many CCT services honor these requests, whereas others make their own determination based on the patient report provided.

Dispatch centers should also be cognizant of certain equipment, medications, or infusions described when taking IFT calls. The following information should raise a flag for the call taker that the transport likely requires a CCT team:

- Mechanical ventilation
- Infusions running into vascular access devices
- Vasoactive medications
- Blood or blood product infusions (eg, blood, plasma, platelets, cryofibrinogen)
- Mechanical circulatory support devices (eg, intra-aortic balloon pump, extracorporeal membrane oxygenation, ventricular-assist device)
- Patient instability requiring frequent interventions such as sedation, paralytics, or analgesia

Transport Choreography

Communication breakdowns are the root cause of many, if not most, adverse outcomes for patients during CCT. Communication begins with the receipt of a request for transport. Dispatch center staff talk directly with a referral source to obtain medical details, insurance information, and demographic information needed to prioritize the request, determine patient acuity, and assign appropriate resources (equipment and personnel) to the transport.

Transport choreography starts on receipt of a request for transport. Just as it is inadvisable to respond to a 9-1-1 call without knowing the location and type of call, it is inadvisable to roll into a hospital without obtaining details about the patient and equipment needed in advance. Knowing what you are walking into helps you prepare for that situation. A well-choreographed approach to each transport will make the move safer and improve patient outcomes.

Time Frame

The response following the receipt of a request for CCT may vary depending on the circumstances. Some contracts between transport services and referring hospitals specify response times, whereas other facilities rely on the availability and staffing of the service to meet their needs. In general, the critically ill nature of the typical CCT patient suggests a need for the CCT team to arrive within 60 minutes from the time of request. Referring facilities, however, may request a longer or shorter interval depending on patient needs, tests or procedures in progress, and the receiving facility's availability to accept the patient.

The generally accepted time frame for a CCT team to receive the report from the handoff team, package the patient, and begin moving the patient to the transport vehicle is 20 minutes. In situations where additional interventions or procedures are needed to stabilize or prepare the patient for transport, bedside times may be longer. Evidence suggests that extended bedside times are associated with worse patient outcomes. Meeting the 20-minute standard is no easy feat when a complex critical care patient is attached to a variety of medical devices and equipment. It takes practice and skill to achieve this goal.

Planning for the Patient Transfer

Planning should begin on arrival at the referring facility. Always maintain situational awareness of the ingress and egress pathways at this facility, and later at the receiving facility. Failure to plan for the dimensions of these pathways could result in problems with equipment or machinery accompanying the patient not fitting through doorways, preventing you from smoothly exiting the referring facility and accessing your transport vehicle.

Handoff Considerations

Handoff refers to the brief report that staff at the sending facility—generally the bedside nurse, physician, or care provider currently responsible for the patient—submits to the CCTP team when they arrive to accept responsibility for the patient's care. There is no standardized handoff practice between hospital staff and CCTPs; however, safety experts and accreditation bodies recommend that agencies and providers incorporate standardized practices into their routines, including use of checklists. Equipment checklists help avoid omissions so providers will have all the tools and supplies required to manage the patient's condition during transport.

Communicating With Hospital Personnel

It cannot be overemphasized that the worlds of CCT and EMS are far removed from those of the ED and inpatient hospital practitioners. While the medications and care provided are similar, the equipment and practices employed by CCTPs are as unfamiliar to hospital personnel as hospital practices are to CCTPs.

The handoff should include medical records from the sending facility and physician orders for the patient during transport, which are usually accompanied by a physician certification statement (PCS) that documents the reasons for transfer, the potential risks and benefits of the transfer, and the patient's current condition(s). Medical records from the sending facility are sent not only for reference by the receiving facility, but also so the CCTP can confirm the information presented during handoff and answer specific questions not addressed during the handoff that may arise during transport.

Your CCTP team must quickly make two determinations during the handoff: (1) Are the patient's needs within your scope of practice? and (2) Will you be able to safely manage this patient during transport? Certain red flags may become evident during the initial report, warranting further questioning and planning:

- The referring provider tells you that other transport services refused the transfer.
- The medications or equipment required are beyond your training, experience, or scope of practice.

- There is no recent charting on the patient by nursing or medical staff.
- The sending providers seem unfamiliar with the patient.
- Inconsistencies exist between the dispatch information and the information provided during the handoff.
- The patient appears much sicker than described during dispatch, possibly even too sick to move.

In any of these situations, you should consult with not only the sending physician but also your own **online medical control/consultation (OLMC)** before moving the patient. The two most common sources of poor patient outcomes and resulting litigation involving CCT are failure to consult OLMC and inability of the CCTP to recognize or manage patient deterioration during transfer.

Initiating Transport

Once a cursory handoff has been accomplished, the crew can meet the patient/family and begin transferring care. Typically the equipment and stretcher are prepared and the patient is moved to the transport stretcher before transferring the ventilator, infusions, and other devices to the transport equipment. This approach allows all providers to continue discussing and assessing the patient's status while the patient is still attached to hospital equipment. Thus, hospital staff or CCTPs can properly position the patient and administer any necessary sedatives or analgesics needed to maintain the patient's current level of comfort. Once the patient is comfortable and stable, the ventilator, infusions, and other machinery attached to the patient can be assessed, prepared, and transferred to the equivalent transport devices. CCTP providers must remember that once they begin transferring hospital equipment, machinery, and infusions to their transport devices, they have assumed responsibility for the patient.

To avoid errors, two providers should check ventilator or respiratory device settings and compare these settings to both the transfer orders and the hospital's settings at the time of transfer. A

CCTP should read the labels on each IV being infused, trace the infusion line toward the patient, and label the distal end with the name of the medication or fluid. Providers should conduct a “pull-away” test in which they move the transport equipment 1 or 2 feet and carefully examine all tubing, plugs, and cables to ensure everything previously connected to hospital equipment has been successfully reconnected to the transport devices.

As noted earlier, problems occur quite frequently during CCT. Anticipating those problems and being prepared to address them require interpersonal as well as technical skills. During handoff, ask the hospital providers about any anticipated issues during transfer. Personnel caring for the patient want to see the good care they have provided continued and the best possible patient outcomes achieved. They may offer valuable insights into titration of infusions, positioning, and management of the patient, based on their experiences caring for this person. Make your best calculations about necessary oxygen, medications, fluids, electrical needs, and battery power. Any shortages can lead to poor patient outcomes. Anticipate and plan for equipment failures or accidental dislodgements of tubes, drains, venous access, or other lines. Subsequent chapters will address specific concerns associated with ventilators, pacemakers, and mechanical circulatory support devices during transport.

Transporting by Ground Versus Air

Each mode of transporting critically ill and injured patients has its own set of advantages and disadvantages. **TABLE 1-1** lists some of the advantages and disadvantages of each mode.

TABLE 1-1 | **Advantages and Disadvantages of Transportation Modes**

Transportation Mode	Advantages	Disadvantages

Transportation Mode	Advantages	Disadvantages
Mobile (ground) unit	• Large interior • Quieter than aircraft • No special vehicle housing needed • Less expensive to operate and maintain • Less specialized training needed to operate vehicle (emergency vehicle operator course) • Multiple provider capabilities • Less weather dependent • Fewer height and weight limitations • Fewer adverse effects on patient and crew	• Usually limited to single-patient transport • Slower than aircraft • Limited travel distance

Transportation Mode	Advantages	Disadvantages
Rotor-wing aircraft (helicopter)	• Speed (100–180 mph) • Specialized personnel and technology needed or provided • Few altitude ramifications below 2,000 ft (610 m) • Can service a larger catchment area • Two-patient capabilities	• Restricted by weather conditions • Interior space limitations • Expensive to operate and maintain • Special landing requirements • Need for FAA communications • Adverse effects on crew members and patients • Expensive for patient • Requires special vehicle housing • Limited space for providers and equipment • Weight limitations

Transportation Mode	Advantages	Disadvantages
Fixed-wing aircraft (plane)	• Speed • Multiple-patient capabilities • Capable of traveling great distances • Specialized personnel and technology needed or provided • No weight limitations • Instrument-assisted flying	• Adverse altitude considerations • Adverse effects on patient and crew • Need for FAA communications • Expensive for patient • Expensive to operate and maintain • Can serve only a small portion of the community • Requires special vehicle housing • Special landing requirements

Abbreviation: FAA, Federal Aviation Administration

The decision to transport a patient by ground ambulance or helicopter should be made as rapidly as possible. In most cases, the CCT patient needs expedient transport to a tertiary care center that can provide care not available at the present location. Helicopters allow for more rapid transport than ground vehicles because they can bypass vehicular traffic, intersections, and traffic signals, which might otherwise delay the total transport time. Nevertheless, even though a helicopter travels much faster than a ground ambulance, it is not always the most practical solution for transporting a patient to a tertiary care center. Helicopters are usually strategically located throughout a geographic area. Depending on the location of the referring hospital, a helicopter may have a lengthy travel time to reach the patient. At times, a helicopter may already be committed to another mission, significantly extending the response time. In such situations, a critical care ground ambulance may be significantly closer; thus, the most reasonable solution may be ground transportation.

Patient acuity is another major determinant of whether to transport by ground or by air. The referring physician, who remains responsible for the patient until care is transferred to the CCTP team, typically makes this decision. Time-sensitive conditions that may require air transport include the following:

- Acute myocardial infarction
- Acute cerebrovascular accident
- Severe traumatic injury
- Acute intracranial hemorrhage
- Surgical emergency (eg, acute aortic dissection, amputation requiring limb reattachment)
- Major burns

This list is not all-inclusive, and many other conditions and situations are particularly relevant when selecting the transportation mode. Each case must be evaluated individually, and a determination made after all data have been reviewed.

Because practical considerations might preclude use of the preferred transportation mode, an alternative transport method must be identified to ensure the patient will arrive at the accepting facility within a reasonable time frame. For example, a clinical coordinator could decide to transport a patient by helicopter or fixed-wing service, but bad weather might rule out flight. Sending a ground unit may be more harmful to the patient due to the extended time needed to reach the accepting facility. In most such cases, providers opt to wait for the weather to improve and launch the aircraft as soon as is practical. When the distance from the sending facility to the accepting facility is not lengthy, the CCTP team may choose to complete the mission by ground.

Helicopter Shopping

Helicopter shopping, a practice defined by the Federal Aviation Administration (FAA) as “the practice of calling, in sequence, various operators until an operator agrees to take a flight assignment, without sharing with subsequent operators the reasons the flight was declined by previously called operators,” is often cited as a contributing factor in fatal air medical crashes.

Medical Oversight

The complexities encountered in CCT patients require a very sophisticated level of care and an equally high level of medical direction. It is imperative that the service **medical director** has an active role in all aspects of the service that relate to patient care. In addition to a comprehensive set of triage, treatment, and transport protocols that include standing orders for the CCT team, OLMC must be available to CCTPs at all times **FIGURE 1-4**. OLMC can be helpful when CCTPs find it necessary to exceed or deviate from written protocols or standing orders; when unforeseen or unpredictable situations arise during CCT; in situations where patient complexity exceeds that ordinarily encountered; and in circumstances where CCTPs are unable to reach agreement with a sending or accepting provider regarding orders for patient care during transport.

FIGURE 1-4 Online medical control involves working directly with a medical control physician via phone or radio.

© Mark C. Ide.

While EMS physicians typically serve as medical directors for transport services, CCT may require expertise and experience outside the scope of an EMS-trained physician's practice. Depending on the breadth of services delivered and the equipment used, CCT services may require intensive care physicians (intensivists), critical care physicians, surgeons, or anesthesiologists to assist in providing medical control and oversight of their transports. Often, several physicians may need to work collaboratively to provide CCT medical control and oversight. Medical oversight is equally important in examining outcomes, the effects of care provided, the efficiency and compliance with processes in place, and all aspects of the service's quality assurance and improvement programs.

State and National Standards

In the United States, standards for CCT vary considerably from state to state. Most CCT programs follow national standards for training and equipment issued by professional organizations with an interest in CCT. As mentioned previously, the CMS describes SCT as requiring care beyond the paramedic’s scope of practice.

Although individual states may define the specific training required for a paramedic to qualify as a CCT provider, not all states have such requirements. In the absence of state requirements, CMS relies on regional and sometimes even agency-level requirements. Some states, such as Maryland, require any air medical service that operates in the state to be certified by the Commission on Accreditation of Medical Transport Systems (CAMTS). In most states, however, a state organization governs the licensure or certification of air medical services and their practitioners. For example, in Pennsylvania, the Department of Health licenses air medical transport services and prehospital care providers.

A CCTP’s scope of practice may also vary according to their level of certification and the state in which they practice. For example, RNs may administer nearly any medication ordered by a licensed prescriber, whereas paramedics are often restricted to medications approved and listed in their protocols or their state’s prehospital formulary. The most accurate information on regulations governing organizations and scope of practice is available from the state agency responsible for EMS accreditation and licensure.

The National EMS Scope of Practice Model outlines a framework under which all EMS providers, including CCTPs, operate. There are four elements in this model:

- **Education.** Cognitive, psychomotor, and affective learning that a person must undergo to act as a provider

- **Certification.** External verification of competencies that a provider has achieved through examination
- **Licensure.** Legal authority granted to an individual by the state to perform certain activities
- **Credentialing.** Clinical determination from a physician medical director that a provider is authorized to perform a skill or role

By the time EMS providers become CCTPs, they have already completed this process for their paramedic and/or nursing licensure, but they must continue to engage in professional development throughout their career. Sometimes a person might move from one state to another and need to become licensed there, or the person was credentialed to perform a certain procedure for a former employer, through the medical director, but is not credentialed at a new service. Providers must embrace education and training throughout their career.

National EMS-IDs

In 2020, the National Registry of EMTs launched the National EMS-ID number system. An EMS-ID is a 12-digit identification number issued at no charge to all EMS professionals, ranging from EMRs to paramedics, and to students entering the profession. This number is automatically generated by the National Registry when a person creates an account. For EMS providers with an existing account, an EMS-ID is created retroactively. Unlike the number issued by the National Registry (NR Number) when an individual becomes certified, EMS-IDs do not change as the person's certification level changes. Thus, all of the various certification numbers professionals may obtain in their career are tied back to the single EMS-ID.

There are no national consensus standards on CCT training courses, likely owing to the wide variation in CCT practices. The scope of services can range from transporting a mechanically ventilated patient with an arterial line and chest tube and several intravenous (IV) infusions to transporting a patient on extracorporeal membrane oxygenation with a dozen IV infusions. The typical level of care provided drives the additional training that CCTPs undergo. In general, a basic course covering the fundamentals of CCT requires at least 80 hours of additional training.

Reimbursement

Ambulance transport is expensive, and air medical transport is *very* expensive. CCT is even more costly than routine transport. In many cases, insurance reimbursement does not adequately cover transport costs, especially when overhead and operational expenses are factored in. The complexities of reimbursement, from determining the need for CCT to selecting the closest appropriate receiving facility and beyond, exceed the scope of this clinical text. Suffice it to say that health care reimbursement is undergoing a major shift from paying for care delivered to paying for health outcomes achieved. It is only a matter of time before quality and outcomes measures are connected to CCT reimbursement.

Well-Being

Well-being, according to the Centers for Disease Control and Prevention, is “a positive outcome that is meaningful for people and for many sectors of society, because it tells us that people perceive that their lives are going well”; it indicates that people are comfortable, healthy, and happy. Well-being is also a course component in EMT and paramedic programs, and the same tenets that apply to patients apply to the CCTP.

Resilience, a person’s ability to withstand negative pressure, or “bounce back” from difficulties, is associated with maintaining well-being. The three key determinants of personal resilience are thought to be biology (genetics), attachment, and control.

- *Genetics* is a component of a person’s biologic makeup and generally is not under the person’s control. One interesting characteristic of CCTPs, which is shared by paramedics and the nurses and physicians who work in ICUs, is the tendency for other family members to work in the same or similar high-stress occupations. This familial connection suggests there is a genetic predisposition toward resilience.
- *Attachment* refers to a person’s capacity to bond or form significant relationships with others. Associated with this aspect of personal resilience is the capacity for empathy, a characteristic commonly seen in CCTPs.
- *Control* refers to the degree of mastery a person feels over their environment, social competence, self-esteem, autonomy, and sense of purpose in life.

Providers can maintain and even improve their sense of wellness by supporting these foundations of resilience. Encouraging the development of these building blocks in coworkers, patients, and children helps to facilitate resilience in others as well.

Stress

Stress is often defined as the reaction of the mind or body to a demand for change. Stress is both physical and psychological; that is, physical stress such as that resulting from a traumatic injury always has a psychological component. Conversely, psychological stress, such as that resulting from an argument with a coworker, invariably has a physical component.

We obviously need some level of stress to remain alive, and virtually any stressor will affect people differently. There is a tendency, especially among people in high-stress occupations, to associate stress with negative happenings. This is an incorrect assumption: Social scientists have long known that joyous life events, such as getting married, getting a new job, buying a new home, and celebrating holidays, are just as stressful as unpleasant events, such as death of a spouse, termination from a job, jail sentence, or traffic crash. The need to assess all life events for their stress-inducing value is important for CCTPs, whose role entails unpredictable events that could be significant stressors. Managing life stress by spreading out controllable events such as job changes, marriage, home buying, and vacations can allow leeway for managing the stress associated with these unpredictable job-related events. Focusing on such cumulative stress is important for each of us, as stress tolerance varies from person to person.

Stress in the CCTP most likely encompasses a combination of the same stressors seen in field EMS providers and the stressors most often reported by ICU personnel. The most frequently reported stressor by field EMS providers is poorly managed organizations. Critical care nurses most commonly cite negative interactions with coworkers.

Curiously, people who choose to work in high-stress occupations—such as CCTPs, paramedics, ICU nurses, surgeons, and airline pilots—have key personality differences from the average citizen. The primary difference is an innate addiction to the hormone adrenaline, or a sense of happiness resulting from events that elevate blood levels of adrenaline. Most people, when experiencing high levels of adrenaline, become anxious, fearful, and uneasy; they are often terrified, in fact—quite the opposite of happiness. Therein lies a character insight that few appreciate: Not every person is suited to work in a high-stress occupation. Indeed, many people are unable to perform in a fast-paced, high-stress environment. The relatively few members of a society who enjoy the stress associated with the release of catecholamines (such as adrenaline) are the same people who tend to be successful at high-stress occupations, such as CCTPs.

CCTPs need a solid personal stress management program and resources they can avail themselves of when they encounter extremely stressful situations at work. Some suggestions for a personal stress management program include the following:

- *Condition your mind and body.* Maintaining a healthy weight and diet, including participation in a regular exercise program, helps avert injury in the very physically demanding job of a CCTP. Moreover, it induces a mental feeling of well-being that correlates with good physical health and fitness.
- *Listen to your inner voice.* In his book *The Gift of Fear*, Gavin de Becker interviewed survivors of violent crimes and concluded that they, like most members of society, had learned to suppress intuitive thoughts that could have alerted them to danger. Becoming more in touch with their inner voice helps alert CCTPs to potential stressors and helps them avoid bad situations before they become worse.
- *Never stop growing and learning.* Critical care is a constantly changing and evolving science and art. Staying current with trends and new technologies helps CCTPs achieve a sense of mastery over their work. They are present at the darkest moments of other people's lives—an experience that few others are privileged to have. CCTPs can glean life lessons from these experiences, if they choose to.
- *Be positive.* Interactions with others often affect the CCTP's mood. Likewise, how the CCTP interacts with others has a

greater influence on the overall work environment than the CCTP might imagine. Spoken words can be either positive or negative. Positivity and a sense of humor create a highly desirable work environment.

- *Have a life outside of your work.* Balance is important in any profession, but it is particularly important in high-stress professions. Activities and friendships outside of work help CCTPs relax and view the world from a different perspective.

Recommendations for acute stress situations involving emergency responders such as CCTPs have evolved considerably over the years. **Critical incident stress debriefing (CISD)**—an approach favored since the 1980s to manage the psychological aftereffects in emergency personnel after particularly distressing responses—has now been largely replaced by the principles of **psychological first aid (PFA)**. CISD requires a specially trained team and has the potential to create iatrogenic harm from mandatory attendance, practitioner error, mixing of groups, and a variety of preexisting conditions that may unknowingly be present in participants. In contrast, PFA is implemented within the workplace by management and coworkers with an emphasis on encouraging personal resilience.

Unquestionably, every emergency responder and CCTP should have access to professional assistance with stress management. Every CCTP program should have a protocol for action following a serious event, availability of an employee assistance program (EAP) for employees and their families, a department chaplain, screening tools that supervisors and coworkers can use to assess employees when a concern arises, and educational resources for employees and their families on dealing with acute stress situations. The ready availability of EAP services is crucial. CCTPs are not immune to routine life stressors or personal difficulties such as marriage, family, financial, or substance use problems, all of which may considerably impair their ability to function in this high-stress occupation.

Safety

Personal safety is a crucial issue for all CCTPs, and one that feeds directly into well-being. CCTPs may work in a variety of hazardous environments, either in the external environment or within the confines of the transport vehicle. Consequently, appropriate safety gear and clothing are necessities for every member of the CCT crew. CCTPs should ensure that they properly and consistently wear the appropriate safety gear (eg, personal protective equipment [PPE], N95 mask) and clothing **FIGURE 1-5**. At a minimum, safety gear should meet the following criteria:

FIGURE 1-5 Proper safety gear and clothing, including snug-fitting head and eye protection, leather boots, and flame-retardant gloves. Layers should be worn underneath the uniform and for additional protection. If involved in scene transports, the CCTP uniform should also include reflective material or striping.

© Jones & Bartlett Learning.

- Clothing should fit properly, and flight clothing should be flame retardant. Clothing should include a uniform or flight suit, outerwear such as a coat or vest, and undergarments. Clothing should never be tight or loose fitting.
- Clothing should be layered for proper ventilation and heat regulation. Long-sleeved shirts and pants limit water loss and reduce the potential for exposures.
- Head and eye protection should fit snugly and meet or exceed Occupational Safety and Health Administration (OSHA) specifications.
- Leather boots should be worn to protect feet against the elements and fire. Flame-retardant gloves should be available to protect hands against the elements and fire.
- Uniforms should have reflective materials or striping to increase nighttime visibility of CCTPs at crash scenes or when it becomes necessary to exit the transport vehicle on a roadway.

Interpersonal Communication

Communicating effectively with patients, families, and other health care providers may be the most important determinant of how competent and capable a CCTP is perceived to be. Rarely, if ever, does a patient survey praise a provider's evident proficiency in starting an IV line or safely drawing up and administering a medication. Instead, compliments, and indeed criticisms, most often center on how personable, concerned, friendly, and communicative a provider or CCTP team was (or was not) with the patient, family, and others. No matter how acutely ill a patient is, members of the CCT team must make every effort to communicate their assessment of the situation and plan of care to the patient and family.

Communication starts with an introduction of each team member. These simple introductions help comfort patients and families. When family members desire, they should be in the room when the team assesses the patient.

When preparing to depart with the patient, providers should give family members time to speak briefly with the patient and should answer any questions they have. Requests for a brief prayer by members of the clergy or others should be honored. Although every second counts when transporting critically ill or injured patients, such brief moments spent supporting family involvement have positive effects that words cannot describe.

Quality Assurance and Improvement

A **quality assurance and improvement (QA&I) program** is an essential part of the overall health care system in the United States. The primary function of such a program is to generate data that are then used to improve the quality of service provided. Thus, a QA&I program is an integral component of a successful CCT program. CCTPs regularly provide advanced care to the "sickest of the sick," often in uncontrolled, unpredictable environments. An effective QA&I program serves as a checks-and-balances system to protect stakeholders.

Once financial and human resources are devoted to a QA&I program, the first step is to define quality. Many CCT programs use their mission statement to define what quality means to their stakeholders. Once this definition is in place, measurable indicators of quality must be established and baseline data must be obtained.

The second step is to collect and analyze data. Data can be obtained from various sources. Most CCT programs obtain data, at a minimum, from patient charts, dispatch records, and customer feedback surveys. Once obtained, these data must then be analyzed for meaning and application to the program's goals, objectives, and indicators of quality.

The third step in the QA&I process focuses on improving quality, which requires use of the data analysis results and development of an understanding of underlying issues. For example, if an audit of patient charts reveals that several CCTPs are incorrectly documenting the use of transport ventilators, and analysis of the reason for the incorrect documentation reveals a lack of knowledge, a continuing professional education course on effective documentation for ventilator-dependent patients can be conducted. The QA&I program should direct the continuing professional education for transport program staff.

Benchmarking is a popular concept in quality circles and has considerable value to any CCT program. It is extremely helpful for an agency to participate in shared databases and to seek out opportunities to compare the service's own data against the data from other CCT programs. Without the ability to compare and contrast findings to others in the industry, the QA&I program will operate in a vacuum and might venture off on the wrong track.

Two sets of metrics widely used by CCT programs are the Ground Air Medical qUality Transport (GAMUT) database and the National EMS Quality Alliance (NEMSQA) statistics. GAMUT is a free resource for transport teams offered by the GAMUT Quality Improvement Collaborative. NEMSQA publishes quality metrics specific to EMS. Both gather and analyze quality-related data from a broad sample of the CCTP community, then disseminate metrics based on these data that individual services can use to benchmark themselves against other services.

Since 2007, quality activities across the health care spectrum have been driven by the Triple Aim framework developed by the Institute of Healthcare Improvement. The three aims for optimizing health care system performance are improving the patient care experience, improving the health of the population, and simultaneously reducing per capita health care costs. Quality metrics, increasingly tied to reimbursement, are often organized around this framework.

The History of CCT

To fully appreciate the current state of CCT, it is important to recognize how this industry evolved over time. Methods for transporting critical care patients have evolved from horse-drawn carts in the 17th century, to the use of hot-air balloons, to the use of ground, rotor-wing, and fixed-wing vehicles today. As transport methods and equipment advance, it becomes possible to safely move increasingly sicker patients between health care facilities. The skills and equipment used by CCTPs are sometimes requested for 9-1-1 scene responses, recognizing that critically ill patients are not just confined to health care facilities but can be encountered anywhere an EMS system responds. Additionally, routine transfers of patients with high-technology home-based or skilled-nursing medical devices such as ventilators and infusion pumps often fall within the purview of the CCTP. These calls not only help to maintain the CCTP's proficiency, but also provide for greater patient safety, as they tend to be high-risk, low-frequency patient encounters for the non-CCTP.

Ground Transport

Early methods of patient transportation were developed out of necessity to reduce the high rates of **morbidity** and **mortality** among soldiers. Later, the same modes of transportation were used to move critically ill and injured patients to facilities that could provide more definitive care. The first record of moving injured patients was in the 11th century during the Crusades by the Knights of St. John. The Knights of St. John treated and transported injured soldiers after learning about first aid procedures from Arab and Greek physicians—a service that is considered the birth of the first emergency medical providers. At the same time, any soldier who carried an injured comrade to receive medical treatment would receive a small monetary reward.

Ground transportation was first used to evacuate injured soldiers in 1792, during the French Revolution. A surgeon in the French army, Dominique Jean Larrey, noticed that many of his countrymen lay wounded on the battlefield for as long as 36 hours until they were evacuated by fourgons, or multihorse wagons **FIGURE 1-6**. This delay in transport resulted in the death and disability of many soldiers, which Larrey found unacceptable.

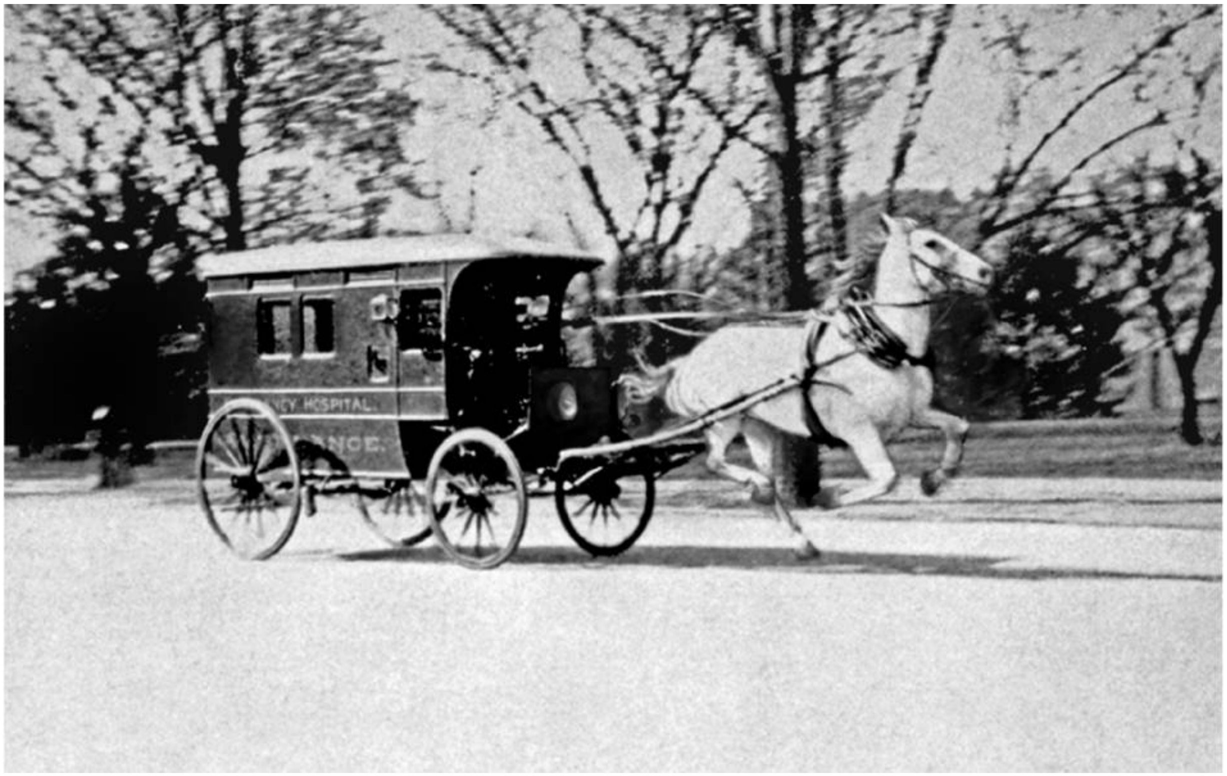

FIGURE 1-6 The first vehicles used for transport of casualties were horse-drawn wagons.

© National Library of Medicine.

Larrey designed and produced several two- and four-wheeled carts called *ambulance volantes* (flying ambulances), which were both fast and maneuverable **FIGURE 1-7**. These carts were used to transport surgeons and equipment to the battlefield to give first aid and then return the wounded to nearby field hospitals. Larrey's flying ambulance was the first recorded use of an evacuation system to help improve the survival rates of soldiers. He is also credited with creating the first official army medical corps using stretchers, handcarts, and wagons as a means of transporting injured patients.

Description

The surgeon Jonathan Letterman instituted the first US ambulance service in 1862 during the Civil War at the Battle of Antietam. As director of the Army of the Potomac, Letterman developed a plan for an integrated medical treatment and evacuation system with its own vehicles, facilities, and personnel **FIGURE 1-8**. This system, which became known as the Ambulance Corps, was the basis of Army medical doctrine. On June 23, 1917, the US Army Ambulance Service was established as a descendent of the initial Ambulance Corps.

During this time, the use of train ambulances, steamboat hospitals, and car or trolley ambulances was popular in some cities.

In 1869, Bellevue Hospital established the first US city ambulance service in New York City **FIGURE 1-9**. The hospital's Center Street Branch dispatched ambulances via telegraph and was staffed with physicians or surgeons from the hospital. Incredibly, the ambulance responded to more than 1,800 calls throughout the city of New York that first year. As the call volume increased, it became more difficult to staff the ambulances without decreasing the number of physicians in the hospital; in response to this problem, the hospital began placing orderlies or kitchen or janitorial staff on the ambulance. Because these employees had little or no medical training, responded without equipment, and frequently arrived at the scene hours after being dispatched, the mortality rate of seriously ill and injured patients increased dramatically. The continued population growth and the Industrial Revolution fueled the need for better training and easier access to rapid prehospital emergency medical care.

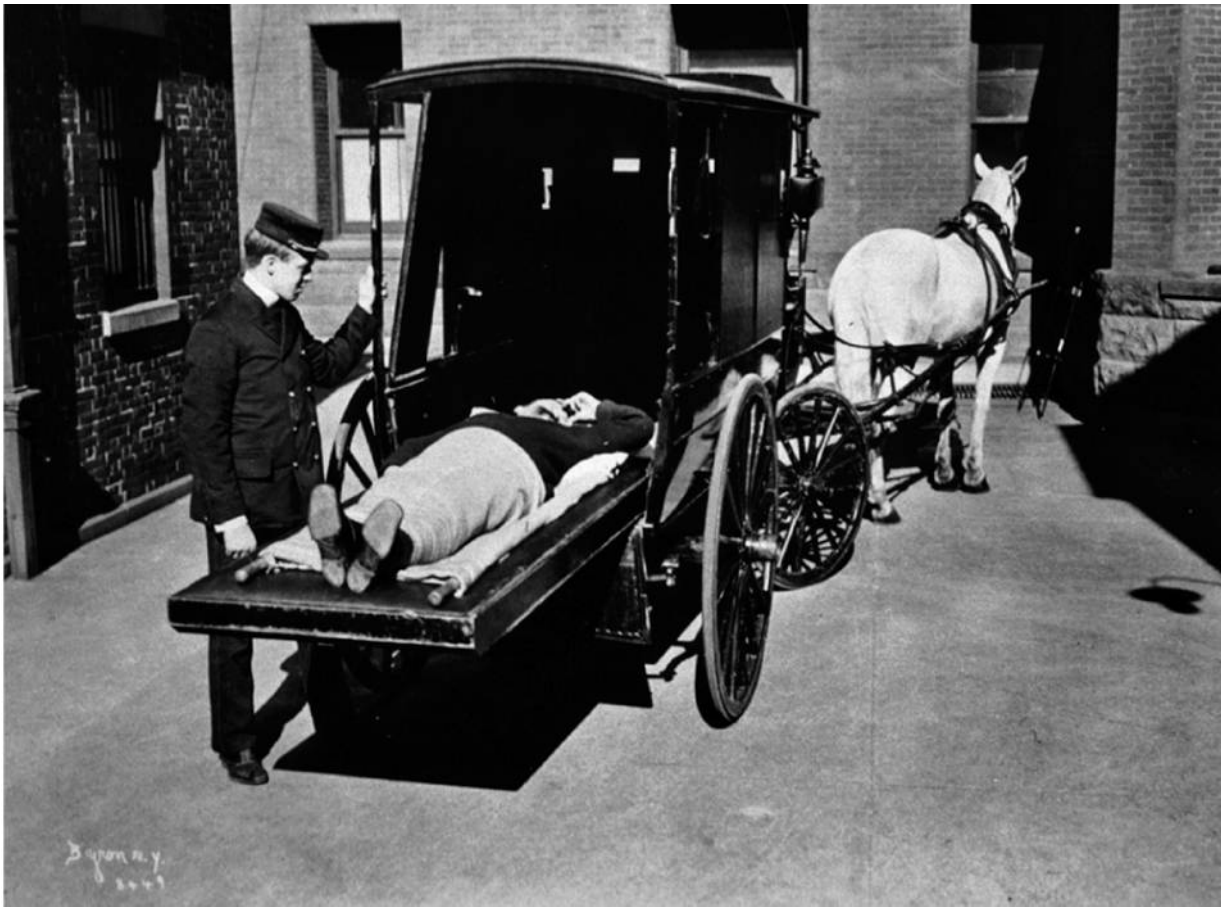

FIGURE 1-9 One of New York City's early ambulances.

In 1899, a group of businessmen developed the first motorized ambulance in Chicago and donated it to the Michael Reese Hospital. This vehicle weighed 1,600 pounds and could travel at speeds up to 16 miles per hour. In the early 1900s, ambulance crews evolved to include a driver and a person responsible for patient care, but generally the crews only picked up and delivered the patient to a base hospital.

The next milestone for prehospital care came in 1966 in Dublin, Ireland, with the provision of prehospital coronary care by physicians. Research by Francis Pantridge, a physician, indicated that most patients experiencing treatable ventricular fibrillation developed this fatal arrhythmia outside the hospital. Pantridge advocated for portable, lightweight, battery-driven defibrillators to be carried as part of the rapid response system he had developed. His foresight was the driving force for the current use of defibrillators by paramedics on mobile coronary care units and the automated external defibrillators (AEDs) used by the lay public.

Prehospital defibrillation was not used in the United States until 1969, shortly after the Miami, Florida, Fire Department, under the direction of Eugene Nagel, MD, instituted the nation's first paramedic program. Physicians in Los Angeles, California; Seattle, Washington; and Columbus, Ohio, followed Nagel's lead and began paramedic programs in their states, hoping that such prehospital emergency care would reduce preventable deaths. Today, prehospital and interfacility transports are accomplished not only by ground, but also by air.

Air Transport

After witnessing balloon flight demonstrations by the Montgolfier brothers in 1784, physicians began to consider the benefits that flight could bring to their patients. However, it was not until 1870 that the first documented case of air medical transport took place during the Prussian Siege of Paris, when 160 wounded soldiers and civilians were transported from the battlefield by hot-air balloons. At the time, this method was considered a radical means of transport and was met with harsh criticism; improvements were subsequently made. During the period between 1890 and 1910, M. de Mooy, chief of the Dutch Medical Service, pursued the idea of using litters suspended from balloons to transport patients.

On December 17, 1903, Orville Wright climbed into the plane he and his brother Wilbur built for the second attempt at flying a motorized plane. The site was Kill Devil Hills, North Carolina, and the

Wright brothers' plane stayed airborne for 12 seconds and flew for 120 feet before landing under the power of its pilot, making history as the first pilot-operated airplane.

In 1909, Captain George Groaman of the US Army Medical Corps built a plane specifically designed to carry patients; unfortunately, it crashed during testing and never received government approval. The first successful use of a motorized aircraft for transporting patients occurred 8 years later, when a plane named the French Dorand AR II served as an air ambulance, transporting patients. During the next several decades, the air medical transport industry grew, predominantly as part of the military. In 1914, Igor Sikorsky invented the first helicopter to fly for more than just a few seconds, which the military later used to transport wounded soldiers from the battlefield to facilities offering definitive medical care.

After World War I, the US Army took a new interest in the development and use of air ambulances. The chief surgeon of the Army proposed modifications to the de Havilland aircraft, making it capable of transporting a pilot, a medical officer, and two patients. This arrangement became the standard for the evacuation of injured soldiers during wartime. Further advancements continued to be made, however, and in the 1930s, air ambulances were specifically designed with multiple engines, heated cabins, and short runway capability.

During the next decade, the push to create helicopters capable of transporting patients continued. On April 23, 1944, several wounded airmen were transported via helicopter in Burma during World War II. This event is thought to be the first time wounded soldiers were transported via this means, marking a new era of air medical transport. After the war, the military determined that air evacuation of wounded patients from battlefields would be a major goal. The first official military rescue evacuation was made on August 4, 1950, one month after the start of the Korean War. Wounded soldiers were transported to mobile army surgical hospital (MASH) units on cots fitted on the skids of Bell-47 and Sikorsky S-51 helicopters **FIGURE 1-10**. The drop in the mortality rate during this war was directly attributed to the use of helicopters to rapidly evacuate wounded soldiers from combat and deliver them to surgical care.

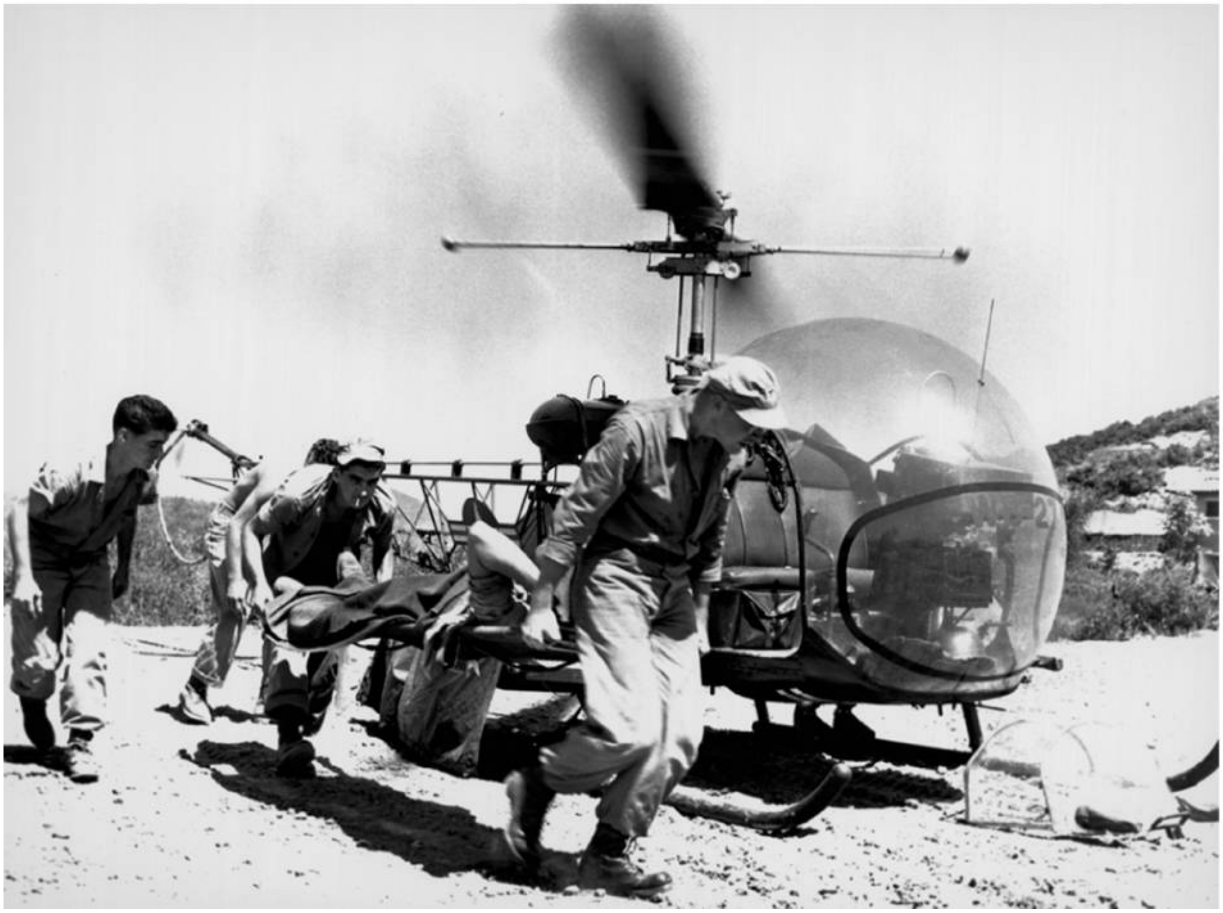

FIGURE 1-10 Soldiers wounded during the Korean War were sometimes evacuated on litters strapped to the skids of aircraft.

The Vietnam War brought a significant change in the removal of wounded patients from the front lines. The majority of battlefield rescues, stabilizations, and evacuations were carried out by a much larger helicopter, the Bell UH-1 (Huey), code-named *Dustoff* **FIGURE 1-11**. This helicopter, which was capable of carrying more patients and personnel, could accommodate patients inside the aircraft, where they could receive medical care en route to the receiving facility. The Vietnam War ultimately saw the transport of more than 800,000 patients to specialty care facilities. The marriage of rapid air transport to specialty care facilities proved successful and kindled interest in similar services in the civilian arena.

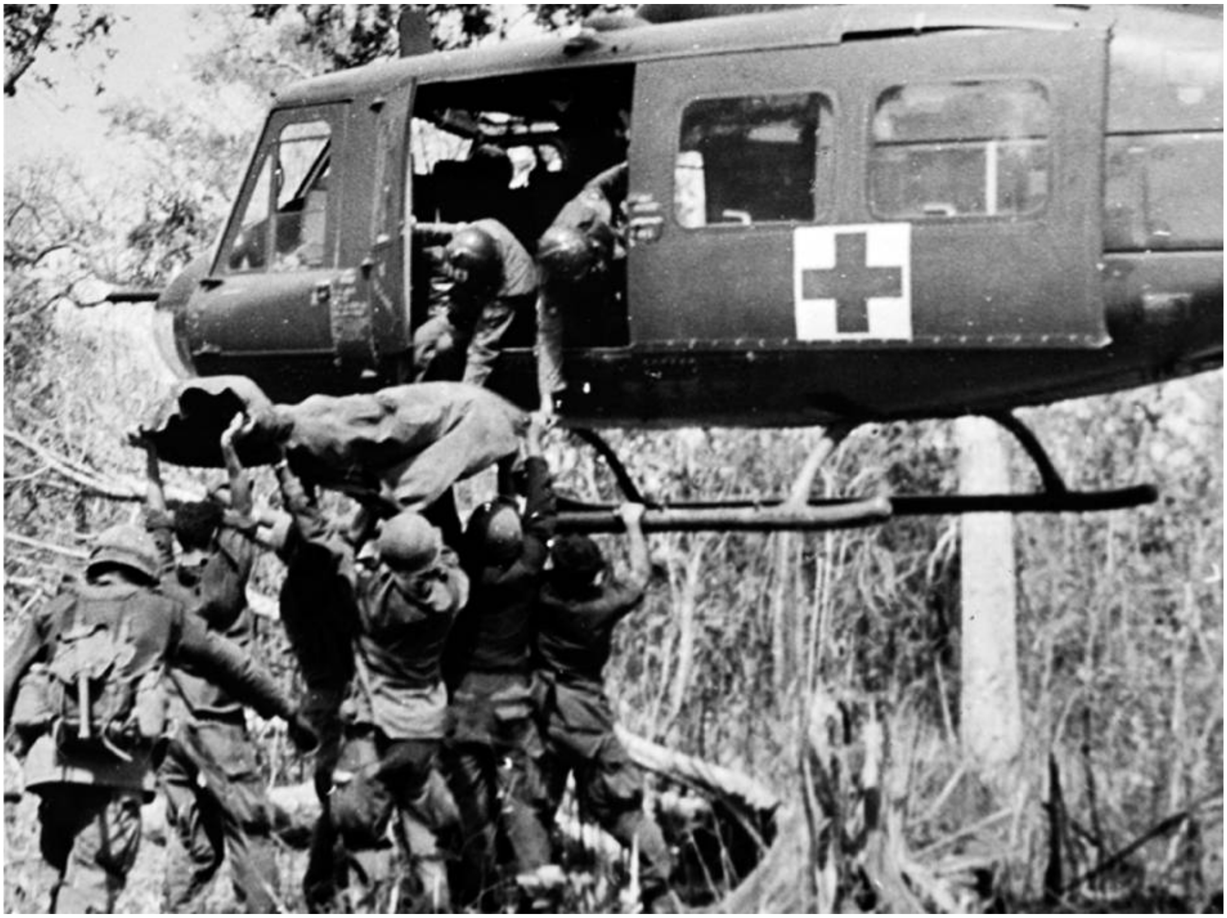

FIGURE 1-11 The Bell UH-1 helicopter, code-named *Dustoff*, evacuated patients during the Vietnam War.

Medical evacuation (medevac) helicopter transport during the Vietnam War emphasized speed with little standardization or enhancement of care during transport.

The Vietnam model met with significant challenges in Iraq and Afghanistan owing to far more extensive evacuation times, typically averaging 2 hours. Tail-to-tail flights were often needed to keep medevac crews in their assigned areas. To facilitate better care, the Army deployed UH-60 Black Hawk helicopters staffed by flight medics, most of whom had extensive experience as civilian paramedics. The improved survival observed with this configuration led to enhanced training of military flight medics, equivalent to that of their civilian counterparts.

In 1958, Bill Mathews, a northern California businessman who lived in the small town of Etna, became the first person to organize a civilian air medical service. His idea initially met with skepticism from the town's 700 residents. Fortunately, Granville Ashcroft, the area's only physician, began using the helicopter to transport patients. Soon the town druggist also started using the helicopter to deliver medications during emergencies.

Later, during the 1960s, European countries instituted helicopter programs that were dedicated to patient care and transport. In that same period, the United States saw the emergence of several civilian- and government-funded helicopter projects. These projects sought to study the feasibility of using helicopters to transport patients in the civilian arena. In 1966, the National Institutes of Health and National Academy of Sciences published *Accidental Death and Disability: The Neglected Disease of Modern Society*, a report that paved the way for the initiation and growth of civilian air medical transportation programs; it recommended the development of a system designed to transport patients via air ambulances based on the successful military model.

In 1969, the state of Maryland received a grant to purchase a Bell JetRanger helicopter and instituted the nation's first public service medevac program **FIGURE 1-12**. The four helicopters, staffed with paramedics, were part of the Maryland State Police and were strategically stationed throughout the state so that they could provide quick responses to emergencies. When the helicopters were not being used for medical emergencies, they could be used for law enforcement missions.

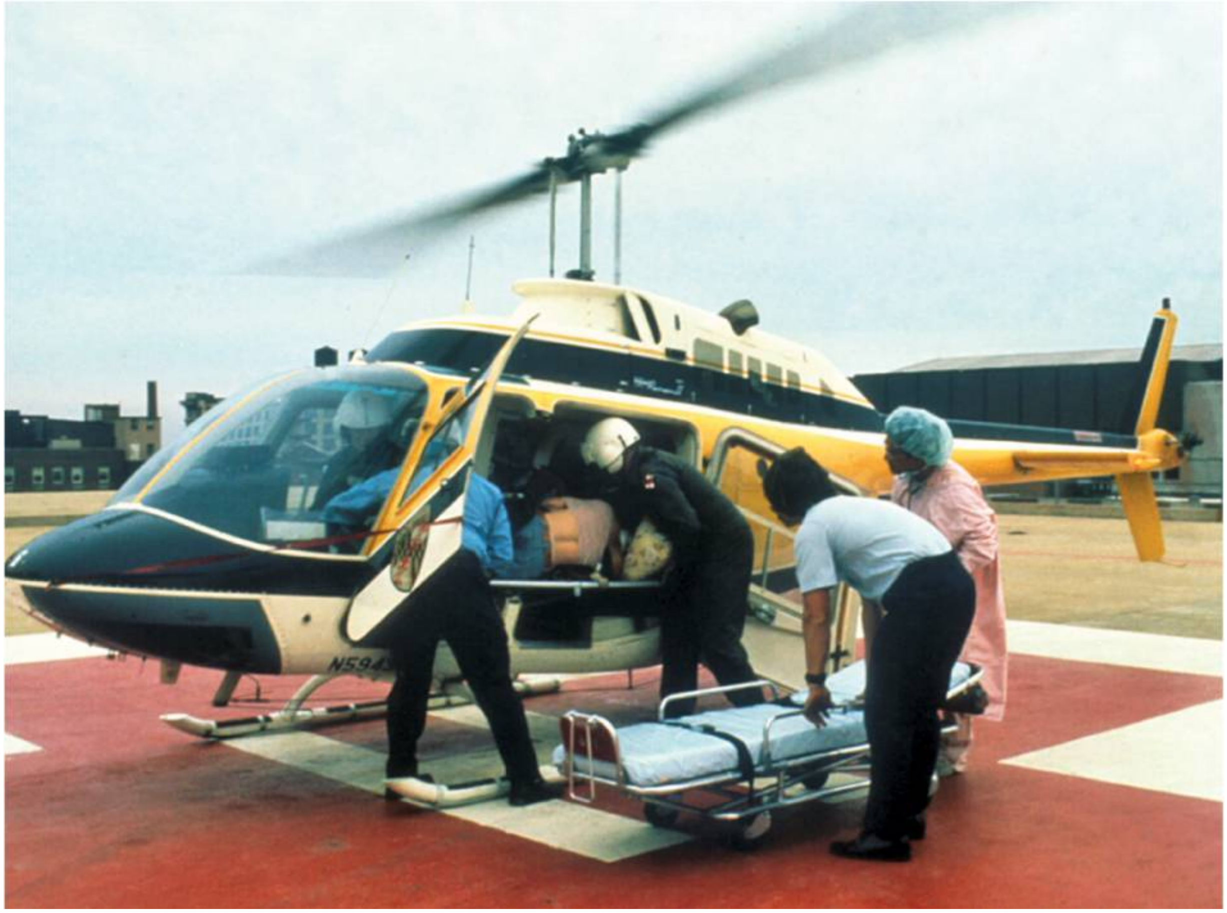

FIGURE 1-12 The Bell JetRanger helicopter was used for the first public service medevac program.

In 1972, the first hospital-based air medical transport program was established at St. Anthony's Hospital in Denver, Colorado. Following continued skepticism about the civilian use of helicopters for medical transports, the National Highway and Transportation Safety Administration (NHTSA) released a study titled *Helicopters in Emergency Medical Systems: Experience to Date*. This study suggested that the use of helicopters in urban settings was not realistic and offered little or no advantage over ground-based EMS systems. In 1981, the NHTSA released a second report titled *Air Ambulance Guidelines*, in which Willis Winert, MD, indicated that air ambulances were improperly equipped to handle critically ill or injured patients and were nothing more than flying taxis with removable seats. This statement prompted the FAA to demand better equipment and specially trained crews for air ambulances.

The industry responded to these criticisms by developing the educational programs and specialty certifications mentioned earlier in this chapter. Today, there are more than 100 air medical programs in the United States, each with specially trained flight crews. **FIGURE 1-13** outlines the history of ground and air transport.

Description

Summary

Much attention has been focused on specialty care and CCT since reimbursement fees for such services were established by the CMS and subsequently offered by other insurers. As the health care system continues to evolve, the need to relocate critically ill patients has increased. The sophistication of both CCTPs and the agencies providing CCT has had to evolve to keep pace with the continued demand. Today, a variety of ground units, fixed-wing aircraft, and rotor-wing aircraft are used for CCT, and specialty certifications and educational programs are required for the personnel who staff them.

Despite the high degree of specialized training required for CCT teams, clinical care is but one aspect evaluated when assessing the quality of clinical care transports. Excellence in clinical care is not a "nice to have," but rather an expectation in today's health care environment. CCTPs must remember that an incident that they consider a "routine trauma case" is most likely a life-changing event for patients and their families. With this in mind, CCTPs must look and act in a professional manner at all times, even as they manage their own stress levels and ensure the safety of both themselves and their patients. In addition, CCTPs need highly effective communication skills for their interactions with patients, families, and other health care providers.

CASE STUDY

Your CCT team is called to a community hospital to transfer a 34-year-old woman with end-stage (Class 4) pulmonary arterial hypertension to a tertiary medical center for specialized care and management. The patient presented to the local hospital during a blinding snowstorm with acute shortness of breath. Her family, who accompanied her, were unable to drive the 90 minutes to the tertiary center where she usually receives her care. Her medications include home oxygen, sildenafil, calcium channel blockers, and a continuous infusion of IV epoprostenol.

The nurse attending the patient indicated that she appeared to have pulmonary edema on arrival at the ED, some 2 hours previously. The patient was treated aggressively with high-flow oxygen and diuretics, and her symptoms improved. The nurse seems unfamiliar with the oxygen device the patient is currently using, which you recognize as a high-flow nasal cannula (HFNC) at 40 L/min with a fraction of inspired oxygen (FiO_2) level of 1.0. You review the transfer orders and note that they call for oxygen by nonrebreathing mask, cardiac monitoring, and continuation of the IV epoprostenol.

When you quickly assess the patient, you note that she remains tachypneic, with a respiratory rate of 34 breaths/min; she has some slight intercostal retractions, crackles in the bases of both lungs, and an oxygen saturation of 93% on the HFNC. There is no central or peripheral cyanosis, but the patient appears to have a moderately increased work of breathing. She tells you that she has been intubated multiple times in the past for pulmonary edema and was concerned that this episode would also result in intubation. Her breathing seemed markedly improved once the HFNC was applied, some 30 minutes prior to your arrival.

You recognize that the HFNC is probably delivering a low level of positive end-expiratory pressure and, in conjunction with 100% oxygen, providing a higher level of respiratory support than the nonrebreather prescribed in your transfer orders. You locate the sending ED physician and explain that the patient is currently on HFNC at 40 L/min. A 40 L/min flow, during transport through a major snowstorm that might take twice as long as the usual 90-minute trip, would consume multiple on-board tanks of oxygen, which is much more than is carried on the ambulance. The physician is dismissive of your concerns, insists that her orders for a nonrebreathing mask are sufficient, and encourages you to expeditiously transfer the patient. The RT attending to the patient suggests that adding a nasal cannula under a nonrebreathing mask might be similar to the oxygen concentration provided by the high-flow setup.

Concerned that you may not be able to safely manage this patient during transport, you contact your OLMC for consultation. You review options with your medical control physician, including intubation and noninvasive ventilation. After some discussion with your patient and medical control, you elect to place the patient on bilevel positive airway pressure (BPAP) using your transport ventilator while monitoring end-tidal carbon dioxide ($ETCO_2$) using a nasal capnography cannula. Medical control also orders an additional dose of IV diuretics.

The patient remains comfortable on BPAP with settings of 8/4, and you are able to lower the FIO_2 from 1.0 to 0.7 during transport, with oxygen saturations remaining at 95%. The $ETCO_2$ level is initially 48 mm Hg and stabilizes at 40 mm Hg during transport, which takes a total of 2 hours. The patient's respiratory rate declines to 28 breaths/min and remains there during transport. The patient relates that she feels her breathing has improved, and you note the previously observed intercostal retractions are no longer present.

You arrive at the tertiary receiving hospital, provide your report to the team receiving the patient in the pulmonary ICU, and transfer care to their providers.

1. Who is responsible for deciding whether a patient is stable for transfer?
2. What situations warrant consult with OLMC?
3. When does responsibility for patient care transfer from hospital personnel to the transport team?

Analysis

This case study illustrates an interfacility transfer that could have gone terribly for the patient and transport crew had the CCTP team not consulted OLMC. Initially, the physician caring for the patient is responsible for arranging transfer and stabilizing the patient for transport. Ultimately, however, the CCTP responsible for the patient during transport must decide whether the patient's care needs are within the CCTP's scope of practice and whether the CCTP can safely manage the patient during transfer. It is important to understand that the CCTP is responsible, and likely liable, for adverse outcomes that occur during transport. In any transport, the CCTPs should be confident that the patient's needs are within their scope of practice and that they will be able to manage foreseeable adverse events during transfer. If that is not the case, they should discuss their concerns with OLMC and consider not accepting the transport.

The worlds of prehospital care and CCT differ dramatically from those of the ED and ICU. In any situation where disagreement arises about patient care or physician orders, CCTPs should discuss the issue with the sending providers and clarify orders with the prescriber. If residual concerns or unaddressed needs remain, CCTPs should contact OLMC for clarification. Likewise, when CCTPs are concerned about the stability of a patient for transfer, they should consult with OLMC. Communication is key to safe transfers and good patient outcomes. The time to speak with medical control is prior to a patient decompensating, not after decompensation occurs.

On arrival at the sending facility, the CCTP team should gather information from the sending provider(s). This handoff report, coupled with a cursory assessment of the patient, should allow the team to quickly determine the complexity of the transport, the necessary equipment, and their ability to proceed. Responsibility for patient care transitions from the sending providers to the CCTP team once the patient is transferred to the transport stretcher, which should occur prior to transferring infusions, ventilation equipment, and other devices. This transition is important because it demarcates the point at which the patient has physically moved from the hospital to the EMS or transport environment. It is precisely the same choreography that occurs when EMS providers deliver a 9-1-1 patient to the ED: The moment the patient is moved from the ambulance gurney to a hospital stretcher, the patient becomes the responsibility of ED providers.

PREP KIT

Ready for Review

- Critical care is intensive care and monitoring provided to patients with life-threatening conditions who require constant monitoring and treatment with drugs and equipment to sustain life.
- CCT is the provision of medical care to a critically ill or injured patient during ground or air transport.
- Interfacility transport (IFT) and specialty care transport (SCT) are distinctly different entities. IFT is the transport of a patient between two health care facilities. SCT, as defined by the Centers for Medicare and Medicaid Services, is the interfacility ground transport of a critically ill or injured patient, including provision of medically necessary supplies and services that are beyond the scope of practice of paramedics.
- CCTPs may include EMTs, paramedics, nurses, physicians, and specialty health care personnel such as RTs and perfusionists.
- CCTPs must be able to provide care at the same level, or sometimes a greater level, than their non–critical care counterparts.
- CCTPs must be educated and skilled in the use of advanced practice procedures that may fall outside of their formal medical education. They must be lifelong learners who pursue continuing education to keep up to date with changes in clinical practice.
- Crew configurations vary as much as the types of ambulances and helicopters. The configuration depends on the staffing policy of the organization. The most common configurations are nurse and paramedic, nurse and RT, and nurse and physician.
- Additional crew members, including perfusionists and neonatal or pediatric intensivists, may be required for transport of certain patients.

- Modes of transportation may vary widely by agency and by region of the country. Possible modes of transport include ground units, rotor-wing aircraft, and fixed-wing aircraft.
- The transportation mode to be used is dictated by patient acuity, the distance between the sending and receiving facilities, the weather conditions, and the topography of the region.
- Mobile, or ground, units (ambulances) are generally used to transport critically ill and injured patients up to distances of 50 miles (80 km) from the patient's location to the receiving facility.
- Rotor-wing aircraft (helicopters) are used to transport critically ill and injured patients in rural settings and can travel distances of up to 150 miles (240 km).
- Fixed-wing aircraft (airplanes) are typically used to transport critically ill and injured patients for distances of 150 miles (240 km) or more.
- Communication breakdowns are the root cause of many adverse patient outcomes during CCT.
- When a transport is requested, dispatch personnel obtain pertinent information about patients and their condition from the referring facility. A clinical supervisor or algorithm should be used to determine the appropriate crew configuration and mode of transportation.
- A CCT team should be dispatched and used for patients who meet any of the following criteria: mechanical ventilation, vasoactive medications, blood product infusions, mechanical circulatory support devices, and unstable conditions requiring frequent interventions such as sedation, paralytics, and/or analgesia.
- The generally accepted time frame for an CCT team to receive the report from the handoff team, package the patient, and begin moving the patient to the transport vehicle should not exceed 20 minutes. In situations where additional interventions or procedures are needed to stabilize or prepare the patient for transport, bedside times may be longer.

- On arrival at the sending facility, the CCT team must quickly determine whether the patient’s needs are within their scope of practice and whether they can safely manage the patient during transport.
- In situations where concerns arise, the CCT team should discuss these issues with the sending providers and, if not completely resolved, consult with their OLMC.
- Although a helicopter travels much faster than an ambulance, in some cases a ground ambulance may be located significantly closer to the patient and, therefore, is the preferred transportation mode.
- Patients with the following time-sensitive conditions are typically transported by air; these conditions include acute myocardial infarction, acute cerebrovascular accident, severe trauma, acute intracranial hemorrhage, the need for emergency surgery, and major burns.
- Weather issues may prohibit a flight from taking place. Usually, a decision is made to wait for the weather to improve and launch the aircraft as soon as practical.
- The basic concept of a CCT service is to rapidly transport CCTPs to a patient, stabilize the patient’s condition, and transport the patient to the receiving facility as quickly as possible.
- Medical control within CCT systems includes protocols and OLMC. Protocols in a CCT setting are typically much more aggressive than those found in other aspects of prehospital care.
- Standards for CCT services vary from state to state; however, most CCT programs follow national standards. Usually, a state organization governs the licensure of air medical services and their practitioners.
- A CCTP’s scope of practice varies according to their level of certification and the state in which they practice.
- Health care reimbursement is undergoing a major shift from paying for care delivered to paying for health outcomes achieved,

and it is only a matter of time before quality and outcomes measures are connected to CCT reimbursement.

- Resilience, defined as a person's ability to withstand negative pressure or "bounce back" from difficulties, affects the well-being of both CCTPs and their patients. The three key determinants of personal resilience are thought to be biology (genetics), attachment, and control.
- CCTPs, like anyone else working in a high-stress profession, need not only a solid personal stress management program, but also resources they can avail themselves of when they encounter extremely stressful situations at work.
- Appropriate safety gear and clothing are necessities for every member of the CCT crew. They include layered clothing with reflective materials and flame resistance, head and eye protection, and leather boots.
- Interpersonal communication is as important in CCT as it is in other health care settings. CCTPs should introduce themselves to patients and family members and maintain both their professionalism and a caring demeanor.
- Quality assurance and improvement programs are an essential part of the overall health care system. Most CCT programs obtain data from patient charts, dispatch records, and process customer feedback surveys, which they can then use to inform their QA&I programs.
- Ground and air transport have evolved along with changes in transportation and technology. Since its earliest days of removing soldiers from the battlefield for treatment, CCT has become a sophisticated endeavor that combines a solid health care knowledge base with use of advanced medical technology and excellent interpersonal skills.

Vital Vocabulary

Benchmarking The process of comparing an organization's processes and performance to those of the overall industry or the best practices from other companies.

critical care Constant, complex, detailed health care as provided in various acute life-threatening conditions; the ability to deal with such situations rapidly and with precision using various advanced machines and devices for treating and monitoring the patient's condition.

critical care patient Any patient who experiences an actual or potential life-threatening illness or injury that requires continual monitoring and care by a specially trained physician, registered nurse, or paramedic.

critical care transport (CCT) The transport of a patient from an emergency department, critical care unit, or incident scene during which the patient receives the same level of care as was provided in the hospital or originating facility.

critical care transport professional (CCTP) A health care professional who has successfully completed a recognized critical care program and meets the minimum qualifications set forth by the employing transport program.

critical incident stress debriefing (CISD) An approach favored since the 1980s to manage the psychological aftereffects in emergency personnel after particularly distressing responses; it requires a specially trained team and has the potential to create iatrogenic harm.

dispatch The person or organization that receives the request for critical care transport and contacts the critical care transport team with the details of that request to ascertain the team's availability.

fixed-wing aircraft A transportation mode typically used to transport critically ill and injured patients distances of 150 miles (240 km) or greater; also called airplanes.

handoff The brief report that staff at the sending facility—generally the bedside nurse, physician, or care provider currently responsible for the patient—submits to the CCTP team when they arrive to accept responsibility for the patient's care.

interfacility transport (IFT) The transport of a patient between two health care facilities.

medical director A physician who provides guidance and oversight for the practice of a critical care transport service's personnel.

mobile intensive care units Ambulances or helicopters that are used only for maintaining specialized or intensive care treatment; they are used primarily for interfacility transports.

morbidity An illness or an abnormal condition or quality; the rate at which an illness occurs in a particular area or population.

mortality The condition of being subject to death; the number of deaths per unit of population in any specific region, age group, disease, or other classification.

online medical control/consultation (OLMC) Immediate medical direction provided to critical care transport professionals in outlying locations by a physician; a system in which field personnel contact an emergency department physician via telephone or radio for a consult.

perfusionists Highly trained technicians who are intimately familiar with the operation of intra-aortic balloon pumps and adult and pediatric extracorporeal membrane oxygenation machines, and who may assist during any medical situation, including critical care transports, in which it is necessary to support or temporarily replace a patient's circulatory or respiratory function.

psychological first aid (PFA) An evidence-based approach to managing psychological aftereffects in emergency personnel after particularly distressing responses that relies on the concept of human resilience.

quality assurance and improvement (QA&I) program A program that seeks to generate data that are then used to improve the quality of service provided.

resilience A person’s ability to withstand negative pressure or “bounce back” from difficulties.

rotor-wing aircraft A transportation mode used to transport critically ill and injured patients in rural settings distances of up to 150 miles (240 km); also called helicopters.

specialty care transport (SCT) The interfacility ground transport of a critically ill or injured patient, including provision of medically necessary supplies and services that are beyond the scope of practice of a paramedic; a term used by the Centers for Medicare and Medicaid Services in determining whether transport charges are reimbursable.

stress The reaction of the mind or body to a demand for change; it can have either positive or negative effects.

well-being “A positive outcome that is meaningful for people and for many sectors of society, because it tells us that people perceive that their lives are going well” (Centers for Disease Control and Prevention); a state of being comfortable, healthy, and happy.

CHAPTER 2

Medical-Legal Issues

Matthew R. Streger, JD, MPA, NRP

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the basic concepts of negligence and the four findings required to establish an act of negligence (pp 28–29).
2. Explain the laws that determine whether a health care provider can be found responsible for an injury (pp 28–29).
3. Describe the concept of *respondeat superior* and the conditions under which providers may not be protected by their employer's liability insurance (pp 29–30).
4. Describe the legal principle of consent and the concepts of informed, expressed, and implied consent (pp 30–31).
5. Discuss how competence and decision-making capacity (DMC) are assessed in establishing consent (pp 30–31).
6. Explain the importance, from a legal standpoint, of proper documentation in the patient care report (p 32).
7. Discuss the Emergency Medical Treatment and Active Labor Act (EMTALA), its implications for critical care transport, and the potential consequences of violating the law (pp 32–33).
8. Discuss the general concepts established by current EMTALA case law (p 33).
9. State the major steps and pertinent issues in accepting a patient transfer (pp 33–34).
10. State the responsibilities of critical care transport professionals during transport (pp 37–38).
11. Explain the role of other health care providers who accompany the patient during transport (pp 38–39).
12. Discuss the ways in which communications capabilities and agreements about medical direction affect medical decision making in the transport environment (p 39).
13. State the major steps and pertinent issues in transferring care to the receiving facility (pp 39–40).
14. Describe how risks can be minimized in the critical care transport environment (p 40).
15. Explain accurate and complete documentation for a transport, including its critical nature in protecting against liability claims (pp 39–40).

Introduction

Of all the areas in which health care providers operate, the legal world can be the most unfamiliar and uncertain. EMS providers often have little training and experience in this area, where the consequences of errors or inaction can be damaging both for the provider individually and for the EMS agency as a whole. The education that providers do receive in regard to legal issues is often intermingled with bad information shared through anecdotal stories and misunderstandings. A shortage of subject-matter experts in the medical-legal realm with EMS or health care experience makes it all the more difficult to ensure providers are receiving sound information.

Health care providers, including EMS professionals, must familiarize themselves with legal concepts and terms to operate effectively and protect themselves in this area. They must understand the laws that apply where they practice, know the local protocols and their limitations, have appropriate documentation skills, and maintain proper communications and interpersonal dynamics with other providers and other health care professionals, patients, and family members.

This chapter examines the real-world issues facing critical care transport professionals (CCTPs), including civil liability, and specific laws such as EMTALA and HIPAA. Of course, this is an ever-evolving area of practice, and CCTPs should continually monitor changes in the law, including relevant legal cases that are binding on their practice. Throughout this chapter, we will look for best practices and ways to limit risk and ensure regulatory compliance.

General Concepts of Liability

Any discussion of legal issues associated with the transportation of critically ill or injured patients must start with an understanding of the basic concepts of negligence. **Negligence** is an area of civil **tort** law—that is, the law that deals with harm rendered by one person or entity against another **TABLE 2-1**. Negligence's foundations largely lie in **common law**, which is case law established by prior disputes, in court, that is published to guide future proceedings. However, certain aspects of negligence law originate in **statutes**. Usually, cases brought in negligence law are state-law cases, and for this reason each state has its own independent body of law in this area. While the basic concepts may be related, certain details, such as statutes of limitations, comparative negligence, and immunity laws, can vary widely in different jurisdictions. Health care providers also may have criminal liability for some improper acts or may have administrative liability related to their state's licensure or permission to practice.

TABLE 2-1 Areas of Law

- **Criminal law.** Wrongs against the rules of the "state"
- **Civil law.** Wrongs between people or entities
- **Administrative law.** Wrongs committed by people who are granted permission to practice by the state

© Jones & Bartlett Learning.

Negligence Law

A finding of negligence requires that four criteria be met **FIGURE 2-1**:

1. The health care provider had a **duty to act**.
2. The provider committed a **breach of duty to act**.

3. The patient suffered **damages** as a result of the breach of duty.
4. The damages were **proximally caused** (foreseeable) from that breach of duty.

FIGURE 2-1 Four criteria are considered when determining whether a provider has behaved negligently. Consider a scenario in which a paramedic has intubated a patient in respiratory failure. The paramedic has been called to respond to a respiratory emergency (1: duty to act). He must confirm correct placement of the endotracheal tube. His EMT partner suggests that the tube may not be placed correctly because there is no chest rise with ventilations. The paramedic does not attach end-tidal capnography (even when suggested by his partner) to confirm tube placement, and the tube was placed incorrectly (2: breach of duty to act). The patient, who was awake and alert prior to intubation, remains comatose and is discharged to a long-term care facility (3: damages to patient). The paramedic would be guilty of negligence because the consequences of an unrecognized esophageal intubation are foreseeable (4: proximate causation).

© Thinkstock Images/Stockbyte/Getty Images.

The breach of duty can be either an act of omission, which means not doing something that should have been done, or an act of commission, which means doing something that should not have been done or doing something improperly. If any of these elements is missing or cannot be proven, then there will be no finding of negligence.

The most critical point regarding negligence is that there is no requirement of intent to cause harm. A finding of intent changes the nature of the charges; it can lead to punitive damages awarded to the plaintiff in a civil lawsuit or to criminal charges against the defendant. Negligence is simply a mistake that leads to harm, and the law provides that the person who injures someone else through a mistake should compensate the victim.

Negligence cases must be brought within a set time, called the **statute of limitations**; after that time limit expires, the plaintiff will be unable to file a lawsuit. The statute of limitations is usually 2 years but varies from state to state. It may be longer if the patient is a minor (the clock does not start until the patient is 18 years of age) or if the patient did not know they were the victim of negligence, called the **discovery rule**. However, the discovery rule does not apply if the patient should have known that the negligent act occurred. For example, if the patient experiences pain or limitation after the adverse event but delays investigating the cause, the discovery rule will not apply. In many administrative matters (ie, instances where providers have a duty to act), there is no statute of limitations.

Other Standards and Immunity Laws

Negligence is not the only standard that can apply to health care providers. Some laws apply a higher standard that must be reached to find a health care provider responsible for an injury. One of these standards is **reckless conduct**, which is a more serious finding than typical negligence. Often termed *gross negligence*, it involves consciously disregarding the known risks of a course of action. Another standard is **willful and wanton** misconduct, which usually requires an intentional act of misconduct. Many state immunity statutes provide for one of these higher standards to be applied in EMS provider cases, and they often look more closely at the specific type of action being performed. For example, clinical judgment errors often require a higher standard to find the provider liable, whereas improper vehicle operations are usually evaluated based on a negligence standard.

Another type of immunity often afforded EMS providers is **sovereign immunity**, which covers only governmental entities. This immunity can align with the reckless or willful and wanton requirements, or it can differentiate between ministerial acts and discretionary acts. Ministerial acts are those that require a specific act given a set of circumstances, whereas discretionary acts are those in which the provider has some latitude in decision making. Sovereign immunity usually protects providers in the case of discretionary acts, because the law wants to encourage people to make necessary decisions without fear of reprisal; however, it does not offer protection for ministerial acts, for which people need not use their judgment. In terms of clinical protocols, judgment regarding a differential diagnosis or hospital destination choice would be covered under immunity, because it involves a discretionary act, but failure to follow a mandatory protocol element (eg, verifying endotracheal tube placement) would not be covered by immunity.

Insurance

Most CCTPs are covered by their employer's professional liability insurance, or other insurance, owing to ***respondeat superior***—the legal concept that an employer is responsible for the acts of its agents. There are two limitations of this type of insurance coverage: (1) The act in question must occur while the person is employed and (2) it must be within the person's **scope of practice** and reason for employment. An employer who believes the employee has acted beyond their authority may decline to cover the employee for a bad act, leaving that person responsible for paying for the costs of their legal defense and any damages. Needless to say, these costs can be substantial. Often, for these reasons, employers will not pay for a defense involving criminal or administrative wrongdoing; thus, it is important that providers stay within their practice boundaries.

Finally, providers must remember that their employer will not cover them for acts they undertake while they do not have a duty to act, such as rendering aid as a bystander. Good Samaritan statutes often confer immunity to bystanders who render aid, but this is not always the case. Even if providers render assistance while they have no duty to act, they must act reasonably and competently as another reasonable off-duty CCTP would.

Many people question the need to obtain private malpractice insurance, often fearing that they will be sued in civil court because they have "deep pockets." This is a misinformed fear, as plaintiffs' counsel typically will not know about insurance coverage until after a lawsuit is filed. Moreover, private insurance may cover administrative or licensure actions where an employer may not.

The Patient's Right to Decide

The right to bodily integrity is well established in law. Numerous court cases have affirmed the right of individuals to determine what can be done with their body, subject to various limits, and many states have established stronger protections for individual autonomy. Various court cases have interpreted and limited these protections, so each jurisdiction may have different laws. One protection is especially common, however: the basic right for adult patients to **consent** to medical care. This right relates to all aspects of care, including the physical assessment, any aspect of treatment, and transport decisions, including destination choice.

Competence and Consent

Several legal aspects must be considered in determining consent. First is the presence of legal **competence**, which is typically found when a person reaches the age of majority, commonly 18 years old. Certain factors may lower this age, such as being pregnant, being legally emancipated, or serving in the military. Local laws may lower this age as well, such as when a patient is seeking reproductive treatment or treatment for drug or alcohol addiction. Finally, a court may change this factor by determining that a patient is not legally competent, thereby removing a person's right to make decisions and vesting that right with another person, usually called a guardian. A person may sign an agreement that gives another person the right to make health care decisions for them under certain circumstances. These designations are often called a health care power of attorney or a health care proxy. A living will, which may take the form of a **do not resuscitate (DNR) order** or **physician orders for life-sustaining treatment (POLST)**, is a legal document that establishes in advance what care a person wants, and does not want, in the event that they are found to lack competence.

Clearly, the determination of competence does not rest with health care providers, including CCTPs. The provider's analysis in the context of critical care transport focuses on assessing a person's **decision-making capacity (DMC)**. The determination of DMC is not a simple task, and there is no clearly established legal guideline for making this decision. CCTPs must instead analyze the totality of the circumstances and decide if a patient's brain is functioning well enough to process information.

Decision-Making Capacity

Determining decision-making capacity typically includes an assessment of:

- Orientation
- Substances that can alter mentation
- Clinical conditions that can alter mentation, such as hypoxia, hypovolemia, hypoglycemia, and seizures
- Environmental factors, such as language barriers and people in the environment of care

DMC starts with orientation, but it does not end there. While a patient who is not fully oriented almost certainly does not have DMC, a person can be alert and fully oriented and yet not have DMC. As an example, consider alcohol intoxication. Picture a person who has been out drinking and is clearly intoxicated to the point of having slurred speech and unsteady gait, but who can still answer the basic questions about orientation to person, place, and time. This person most likely is impaired to the point of not having the capacity to process information about health care decision making.

Other factors can also impact a patient's DMC. Countless medical conditions can prevent a person's brain from effectively processing information; examples include hypoxia, hypoglycemia, hypothermia, seizures, and sepsis. Similarly, environmental factors can impact a person's ability to make decisions about their health care; for example, an abusive person at the scene may influence the patient's decision making.

Determining a patient's DMC is simply a matter of making sure the "computer" in the person's head is turned on and booted up, has input/output devices installed, and is ready to process.

Consent and Refusal

Once the patient's "computer" is working properly, you must give it the information to process. **Informed consent** is the process of proposing to the patient a course of action (assessment, treatment, transport), the risks associated with that action, the benefits associated with the action, and any reasonable alternatives, and then allowing the patient to decide if they want you to proceed with the action. Consent is ideally obtained in writing, and confirmed with a patient's signature. Nevertheless, the most important element of informed consent is not the signature, but rather the risk/benefit discussion you have with the patient and their clear confirmation of understanding.

Expressed consent is consent that is clearly communicated by the patient after having been properly informed. This type of consent is required by law unless an exception applies. It is often established by a physician, but CCTPs may obtain expressed consent from the patient under certain circumstances, most notably when the patient is directly under the CCTP's care.

Picture, however, a patient who is so sick that they cannot provide you with informed consent. Perhaps the patient lacks DMC, is unconscious, or is not legally competent to make decisions (often the case with minors when no parent is available). The law generally assumes that a person would want life-saving treatment if offered it, so under these circumstances the doctrine of **implied consent** applies. It is expected that the patient would give expressed consent if able to do so. In most jurisdictions, implied consent applies only when the patient has an emergency medical condition that is serious enough to risk life or disability.

Refusal of any aspect of medical care, most notably transport, is simply an expression of a patient (who has DMC) refusing to consent to care that is being offered after an informed consent discussion. When faced with a person who is refusing care that you believe is in their best interests, you should use all available tools at your disposal to convince the patient to accept your offer. You can try restating your suggestion in clearer terms or with a greater sense of urgency, appealing to friends or family who are present, or enlisting the help of online **medical control** **TABLE 2-2**. Contacting medical control may strengthen your documentation because those calls are often recorded for later use. Finally, remember that a patient may accept your care in part and refuse it in part, and may revoke their consent at any time.

TABLE 2-2 Actions to Deal With Patient Refusal to Consent

- Is the patient legally permitted to refuse care?
- Make multiple, sincere attempts to convince the patient to accept care.
- Enlist the help of others (such as the patient's family or friends) to convince the patient to accept care.
- Make sure the patient is informed in their decision.
- Attempt to get someone to stay with the patient.
- Thoroughly document the situation.

© Jones & Bartlett Learning.

Risks of Failing to Assess DMC and Obtain Consent

CCTPs who fail to assess DMC and obtain informed consent risk liability on several fronts. As previously discussed, the primary risk is negligence. In addition, other significant risks may arise from these failures.

Touching a patient without the patient's consent is called **battery**. Battery is a civil tort, but also may be a crime. Criminal battery involves some aspect of intent to harm, and the specifics of battery vary from state to state. Technically, both the tort and the crime of **assault** simply refer to placing a person in imminent fear of battery. Battery can occur by performing an action or transporting a patient against their will. **Abandonment** is the civil tort associated with terminating a clinical relationship without obtaining informed consent and without transferring care to a clinically appropriate provider; thus, it is the flip side of battery.

CCTPs may also be subject to civil and criminal penalties for violations of federal law, specifically 42 U.S.C. 1983, for compelling transportation against a patient's will. It is often stated that health care providers are not sued for "wrongful life" (a play on the legal ruling of "wrongful death"), but this is simply not the case. Legal cases are often brought against providers for forcing medical care and/or transportation when consent was not granted.

Any of these circumstances can also give rise to investigations and actions by local and state licensing authorities.

Documentation of Competence

All aspects of the assessment of competence, including any associated documents, DMC, and informed consent or refusal, should be objectively documented on your patient care report. This documentation should always use clear, concise, and objective language in reciting the facts that established the patient's DMC, and specifying exactly what risks and benefits were explained to the patient leading to the patient's consent or refusal. It is a wise practice to have patients explain back, in their own words, what you have offered and what you said will happen if they accept or refuse your suggestion.

Case Scenario

In *Lemann v Essen Lane Daiquiris, Inc.* 923 So. 2d 627 (2006), paramedics were called to a bar by police officers to evaluate an intoxicated man for a hand injury. They were told it was a nonemergency call, with no life-threatening injuries. When they arrived at the scene, the patient, 21-year-old Parker Lemann, reportedly told the paramedics he was under arrest, although the paramedics stated that police did not confirm this claim. No witnesses to the altercation were present for police to interview.

Mr. Lemann was able to answer paramedics' questions without difficulty and told them he got into a fight and punched someone and that his hand was hurting. The paramedics found that he was alert, and Mr. Lemann told them he had no other complaints. His vital signs were all normal. His pupils were equal and reactive to light. He denied any loss of consciousness, and a physical examination, which included his head, revealed no injuries other than an abrasion to his hand.

The paramedics at the scene offered twice to take Mr. Lemann to the hospital; both times he refused to go to the hospital. Mr. Lemann then signed a form acknowledging his refusal of transport.

Police officers took Mr. Lemann home. Several hours later, he was found unconscious by neighbors. He was then transported to a hospital and diagnosed with a fractured skull and a subdural hematoma. He died 2 days later.

Mr. Lemann's parents filed a lawsuit against the paramedics and their employer. They argued that paramedics should have taken Mr. Lemann to the hospital despite his lack of consent to be transported. The paramedics responded that Mr. Lemann must have suffered injuries subsequent to their evaluation of him and that he did not have the visible injuries to his head that were noted after his death.

The court ruled that the paramedics were not required to take Mr. Lemann to the hospital because he had the right to refuse transportation. The court further found that "the EMS personnel must balance fulfilling a person's emergency medical needs with respecting a person's wish not to be treated or transported to the hospital." In this case, the court said, paramedics did not observe a head injury while assessing Mr. Lemann, so they acted properly in respecting his refusal of transport to the hospital. The court granted judgment for the paramedics.

Although the published legal decision in this case does not discuss the patient care report, there appears to be no issues or questions surrounding those facts. The paramedics’ documentation of Mr. Lemann’s clinical presentation, DMC, and refusal of care held up to legal scrutiny, a major reason why the paramedics were able to prevail.

Emergency Medical Treatment and Active Labor Act

The Emergency Medical Treatment and Active Labor Act (EMTALA) is a federal law passed by the US Congress in 1986, with the primary goals of ensuring that all patients who need emergency medical care at an emergency department (ED) receive it, and of preventing hospitals from transferring patients to other facilities regardless of their insurance status or ability to pay for services. Even though this law has now been in force for several decades, there are still misunderstood provisions that apply to CCTPs. Because CCTPs primarily transport patients between facilities, several key provisions of EMTALA apply to their everyday practice.

EMTALA Requirements

EMTALA has two main obligations that involve ambulances. The first normally applies to patients who seek treatment for an emergency medical condition in the ED of a hospital that accepts Medicare for payment (which is virtually every ED in the United States). Any person who presents for treatment for an emergency medical condition must receive a medical screening exam and stabilization to the extent of the hospital's capabilities without consideration for the patient's ability to pay. This provision typically applies to ambulances that operate in the 9-1-1 system, or equivalent, and the hospital ED. EMTALA includes many details about how and when these requirements apply, including the requirement for "presentation" on hospital property and the immediate surrounding area, but most of them are not relevant to the CCTP.

However, the use of landing facilities for air medical units at hospitals is directly relevant to the CCTP. Current Medicare guidelines provide that EMTALA requirements are not triggered if a ground ambulance and crew are using the hospital's landing facilities as the facility of convenience; in this case, the patient is not considered to be presenting to the hospital for treatment for an emergency medical condition, and EMTALA obligations are therefore not triggered. However, if the CCTP requests any assistance from the hospital's personnel, then the EMTALA transfer obligations discussed next apply.

Medical Screening Exams

When a patient presents to the hospital for treatment of an **emergency medical condition**, the **medical screening exam** and stabilization requirements are triggered. An emergency medical condition is defined by the Centers for Medicare and Medicaid Services (CMS), in part, as "a condition manifesting itself by acute symptoms of sufficient severity [including severe pain] such that the absence of immediate medical attention could reasonably be expected to result in . . . serious jeopardy to the health of a patient, including a pregnant woman or a fetus."

The medical screening exam is not a triage exam. It must be performed by a physician, physician assistant, or nurse practitioner and is limited by the capabilities of the hospital. If the hospital does not have a particular diagnostic capability, it is not held responsible for not performing that study. The medical screening exam should include (1) a triage record; (2) initial vital signs; (3) oral history; (4) physical examination; (5) use of appropriate diagnostic resources to determine if an emergency medical condition exists; (6) use of on-call physicians, if necessary; and (7) discharge vital signs.

The medical screening exam requirement is triggered when the patient is within 250 yards of the hospital, or on hospital property, and is seeking treatment for an emergency medical condition. Thus, a patient who presents to the front door of a hospital rather than the ED entrance is considered to have presented for purposes of EMTALA. Also note that many critical care ambulances and air medical units are hospital-owned, making them "hospital property" for purposes of EMTALA. This does not mean that all patients in a hospital-owned vehicle must be transported back to the owning hospital, but it does mean that the patient must receive a screening exam; failure to ensure it happens may constitute an EMTALA violation.

Finally, stabilization means that within a reasonable degree of medical certainty, no "material" deterioration should occur from or during the transfer. In the case of a pregnant woman having contractions, stabilization is defined as delivery of the baby (or babies) and placenta.

Transfer Obligations

CCTPs typically deal with the EMTALA transfer obligations on a daily basis. The sending facility is responsible for arranging safe transport, including ensuring that qualified personnel and appropriate equipment are used. The receiving facility may actually perform the transport with its CCTP team, but that does not absolve the sending facility of its responsibilities. It is also the sending facility's responsibility to ensure that informed consent is obtained from the patient, or from a legally valid representative, prior to transport. The sending facility is also responsible, under EMTALA, for sending the medical records with the patient and ensuring that the receiving facility has space for the patient, has qualified personnel for managing the patient's medical condition, and accepts the patient. The records must also include a transfer form and certificate of medical necessity for Medicare patients.

In regard to the stabilization requirement, it is understood that many patients transported by CCTPs are not "stable." In fact, the very lack of stabilization is often the reason for the transport. For unstable patients, the sending physician must certify that the medical benefit outweighs the risks of transport, with that risk/benefit analysis and certification being clearly documented in the records.

The receiving hospital does not have to facilitate a "bed-to-bed" transfer but must have capacity for the patient. Capacity for the receiving hospital can be established in any way that that facility has established capacity in the past. For example, if the hospital admits patients through the ED, and typically holds overflow patients there, then the hospital must do that for any requested EMTALA transfer. It is an EMTALA violation, sometimes called "reverse dumping," for a hospital to refuse a patient if it has the specialty services that the patient requires and has the capacity to accept the patient.

A sending facility must receive agreement from a physician at the receiving facility to accept the incoming patient, and this acceptance must be documented; however, it does not have to be accomplished by physician-to-physician contact. This acceptance may not be delayed while the accepting physician receives approval from the hospital's administration. Furthermore, on-call physicians must come to see a patient at either the sending facility or the receiving facility, respond in a timely manner, and provide services if they ordinarily do so. The failure to provide any of these elements that leads to a patient transfer is an EMTALA violation.

EMTALA Violations

EMTALA is geared toward hospital and physician conduct; it was never intended to apply to the EMS community. If a hospital or physician is found to have violated the provisions of this law, several possible penalties may be imposed:

- A hospital may be fined between $25,000 and $50,000 per violation.
- A physician may be fined up to $50,000 per violation.
- A hospital or physician may be terminated from the Medicare and Medicaid programs.
- A patient may seek **civil damages** against a hospital or physician for injuries arising out of an EMTALA violation.

The fact that a non–hospital-based ambulance service may not be subject to the provisions of EMTALA does not mean that you or your service is absolved from all liability under this law. Although you cannot be held accountable for injuries arising out of an EMTALA transfer, the patient, or the patient's family, may file a lawsuit alleging malpractice or negligence against anyone involved.

EMTALA Case Scenarios

Many EMTALA cases have bearing on critical care transport. Specific judgments made in particular EMTALA cases include the following findings:

- EMTALA is not a substitute for malpractice action.
- Emergency stabilization prior to transport does not guarantee against patient deterioration en route.
- A patient can be transferred, even if unstable, if the benefits of transfer outweigh the risks.
- Stabilization relates to available capabilities.
- The patient must present to the ED or be on a hospital campus to trigger EMTALA coverage.
- Admission to inpatient care ends the EMTALA medical screening exam process (unless admission is used to avoid EMTALA requirements).
- An inpatient who becomes unstable and requires transfer is covered by EMTALA.
- The patient must have an emergency medical condition for EMTALA to apply.
- The physician has an obligation to "certify" transfer.
- Active labor requires treatment.

These examples of lessons learned from EMTALA cases give CCTPs an idea of the implications of EMTALA and suggest how this law might be applied in the critical care transport setting. The following are examples of the specific judgments in the preceding list.

Transfer Benefits Versus Risks

In *Heimlicher v Steele*, 615 F Supp 2d 884 (ND Iowa 2009), Ms. Heimlicher was an expectant mother who came to the hospital after experiencing severe pain and bleeding. An ED physician, Dr. Steele, failed to properly diagnose her condition. Dr. Steele ordered the transfer of Ms. Heimlicher to a hospital 100 miles away.

A nurse sent the ultrasonogram to a radiologist who was on call, who told her the images showed mass versus hemorrhage versus fibroid. Dr. Steele testified that he had never been advised of these findings, and if he had been informed he would have ordered an immediate cesarean section.

During transport, Ms. Heimlicher "almost immediately began experiencing too-rapid contractions, profuse vaginal bleeding, and severe pain in her abdomen," and the fetal monitor showed that the baby was in distress. The ambulance did not turn back, but rather continued to transport Ms. Heimlicher to the second hospital. The baby was stillborn.

The court found that there are three circumstances under which the hospital would have been justified in transferring Ms. Heimlicher and not been liable under EMTALA: "(1) her emergency medical condition was stabilized (EMTALA § (c)(1)); (2) her emergency medical condition was not stabilized, but she requested transfer to another hospital (EMTALA § (c)(1)(A)(i)); or (3) her emergency medical condition was not stabilized, but a physician signed a certification that the medical benefits reasonably expected from medical treatment at another hospital outweighed the increased risks to her and her unborn child from the transfer (EMTALA § (c)(1)(A)(ii))."

The court concluded that Ms. Heimlicher had not been stabilized and had not requested transfer. It also found that Dr. Steele failed to properly weigh the risks and benefits. Under these circumstances, the court found that the hospital had violated EMTALA. The court did not find the transport service had any liability under EMTALA.

In *Ramos-Cruz v Centro Medico del Turabo*, 642 F.3d 17 (1st Cir. 2011), Jose Ramos Lopez presented to the ED at Centro Medico del Turabo (CMDT) with a history of abdominal problems and experiencing abdominal pain. The ED physician diagnosed him with upper gastrointestinal bleeding.

CMDT did not have a gastroenterologist available to treat Mr. Lopez, so Dr. Ramon, the treating physician, arranged to have him transferred to San Juan Medical Center (SJMC) for treatment by a gastroenterologist there. Dr. Ramon signed a certification at the time of transfer stating that the benefits of transfer were greater than the risks. However, in the section titled "explain why the benefits of transfer for the patient . . . are greater than the risks, if any, for the transfer," Dr. Ramon documented simply "gastroenterologist." Mr. Lopez was treated for his bleeding ulcer at SJMC, but he began bleeding again later and physicians were unsuccessful in saving his life.

The family sued CMDT under EMTALA, claiming that Mr. Lopez had been improperly transferred. The First Circuit court found that EMTALA was a "limited anti-dumping statute, and not a federal malpractice statute." It also found that by entering only "gastroenterologist," Dr. Roman was making a "summary statement of a more explicit explanation that Mr. Lopez needed a gastroenterologist, none was present at the hospital and, therefore, he needed to be transferred because the benefits of a gastroenterologist outweighed the dangers of transportation." This summary statement alone was enough for the court to find that the hospital had not violated EMTALA.

Stabilization as It Relates to Available Capabilities

In *Cherukuri v. Shalala (DHHS)*, 175 F.3d 446 (6th Cir. 1999), five patients were brought by ambulance to the ED at Appalachian Regional Hospital (ARH) in Williamson, Kentucky. Two had serious internal injuries and head injuries. The hospital had no trauma center or equipment for monitoring anesthesia during brain surgery and had a long-standing policy of not performing neurosurgery on brain injuries. ARH had always transferred patients with these types of injuries to larger hospitals with the expertise to deal with them.

Dr. Cherukuri, a general surgeon, was on call. He arrived and treated the five patients for several hours. After stabilizing their blood pressure and other vital signs, he transferred the two seriously injured patients to the hospital. One patient died during the transfer, and the other survived.

The Department of Health and Human Services (DHHS) fined Dr. Cherukuri $50,000 for each of the two transfers. They claimed Dr. Cherukuri could have performed surgery and stabilized the patients' conditions because an anesthesiologist was willing to "put the patients to sleep." Dr. Cherukuri appealed the decision; DHHS denied the review. He then appealed the decision to the Sixth Circuit Court of Appeals.

The Circuit Court dismissed the fine and all EMTALA charges against Dr. Cherukuri. In doing so, the Court of Appeals looked to the act, which states that a patient whose condition has not been stabilized may be transferred (1) only on "a certification that based upon the information available at the time of transfer, the medical benefits reasonably expected from the provision of appropriate medical treatment at another medical facility outweigh the increased risk to the individual . . . from effecting the transfer" and (2) only if "the receiving facility . . . has agreed to accept the transfer of the individual and to provide appropriate medical treatment."

The court found that Dr. Cherukuri did not violate the stabilization provision of EMTALA. Stabilization requires an objective standard of reasonableness based on the situation at hand and "requires merely that a hospital stabilize patients within the staff and facilities at the hospital." The patient must be evaluated and, at a minimum, provided with whatever medical support services and transfer arrangements are consistent with the capabilities of the institution and the well-being of the patient.

Health Insurance Portability and Accountability Act

The **Health Insurance Portability and Accountability Act (HIPAA)** was originally passed in 1996, with the first set of regulations established in 2003. The HITECH Act, which updated HIPAA for a health care world that transitioned to electronic medical records (EMRs), was passed in 2009, with those regulations taking effect in 2013.

The original goals of HIPAA were many, including to allow people to take their health insurance from one employer to another, to create medical spending accounts, and, most importantly, to safeguard the privacy and security of patients' health care information. Despite these seemingly clear objectives, HIPAA's legal implications are frequently misunderstood and the act is often used in a manner inconsistent with its intent and provisions. Understanding HIPAA starts with defining some basic terms and concepts.

Definitions

Protected health information (PHI) refers to health data created or shared by HIPAA-covered entities and their business associates in the course of providing health care and paying or billing for health care services. The key points about PHI are that it must be created by a covered entity; must be related to health status, health care, or payment; and must be linked to a specific individual.

A **covered entity** under HIPAA is one of three things: a health care provider, a health plan (eg, HMO, insurance company), or a health clearinghouse. These entities must transmit health information in electronic form in connection with a transaction covered by HIPAA (payment or administrative) to qualify. Ambulance providers of all kinds are explicitly included in the definition of a covered entity. A **business associate** is a person or entity, other than a covered entity, who performs activities on behalf of, or provides services to, a covered entity that involves access to PHI. Examples of services performed by a business associate include claims processing, quality improvement, practice management, and legal services. Covered entities must have a written agreement with business associates under which all of the standard HIPAA provisions are extended to the business associate.

HIPAA Privacy Rule

The HIPAA Privacy Rule addresses when a covered entity is permitted to use PHI. The default rule under HIPAA is that no party may use or disclose PHI without the patient's (or their representative's) written consent. However, HIPAA provides for numerous exceptions to the default rule.

First, and most importantly, providers may use or disclose PHI to accomplish the three main goals of health care: treatment, payment, and operations (TPO). Treatment is the provision, coordination, and management of health care providers. Payment is the reimbursement for treatment. Operations refers to administrative, financial, legal, or quality improvement services. A covered entity may disclose PHI without the patient's (or representative's) written consent to TPO entities; however, for payment and operations, the covered entity may disclose only the minimum necessary information to accomplish the stated goal. For example, providers may not disclose an entire health record just to accomplish payment, if a "face sheet" will do in that circumstance.

Many other disclosures are permitted under HIPAA without the patient's consent, including those related to public health activities, health oversight, end-of-life matters (funeral directors, coroners, medical examiners), organ and tissue donation, research activities, essential government functions, worker's compensation activities, and prevention of a serious imminent threat to health and safety. Specific disclosures to law enforcement are also permitted, such as identifying a specific person, providing information about a crime victim, and alerting law enforcement to a suspicious death. Likewise, a disclosure would be permitted when required by another specific law, such as reporting gunshot wounds or dog bites. Finally, PHI may be disclosed any time it is required by a judicial order.

HIPAA Security Rule

The HIPAA Security Rule addresses preventing unauthorized use of or access to PHI. HIPAA requires numerous levels of safeguards to protect patient information. Administrative safeguards include policies, authorization, training, and audits. Physical safeguards include hardware and software security, access limits, locks, and cameras. Technical safeguards include authentication and encryption of data.

Other HIPAA Requirements

HIPAA has other relevant provisions, such as the requirement to provide a notice of privacy practices at the time of services or when the emergency is over. It also allows for the correction of errors in PHI and requires that covered entities disclose PHI when requested by the patient within 30 days in the manner in which the patient requests it. This final provision is a common source of HIPAA violations.

HIPAA Violations

The Department of Health and Human Services, Office of Civil Rights, has exclusive jurisdiction over HIPAA violations. There is no private right for people to sue for HIPAA violations, although negligence claims can be brought using HIPAA as the default standard of care.

HIPAA violations range from a $100 fine for a violation that happened without the covered entity’s knowledge and where reasonable diligence could not have prevented the violation, to willful neglect that goes uncorrected, which has a $50,000 minimum fine per violation. For offenses such as knowingly obtaining or disclosing PHI, using false pretenses to obtain PHI, or using PHI for personal gain or malicious harm, criminal penalties may potentially apply as well.

Legal Considerations During Transport Operations

Organizing the Personnel

CCTP qualification requirements are an issue that starts with the state licensing authority. State statutes and regulations will determine what each level of provider can do, and what levels of providers are necessary for certain types of transportation.

EMTALA requires the sending physician to specify the qualifications of personnel accompanying the patient during transport. To determine the level of personnel necessary to care for the patient and manage specialized equipment during transport, the physician should consider that personnel aboard local transport vehicles (ground and air) may be trained in a variety of skill levels, ranging from EMT to paramedic. Some systems also staff transport vehicles with nurses and physicians. Those personnel will be functioning under **medical direction** that provides protocols, including standing orders, for prehospital providers within their system. It is also important that all necessary and appropriate equipment, medications, and supplies that are within the scope of practice of the personnel onboard and that may be required by the patient be available in sufficient quantities. It is your responsibility to ensure the transport vehicle is adequately stocked **FIGURE 2-2**.

FIGURE 2-2 The critical care transport professional is responsible for making sure the vehicle is adequately stocked.

© VanderWolf Images/Shutterstock.

If the patient's current condition and all reasonably foreseeable complications can be managed within the licensure, training, and capability of the crew on the transfer vehicle, the patient may be transferred without being accompanied by ancillary personnel. However, when faced with the need to provide care beyond your scope of practice, you should request additional personnel for the transport.

Ancillary personnel may have specialized skills (eg, a balloon pump technician or a perfusionist) or may assume overall responsibility for care (eg, a neonatologist for a neonatal intensive care patient). Whenever ancillary personnel assume ultimate responsibility for the care of the patient, you should provide support to them as needed. If the sending facility provides ancillary personnel and special equipment, it is that facility’s responsibility to maintain the special equipment and provide for its return.

Preparing for Transfer

In preparation for transport, obtain the pertinent patient information, including the following:

- Reason for transfer
- Name of the receiving hospital and/or physician
- Level of care the patient needs during transport
- Treatment provided at the sending facility
- Medical treatment and drug orders for the duration of the transfer
- Any devices, such as ventilators or infusion pumps, that are necessary
- Complications to anticipate

In addition, obtain the name of the receiving physician before transport to avoid an unnecessary delay, embarrassment, and potential conflict at the receiving facility.

Review the transport orders for treatment *before* leaving the sending facility. Ensure those orders do not exceed your scope of practice. If they do, talk with the sending physician to modify the plan of care. If the plan cannot be modified, the sending facility must provide additional personnel to accompany you and facilitate the provision of needed care.

Communicating With the Health Care Team

When preparing for a transport, you should make every effort to communicate effectively, professionally, and succinctly with other members of the health care team. In some rare cases, conflict may arise between you and the sending physician regarding the interventions needed before transport. If this happens, state your concerns clearly and professionally. If there is still disagreement, contact the receiving facility's physician to attempt a cooperative resolution. If the situation cannot be resolved, contact the critical care transport agency's medical director for assistance. The ultimate decision may be to refuse to transport, but it should be carefully considered. Use extreme care and make sure your decision is reasonable and in the patient's best interests.

Some requests for transport may originate in a physician's office or clinic. The physician in this setting may not be familiar with your local protocols. In this situation, you should thoroughly communicate your capabilities and limitations to the sending physician. A plan of care that is within your scope of practice must be developed. If the physician is unwilling to help you develop such a plan, politely insist that the sending physician accompany the patient to the receiving facility **FIGURE 2-3**. If the sending physician is unwilling to do so, proceed as outlined in the preceding paragraph or contact medical control for assistance in resolving the conflict. Also consider having the sending physician speak directly with medical control to develop a plan of care for transport. In many circumstances involving conflict, you may become the mediator, with the goal of making sure the patient gets the best care. If you keep this objective in mind, you will be in the right almost every time!

Working With Medical Direction

During transport, you will usually operate with **off-line medical direction** using established written protocols or standing orders. If treatment beyond protocol is indicated or consultation is needed, establish contact with medical control and proceed under **online medical direction**. Make sure that online medical direction will be readily available before you begin the transport. Also, confirm that the sending and receiving physicians understand who will provide medical direction and that this may necessitate an alteration in the established plan of care. Sometimes the distance ranges of communications equipment may require shared responsibility between the sending and receiving physicians or even with the transport agency's medical director.

Protocols should include appropriate actions for cases in which communication with the established medical director is not possible. When continuous communications are not available, transport orders should enable you to respond appropriately to medical crises and changes in the patient’s status. Standing orders or protocols may be developed to meet these needs.

You may need to remind the sending physician that prehospital protocols for EMS systems do not automatically apply in the interfacility transport environment. Prehospital protocols may be limited to use in specified environments by personnel who are described under state rules for the EMS system; hospital personnel who accompany the patient usually do not fall under these protocols and often are not familiar with them. When sending physicians write transport orders, they should designate the protocols by name in the transport orders, write pertinent sections into the orders, or attach a printed copy.

Completing the Transport

On arrival at the receiving facility, you must ensure continuity of care by giving a report to the designated receiving care provider. This report should include the following information:

- Patient’s name, age, and sex
- Names of sending physician and facility
- Reason for the transfer
- Brief review of body systems
- Patient’s history
- Medications administered
- Fluid intake
- Summary of the patient’s condition during and tolerance of the transport in a clear, concise, and logical format

Transfer specimens, records, and laboratory and radiography results to the receiving provider, and make yourself available to answer questions after the transfer of care.

Documentation

All health care personnel are taught the importance of documentation **TABLE 2-3**. At no time is accurate and complete documentation more important than when providing care for a patient who is seriously ill or in critical condition. When a patient's status changes rapidly and without warning, numerous interventions may be carried out and transfer orders may have to be modified during transport. It is often a challenge to maintain documentation during a transfer that requires your constant attention to the patient.

TABLE 2-3 Purposes of Documentation

- Provides a record of care for CCTPs
- Ensures continuity of care through the health care system
- Facilitates quality improvement efforts
- Provides a mechanism for reimbursement
- Satisfies regulatory requirements
- Ensures legal defensibility of the care provided

© Jones & Bartlett Learning.

Good documentation serves as protection for EMS personnel, and a complete and accurate report is a reflection of good patient care. An accurate, complete, legible medical record implies accurate, complete, organized assessment and management. If you make a mistake, document it. Include all requested information. If the information requested does not apply, include a "not applicable" or "N/A" note. If you look for something and it is not there, document its absence.

If the report is incomplete, others will assume the care was equally incomplete. The implementation of EMRs makes sloppiness a nonissue **FIGURE 2-4**, but that does not excuse the need for accuracy and completeness. Good documentation is a reflection of good patient care!

In the critical care transport setting, in which transfer often represents a team effort, it is important for team members to understand who has the responsibility for each aspect of documentation. When dealing with an acutely ill patient, it is easy to assume that the other team member may have documented an intervention or a set of vital signs, only to learn later that the documentation was not included in either report. Team members should work together at the conclusion of a run to ensure the documentation is accurate and complete.

It is particularly important to record certain essential elements of every transfer:

- Times of each set of vital signs and each assessment finding

- Details and times of each intervention (eg, drug doses and routes of administration)
- Patient responses to all interventions
- Untoward or adverse reactions
- Communications with medical control
- Deviation from transfer orders or standing orders
- Diversion to another hospital
- Refusal of treatment by the patient

If you must amend a run report following its submission to the receiving facility, make sure the amendment is done in accordance with local protocol.

Summary

The legal concepts described in this chapter may seem daunting at first, but are issues that CCTPs deal with every day. A basic understanding of the fundamentals of critical care transport laws can help guide your care and help you avoid negative legal consequences. Local laws vary, but general legal principles such as consent and negligence apply in all jurisdictions. Likewise, all transport providers are subject to, and should clearly understand, EMTALA and HIPAA. You should continue to learn about, become familiar with, and comply with these laws, regulations, and protocols as part of your continued growth as a CCTP.

Remaining calm, professional, and compassionate at all times will help you maintain the proper mindset to provide the best possible care for your patients. Further, it will engender in your patients and their families confidence that you have done your job well, thereby decreasing the likelihood they will file complaints or lawsuits if an adverse outcome occurs. Of course, ensuring that your documentation is clear and complete will go a long way toward protecting you as well.

CASE STUDY

Your critical care transport team has been requested to provide an interfacility transport from a rural hospital. The patient is a 28-year-old woman at 29 weeks' gestation. She presented to the local ED around 2230 hours, reporting contractions every 10 minutes. ED staff placed the patient on a fetal monitor and confirmed their suspicions of preterm labor. The fetal monitor showed normal variability with no decelerations. The patient received a 0.25 mg subcutaneous injection of terbutaline prior to your arrival.

When you arrive, you find the patient in the ED. She has responded to the terbutaline, and her uterine contractions have slowed to 15 minutes apart and are less intense. The physician reports to you and your team that the fetal monitor has shown normal variability with no decelerations. You are assessing the patient and preparing her for transport when you realize that you accidentally left the transport fetal monitor in the ambulance. Given the transport time will be only 20 minutes, you decide not to go to the ambulance to retrieve the fetal monitor; instead, you plan to place the patient on the fetal monitor once you reach the ambulance.

During the short transfer time to the ambulance, the patient's contractions become more frequent. You load the patient into the ambulance and begin your transport. The patient's contractions have now increased to every 5 minutes. Your critical care protocols state to administer magnesium sulfate, with the initial loading dose of 4 to 6 g IV over 20 minutes, followed by a maintenance drip of 1 to 4 g/h. While you are mixing the loading dose, the patient is screaming and crying hysterically in pain. Your partner is attempting to calm her while you prepare the drip.

You place the magnesium sulfate on the transport infusion pump. The pump beeps, indicating that there is air in the line. You disconnect the drip, flush the line, and reattach it to the pump. The pump beeps again, indicating air in the line. You again disconnect the line in an attempt to flush it. The patient continues to scream in pain, and her contractions continue to increase in frequency. You once again flush and reattach the line; the pump gives the green light indicating that it is functioning. Your ETA (estimated time of arrival) to the hospital is 5 minutes. You and your team reassess the patient and determine that the contractions are slowing in frequency.

As you and your team arrive at the receiving hospital, you realize that you forgot to attach the fetal monitor during the commotion. You quickly attach the fetal monitor without reviewing the strip. You unload the patient from the ambulance and transfer her to the obstetrics (OB) unit. You report to the staff that the patient was administered magnesium sulfate because of an increase in her contractions.

You and your team disconnect the patient from your equipment and transfer the patient to the hospital bed. The OB nurse attaches the patient to the hospital fetal monitor and becomes concerned with the fetal monitoring strip. She immediately calls for a physician. The fetal strip shows late deceleration. The nurse and physician ask to see the previous strip during the transport. You report that you forgot to place the patient on the monitor.

The patient is rushed to the operating room for immediate surgery. The infant is delivered with an Apgar score of 0 and requires full resuscitation efforts. The infant does not survive, despite the intense resuscitation efforts.

1. What actions on the part of the critical care transport team were responsible for the infant's outcome?
2. What factors would make this a case of negligence?
3. What has to be proven for a negligence lawsuit?
4. What should have been done to prevent this outcome?

Analysis

The symptoms of preterm labor include a contraction every 10 minutes or more, frequent pelvic pressure, lower back pain, and abdominal cramping. This patient was, indeed, in preterm labor. Terbutaline is used to relax the smooth muscle of the uterus.

In this case, the critical care transport team's conduct was negligent, most certainly by not performing fetal monitoring during transport. The delay in administering magnesium could also qualify as negligence, depending on the circumstances.

PREP KIT

Ready for Review

- CCTPs must familiarize themselves with legal concepts and terms to operate effectively and protect themselves from charges of unlawful conduct. They must understand the laws where they practice and know the local protocols.
- CCTPs must understand the basic concepts of negligence and the following four findings, which are required to establish an act of negligence:
  1. A health care provider had a duty to act.
  2. The provider committed a breach of duty to act.
  3. The patient suffered damages as a result of the breach of duty.
  4. The damages were proximally caused (foreseeable) from that breach of duty.
- Providers may be protected from charges of negligence by laws and statutes requiring a higher standard be reached to find a health care provider responsible for an injury. These higher standards include reckless conduct and willful and wanton conduct.
- Although CCTPs are typically covered by their employer's professional liability insurance through the concept of *respondeat superior*, they may not be covered if they act beyond their scope of practice or if they provide care while off duty.
- Adult patients have a basic right to consent to medical care. Consent should be informed and may be either explicit or implicit.
- Providers must determine the patient's competence and decision-making capacity (DMC) in establishing consent. CCTPs who fail to assess DMC and obtain informed consent risk claims of liability that go beyond negligence, including battery and abandonment.

- All aspects of the assessment of competence, including any associated documents, DMC, and informed consent or refusal, should be objectively documented in the patient care report. This documentation should always use clear, concise, and objective language.
- CCTPs must understand the requirements defined by the Emergency Medical Treatment and Active Labor Act (EMTALA), including the medical screening exam and patient stabilization requirements, and the transfer requirements.
- Hospitals or physicians found in violation of the EMTALA provisions face several possible penalties, including fines, termination from Medicare and Medicaid programs, and civil litigation against the hospital and/or physician for injuries arising from an EMTALA violation.
- Current EMTALA case law has broad implications for interfacility transport, though it was originally developed simply to prevent hospitals from “dumping” patients because of inability to pay. Many EMTALA cases have a bearing on critical care transport, and as more cases are decided, their interfacility transport implications may become more far-reaching. This is a frequently changing area of the law through ongoing court cases.
- CCTPs must understand the purpose and requirements of the Health Insurance Portability and Accountability Act (HIPAA), especially including the concept of protected health information. They must adhere to the guidelines, including the default conditions and the limited exceptions, under which they may share private patient information.
- In preparing for transport, you should communicate fully with the other members of the health care team at the sending and receiving facilities, and a plan of care should be developed that is within your scope of practice.
- In preparation for transport, you need to take the following actions:
    - Determine the reason for transfer.

  - Obtain the name of the receiving hospital and/or physician.
  - Determine whether a BLS, ALS, or CCT provider must accompany the patient and whether the sending facility plans to provide an escort.
  - Obtain information on the treatments provided at the sending facility, the treatments and drug orders for the duration of the transfer, and any potential complications that may arise during transport.
- The sending physician must send copies of medical records with the patient to the receiving facility that document the patient’s current diagnosis and condition, symptoms the patient is experiencing, treatments given, results of tests conducted, written consent of the patient or a person with legal authority agreeing to the transfer, and the physician’s verification that the benefits of transferring the patient outweigh the risks. The sending physician must also send samples of pertinent laboratory specimens.
- As a CCTP, you will typically operate with off-line medical direction using established written protocols. If treatment beyond those protocols is indicated or consultation is needed, you should establish contact with medical control and proceed under online medical direction.
- EMTALA requires the sending physician to designate the qualifications of personnel accompanying the patient during transport and to ensure that all necessary and appropriate equipment, medications, and supplies that may be required by the patient are available in sufficient quantities and are within the scope of practice of the personnel accompanying the patient during transport.
- At the sending facility, you must assess the patient, discuss potential complications with the sending physician, and ensure the sending physician understands the capabilities and limitations of the transport team.
- During transport, you must monitor the patient’s condition, provide the appropriate care within your scope of practice, inform medical

control or the receiving facility of any changes in the patient’s condition or any extenuating circumstances, and maintain thorough documentation.

- On arrival at the receiving facility, you must ensure continuity of care by giving a detailed report to the designated receiving care provider. This report must include all patient information, the names of the sending physician and facility, the reason for transfer, all documentation and records (including the patient’s history, medications, fluid intake, condition during transport, and tolerance of transport), any transfer specimens from the sending facility, and any laboratory and/or radiography results from the sending facility.
- You should be available to answer questions from the receiving care provider after the transfer of care is complete.
- Documentation for every transfer should include the times of each set of vital signs and each assessment finding, the details and times of each intervention (such as drug doses and routes of administration), the patient’s responses to all interventions and any adverse reactions, all communications with medical control, any deviations from the transfer or standing orders, any diversions to another hospital or facility, and any refusals of treatment by the patient.

Vital Vocabulary

abandonment The termination of the patient relationship without assurance that an equal or greater level of care will continue.

assault The unlawful act of placing a person in apprehension of immediate bodily harm without their consent.

battery The unlawful touching of another person without their consent.

breach of duty to act A case in which a health care provider does not conform to the standard of care by providing inappropriate care, failing to act, or acting beyond the scope of practice.

business associate As defined under HIPAA, a person or entity, other than a covered entity, who performs activities on behalf of, or provides services to, a covered entity that involves access to protected health information.

civil damages Monetary compensation awarded to a plaintiff in noncriminal court proceedings.

common law Case law established by prior disputes that is published to guide future proceedings.

competence A legal determination, through a statute or court proceeding, that a person is capable of making personal decisions, including about their health care.

consent Voluntary agreement by a patient with sufficient mental capacity to capably accept or refuse assessment, treatment, or transport offered by the care provider.

covered entity As defined under HIPAA, a health care provider, a health plan, or a health clearinghouse that must transmit health information in electronic form in connection with a transaction covered by HIPAA (payment or administrative) to qualify. Ambulance providers of all kinds are explicitly included in the definition of a covered entity.

damages In a legal context, harm that results from a breach of duty by a health care provider who is found negligent. Usually, the injury is physical.

decision-making capacity (DMC) The determination that a patient's brain is functioning well enough to process information and make health care decisions.

discovery rule A legal rule stating that the statute of limitations for filing a legal case does not begin until the injured party can reasonably be expected to know of the injury.

do not resuscitate (DNR) order A type of advance directive that describes which life-sustaining procedures should be performed if the patient suffers cardiopulmonary arrest.

duty to act A legal obligation of health care providers to render medical care to a certain level. When the duty to act applies varies from state to state.

emergency medical condition A condition manifesting itself by acute symptoms of sufficient severity (including severe pain) such that the absence of immediate medical attention could reasonably be expected to result in placing the individual's health (or the health of an unborn child) in serious jeopardy, serious impairment to bodily functions, or serious dysfunction of bodily organs.

Emergency Medical Treatment and Active Labor Act (EMTALA) A federal law passed by the US Congress in 1986, with the primary goal of preventing hospitals from failing to treat patients, or transferring patients to other facilities, based on their insurance status or ability to pay for services.

expressed consent A patient's voluntary verbal, nonverbal, or written agreement to consent to treatment or transport.

Health Insurance Portability and Accountability Act (HIPAA) A federal law enacted in 1996, providing for criminal sanctions and civil penalties for releasing a patient's protected health information in a way not authorized by the patient.

implied consent The legal assumption made on behalf of a person who is unable to give consent that they would give consent if able to do so.

informed consent The process of proposing to the patient a course of action (assessment, treatment, transport), the risks associated with that action, the benefits associated with the action, and any reasonable alternatives, and then allowing the patient to decide if they want the provider to proceed with the action.

medical control The oversight designed to ensure that actions taken by providers on behalf of patients are appropriate. It is divided into direct (online) medical control, which is available in real time via radio or mobile phone, and indirect (off-line) medical control, such as standing orders and protocols.

medical direction Supervision of medical care by a physician empowered to authorize and review CCTPs, usually through protocols, standing orders, education, and quality improvement efforts.

medical screening exam An exam that is legally required when the patient is within 250 yards of the hospital, or on hospital property, and is seeking treatment for an emergency medical condition; it must be performed by a physician, physician assistant, or nurse practitioner.

negligence Failure to provide the same quality of care (as defined by applicable standards) that is reasonably expected for a provider to give under similar circumstances. Negligence is established when the plaintiff proves four elements: duty to act, breach of the duty, injury to the patient, and the breach as the direct cause of the injury.

off-line medical direction Medical direction given through a set of protocols, standing orders, educational programs, policies, and/or standards.

online medical direction Medical direction in which the care provider is in direct contact with a physician, usually via two-way radio or telephone.

physician orders for life-sustaining treatment (POLST) A legal document that establishes in advance what care a person wants, and does not want, in the event that they are unable to consent to care at the time.

protected health information (PHI) Individually identifiable information (eg, name, Social Security number, and date of birth), health information (eg, laboratory results and medical history), and demographic information (eg, address and telephone number) that is protected by HIPAA.

proximally caused A legal term that describes damages that could have reasonably been anticipated before the breach of duty occurred.

reckless conduct A more serious finding than typical negligence; it involves consciously disregarding the known risks of a course of action. Also called gross negligence.

respondeat superior The legal concept that an employer is responsible for the acts of its agents.

scope of practice The body of knowledge, skills, and therapies that CCTPs can legally apply in patient care, based on training, certification, medical direction, and applicable law.

sovereign immunity A type of immunity often afforded EMS providers that is provided only to governmental entities. This immunity can align with the reckless or willful and wanton requirements, or it can differentiate between ministerial acts (those requiring a specific act given a set of circumstances) and discretionary acts (those in which the provider has some latitude in decision making).

statutes Formal laws passed by a legislative body and signed by an executive.

statute of limitations The time limit within which negligence cases must be filed; it is typically 2 years but varies from state to state and may be longer if the patient is a minor.

tort A wrongful act between people or entities that gives rise to a civil lawsuit.

willful and wanton A more serious finding than typical negligence misconduct; it usually requires an intentional act of misconduct.

CHAPTER 3

Patient Safety

Jeffrey S. Rabrich, DO, FACEP, EMT-P

OBJECTIVES

After completing this chapter, you will be able to:

1. Recognize how health care quality has evolved and is measured (p 48).
2. Define patient safety (p 49).
3. Recognize the various levels of safety violations (pp 49–50).
4. Describe the elements of a safety culture, including a just culture and the characteristics demonstrated by highly reliable organizations (pp 50–51).
5. Identify the various types of errors that arise in health care, including medication and prescription errors, errors related to patient and procedure identification, and errors occurring during transitions of care and handoffs (pp 52–54).
6. Explain the systemic factors that contribute to health care errors (pp 54–55).
7. Describe the process for handling sentinel events (serious adverse events) (pp 55–57).
8. Summarize strategies and techniques to avoid errors, including Six Sigma, Lean, crew resource management, simulation training, and failure mode and effect analysis (pp 59–60).
9. Discuss key factors affecting quality in EMS settings (pp 60–63).

Introduction

The process of a patient entering the emergency medical services (EMS) system begins with the decision by the patient to seek care and ends when the patient is handed off to hospital personnel. Critical care transport (CCT) begins when a referring practitioner or a transfer call center contacts a CCT service with a request to move a patient. In an ideal EMS system (or any hospital setting), the correct medication is given via the correct route to the correct patient, the destination decision is always right, and the differential diagnosis is adequately considered. A patient’s care process is very complex, including many separate components—clinicians, radiology, laboratory, transport, and prehospital care, among others—and all of these groups must coordinate their actions as part of the joint effort that makes up the health care organization. In fact, if one were to create a process map of the steps to safely move a patient from one care setting to another, it would undoubtedly contain hundreds of steps that must be flawlessly executed. In an ideal world, a patient moves seamlessly through the various departments from initial presentation to disposition. Of course, in the real world, the complexities of patient care, among other variables, present many opportunities for process failures, errors, and adverse outcomes. It is the goal of the patient safety organization or the highly reliable organization to reduce the chance of error as close to zero as possible.

History of Quality as a Health Care Discipline

Awareness of health care quality remained minimal and measurement of quality was a slow-moving process until the early 1990s, when several landmark papers on this topic were published. One of the earliest movements for quality began in the early 1900s with Dr. Ernest Codman, a surgeon at Massachusetts General Hospital. Codman was one of the first physicians to insist on recording and reporting on individual physician outcomes—that is, an "end-results system"—to monitor the quality of physician and hospital care. His work led to the establishment of the American College of Surgeons in 1913. Unfortunately, work in improving health care quality languished for much of the 20th century.

Scope of the Problem

In the early 1990s, the Harvard Medical Practice Study reported that almost 4% of hospitalized patients sustained significant adverse events during their care and nearly one-third of these events occurred secondary to human error. This study and others ultimately led the Institute of Medicine (IOM; now called the National Academy of Medicine) to investigate health care quality. The IOM's seminal report on this topic was published in 1999. Titled *To Err Is Human: Building a Safer Health System*, this report not only captivated the medical community, but also caused the media and the general public to become keenly aware of the issue of safety in health care and put this concern on the national agenda.

To Err Is Human reported in 1999 that almost 100,000 Americans were dying each year secondary to medical errors, citing these errors as the eighth leading cause of death in the United States. The major revelation in this report was the concept that failures or errors in care were frequently not the result of individual behaviors or decisions, but rather were often related to the intrinsic processes of care in the health care system. Thus, the IOM suggested, efforts to improve safety should address process-related errors rather than target individuals. Slowly, over time, the idea of system failure rather than human error as the key consideration gained credence within the health care community. Eventually, other organizations, such as the National Quality Forum, the Institute for Healthcare Improvement, and the Agency for Healthcare Research and Quality, invested in efforts to decrease the frequency of medical errors.

Despite these efforts, an analysis published in 2016 suggests that medical errors may now be the third leading cause of death, claiming more than 250,000 lives in the United States each year. However, a more recent study, published by the Yale School of Medicine in 2020, suggests that the number of preventable hospital deaths may be grossly overestimated at 250,000, and is more likely closer to 22,000, with these deaths occurring mostly in patients with a life expectancy of 3 months. While 22,000 is still far too many preventable deaths, emphasis on patient safety and just culture appear to be helping reduce errors.

Quality of EMS Care

In 2007, the IOM published *Emergency Medical Services: At the Crossroads*, a comprehensive look at the current state of EMS at the time and the challenges and limitations of the modern EMS system in the United States. Among the information provided in this report was a review of safety and efficacy of EMS care. The IOM report noted that EMS providers face numerous challenges in delivering care:

> Prehospital emergency care services are delivered in an uncertain, stressful environment where the need for haste and other potential distractions produce threats to patient care and safety. In addition, shift work and around-the-clock coverage contribute to fatigue among EMS providers. Error rates for such procedures as endotracheal intubation are high, especially compared with the same procedures performed in a hospital setting.

Although this topic has not been studied extensively, the critical care transport professional (CCTP) likely encounters more critically ill patients and more complex patient care scenarios than a 9-1-1 responder simply because of the serious nature of an injury or illness that necessitates transfer. Hence, the likelihood of errors may be much greater in the CCT environment than in the usual EMS setting.

The *EMS at the Crossroads* report went on to discuss the six quality aims included in the IOM's *Crossing the Quality Chasm: A New Health System for the 21st Century* report, which had been published in 2001. Specifically, *Crossing the Quality Chasm* insisted that health care should be safe, effective, patient centered, timely, efficient, and equitable **TABLE 3-1**. Each of these characteristics is examined further in this chapter.

TABLE 3-1 Six Quality Aims

- **Safety:** Avoid needless death, injury, pain, and suffering for patients and staff.
- **Timeliness:** Waste no one's time.
- **Effectiveness:** Provide care and service based on best evidence and informed by patient values and preferences.
- **Efficiency:** Remove all unnecessary processes or steps in processes; streamline all activities.
- **Equity:** Provide fair and equitable care and service; treat all patients equally.
- **Patient centeredness:** Honor individual patients—their values, choices, culture, social context, and specific needs.

Data from Institute of Medicine. *Crossing the Quality Chasm: A New Health System for the 21st Century*. Washington, D.C.: National Academy Press; 2001.

The six quality aims have some unique implications in the EMS field. Although EMS systems try to be patient centered and provide the appropriate resources to each patient at the appropriate time, numerous barriers to patient-centered care remain. Barriers include language and care of special populations such as geriatric patients, pediatric patients with and without special needs, and patients who have undergone bariatric surgery, to name a few. Chapter 25, *Bariatric, Psychiatric, and Special Situations*, discusses some of these special patient populations in more detail.

While many of the issues raised in the 2007 IOM report remain valid today, numerous advances have occurred since it was released.

Research has increased dramatically in the prehospital field, the role of the EMS medical director has been given more weight, a medical subspecialty of EMS medicine has been created, and many large EMS agencies have devoted considerable time and personnel to safety and quality efforts. In 2012, the unique knowledge and skill set of EMS medicine was acknowledged when the American Board of Emergency Medicine recognized EMS as an official subspecialty. By creating a specialty certification in EMS medicine, a minimum standard for qualifications and training was established. Part of the core content for EMS medicine is quality improvement and medical oversight of agency quality programs.

In more recent years, several organizations have focused on disease-specific quality measures for EMS systems to ensure key measures are met. For example, the American Heart Association's Mission: Lifeline program recognizes EMS agencies and hospitals that have achieved excellence in caring for patients with ST-elevation myocardial infarction (STEMI). The American College of Surgeons has established trauma measures for EMS. The National Academies of Sciences, Engineering, and Medicine released a report in 2016 titled *A National Trauma Care System: Integrating Military and Civilian Trauma Systems to Achieve Zero Preventable Deaths After Injury*, which provides recommendations geared toward achieving zero preventable deaths.

What Is Patient Safety?

Defining **patient safety** has proved difficult for organizations, because it can be considered a philosophy, a discipline, or an attribute. The World Health Organization provides a fairly simple definition: Patient safety means freedom from unnecessary harm or potential harm associated with health care. The Agency for Healthcare Research and Quality (AHRQ) offers a more complex definition:

> Patient safety is a discipline in the health care sector that applies safety science methods toward the goal of achieving a trustworthy system of health care delivery. Patient safety is also an attribute of health care systems; it minimizes the incidence and impact of, and maximizes recovery from, adverse events.

In this chapter, patient safety is defined as the reduction of risk of unnecessary harm associated with EMS care to an acceptable minimum. The acceptable minimum is defined by the limits of the best available medical evidence, equipment, technology, and human skill.

Error Versus Harm

The impetus for patient safety programs is the body of evidence showing that adverse medical events are widespread and preventable, resulting in too much harm. Emergency medicine, EMS, and CCT are all fields characterized by the need for quick decision making using limited information, complex tasks, and long work hours. These characteristics mean that even the brightest and most conscientious clinician will at times make errors.

When thinking about adverse events, however, it is important to distinguish between the concepts of error and harm. A medical **error** is a preventable adverse effect resulting from care, whether or not it is evident or harmful to the patient. **Harm** is unintended physical injury resulting from or contributed to by medical care. Not all errors will reach patients and cause harm, but it is essential for organizations to study these errors and look for opportunities to improve the processes that allow them to happen. Errors that lead to serious patient harm are rarely the result of just one error involving just one person. Instead, they usually comprise a series of errors or breakdowns in processes, many of which have been occurring for some time, but not all at once. This multifaceted breakdown is often referred to as the Swiss cheese model (discussed later in the chapter) or, in aviation, as links in the accident chain.

Near Misses

Breakdowns in communication that almost led to errors or harm can be referred to as near misses or close calls. A **near miss** is an unplanned event that did not cause injury, illness, or damage, but had the potential to do so; it is indistinguishable from a full-fledged adverse event in all but the outcome. Near misses may occur many times before an actual harmful incident takes place, and provide opportunities to learn from the occasion and identify improvement options.

An example of a near miss is a provider ordering a medication without considering the patient’s allergies; however, a nurse or paramedic checks for allergies and speaks with the provider before administering the prescribed medication. Thus, the provider’s error is caught and the contraindicated medication is not given.

It is widely believed that near-miss events are heavily underreported. Often staff do not report these events because they fear they will be disciplined, they perceive a lack of support or caring by supervisors, or they believe it is unnecessary to report the incident if no patient harm occurred. In fact, near-miss events are among the most important to report, because they provide the organization with an opportunity to analyze its processes and improve safety. Moreover, talking about near misses can be easier for staff because there are fewer liability concerns when no one was harmed.

Medical Errors

Although the study of errors began in the early 1900s, it really took off when the safety of commercial aviation came under scrutiny. In this field, studies showed a system-level approach was the best way to detect and prevent errors. In other words, rather than looking at individuals and deeming every incident to be a single human failure, it was necessary to look deeper and see other confounding factors that may have set the stage for error.

Medical error can be defined as the failure of a planned action to be completed as intended, or the use of a wrong plan to achieve an aim related to health care. Such errors can be categorized as adverse drug events, wrong-site surgeries, falls, burns, pressure ulcers, and mistaken patient identities. High error rates with serious consequences are most likely to occur in the intensive care unit (ICU), operating room, emergency department (ED), and, in all likelihood, CCT. Every error represents an opportunity to improve a process, but to achieve this goal, these errors must be recognized and made known so they can be analyzed.

Safety Culture

Improving the culture of safety within health care is essential in preventing and reducing errors and improving quality of care. The **safety culture** is primarily a locally managed issue, as each hospital or transport service may vary in its perception of this culture and the programs it implements to manage safety concerns. A safety culture encompasses several key features:

- Acknowledging that organizations engage in high-risk activities and determining the importance of consistent safe operations to counteract these activities
- Supporting a blame-free environment where errors can be reported without fear of punishment
- Maintaining organizational commitment to address reported errors and safety concerns

Validated surveys given to providers through the AHRQ, including the Surveys on Patient Safety and the Safety Attitudes Questionnaire, can be used to measure an organization’s safety culture. These surveys ask providers to rate the safety culture of their workplace and the organization in its entirety. The AHRQ provides yearly updated benchmarking data from the hospital survey, including assessments of specific activities, such as teamwork training, development of safety teams, and use of leadership WalkRounds (a concept developed by the Institute for Healthcare Improvement to encourage employees in leadership positions to regularly review safety matters with frontline staff). Such activities have been associated with some improvements in safety culture measurements but are not yet linked to lower error rates.

While hospitals that accept any federal payment are required to participate in the Surveys on Patient Safety on a regular basis, there is no such requirement for EMS organizations. Indeed, few EMS agencies seem to survey their providers regarding safety culture or attitudes regarding safety. To help address this problem, the Center for Patient Safety and the National Registry of EMTs developed a survey specific to EMS, called the EMS Patient Safety Culture Survey. This survey includes some components taken from the AHRQ's Surveys on Patient Safety.

Just Culture

Assigning blame for errors is not a panacea for a less-than-stellar safety culture. Don Norman, author of *The Design of Everyday Things*, highlights the futility of this blame game:

> People make errors, which lead to accidents. Accidents lead to deaths. The standard solution is to blame the people involved. If we find out who made the errors and punish them, we solve the problem, right? Wrong. The problem is seldom the fault of an individual; it is the fault of the system. Change the people without changing the system and the problems will continue.

A key element of an effective safety culture is the concept called **just culture**. A just culture focuses on identifying issues that lead to errors or unsafe behaviors, while still maintaining individual accountability for reckless behavior. It helps distinguish various types of errors, including human error (ie, slips), at-risk behavior (ie, taking shortcuts), and reckless behavior (ie, ignoring required safety steps). Humans are not perfect, so systems should anticipate some level of error; a mistake or lapse can happen to anyone. Human error is typically a product of the current system design and behavioral choices; therefore, it should not be viewed as a punishable action, but rather as an opportunity to improve the systems.

Highly Reliable Organizations

Another concept that contributes to an effective safety culture is the **highly reliable organization (HRO)**. The airline and nuclear power plant industries are populated with HROs that share some common traits. For example, all HROs are preoccupied with failure, and there is an understanding in each organization's culture that failures will inevitably occur. HROs focus on managing these failures, however, so that a failure does not reach the public (the patient, in the health care industry). This drive has led to the redundancy in training, equipment, and maintenance seen in the airline industry. The airlines and nuclear power plants recognize that a person or piece of equipment may fail, so they have put considerable effort into ensuring that a single failure does not cause a catastrophic event (ie, plane crash, nuclear meltdown). In health care, an HRO would focus on double-checks (of high-alert medications, for example) and other systems to ensure that a single failure, which is inevitable, does not lead to patient harm.

Developing a Safety Culture in EMS

Many organizations involved in EMS care have recognized that the harm reductions seen in well-designed patient safety programs in hospitals need to be adapted and developed for EMS systems. EMS agency leaders and medical directors will be critical leaders in furthering this effort.

In 2014, two of the most prominent organizations involved in EMS and emergency care, the American College of Emergency Physicians (ACEP) and the National Association of EMS Physicians (NAEMSP), released a policy statement emphasizing the critical nature of a safety culture in EMS. The statement, which was revised in 2021, reads as follows:

The American College of Emergency Physicians (ACEP) and the National Association of EMS Physicians (NAEMSP) believe that safety must become a foundational component of every emergency medical services (EMS) system. Providing high-quality EMS requires understanding risk and embracing practices to prevent harm to patients, EMS professionals, and members of our communities. EMS physicians should lead development and support of a culture of safety in EMS systems.

We believe:

- EMS systems should partner with national organizations to increase safety in all aspects of EMS.
- EMS systems should support the development, implementation, and ongoing evaluation of comprehensive system-wide safety, quality, and risk management programs.
- EMS safety and comprehensive risk management should be emphasized in both initial and continuing education for all EMS professionals, including EMS physicians.
- EMS systems should implement and support the Just Culture approach to facilitate honest and prompt reporting of risk and error and to support analysis of near miss and adverse events in an environment of professionalism and accountability for systems and individuals.
- Integrated EMS safety data systems with mandatory reporting should be created to promote evaluation of safety programs and to promote research that advances

understanding of safety for EMS professionals, systems, and patients.

- EMS physicians should advocate for EMS safety-related programs coordinated at the local, regional, state, and federal levels based on evidence-based practice and benchmarks.
- EMS physicians should evaluate technologies and equipment for improvements in safety for patients, EMS professionals, and the public.
- EMS physicians should support the development of and adherence to safety standards and guidelines based on the best available evidence.
- EMS physicians should integrate opportunities to limit risk and increase safety within protocols, policies, and standing orders.

A culture of safety in EMS systems. American College of Emergency Physicians website. https://www.acep.org/patient-care/policy-statements/a-culture-of-safety-in-ems-systems/. Revised April 2021. Accessed September 22, 2021.

Common Health Care Errors

Many types of errors can occur in health care. Perhaps most notable are medication and prescription errors, but other, less-common errors include wrong patient identification, transfusion errors, preventable suicides, falls, burns, wrong-side procedures, and errors in transition of care or handoffs. Lucian Leape has identified and categorized these errors **TABLE 3-2**, and some of the most important are discussed here.

TABLE 3-2 Types of Medical Errors

Error Category	Specific Errors
Diagnostic	Error or delay in diagnosis Failure to employ indicated tests Use of outmoded tests or therapy Failure to act on results of monitoring or testing
Treatment	Error in the performance of an operation, procedure, or test Error in administering the treatment Error in the dose or method of using a drug Avoidable delay in treatment or in responding to an abnormal test Inappropriate care
Preventive	Failure to provide prophylactic treatment Inadequate monitoring or follow-up of treatment
Other	Failure of communication Equipment failure Other system failure

© Jones & Bartlett Learning.

Medication and Prescription Errors

Medication-related errors occur frequently in hospitals and to an unknown degree in EMS. Not all result in actual harm, but those that do can have devastating and costly consequences.

The process of a patient receiving a medication is complex and fraught with opportunities for error, including prescribing, dispensing, administering, and monitoring errors. One study conducted at two prestigious teaching hospitals found that almost 2% of admissions experienced a preventable adverse drug event, resulting in increased hospital costs amounting to approximately $2.8 million annually for a 700-bed teaching hospital.

Medication-related errors are studied by examining **adverse drug event (ADE)** incidence. The discussion in this chapter is related to the subset of ADEs considered to be preventable or to occur secondary to error.

Medication Errors in EMS Settings

Children are at higher risk of incorrect dosing for several reasons. Often estimations of children's weights can be significantly different from their actual weights due to EMS providers' inability to accurately estimate weight even when using length-based measuring devices such as the length-based assessment tape. Additionally, many more medication doses are based on weight in children than in adults, so they require weight-based calculations to arrive at the correct total dose—a process that is prone to calculation errors by providers. Adding to the dosing confusion, several medications, such as antibiotics and vasopressors, come in more than one concentration.

In general, each time a dose calculation (such as that based on weight) is performed, the chance of error increases. Additionally, the potential for medication-related errors increases as the average number of drugs administered increases.

Variations in product packaging and labeling increase the potential for medication errors in the EMS environment. Medication manufacturing shortages may compel EMS agencies to substitute medications with which CCTPs are less familiar, medications from different manufacturers that use different labeling or packaging, and medications used as therapeutic substitutions that may have different dosing regimens. For example, recent medication shortages have included $D_{50}W$ (dextrose 50% in water), sodium bicarbonate, dopamine, morphine sulfate, and glucagon. In a high-pressure, uncontrolled environment such as the back of a moving ambulance with a patient who is decompensating or going into cardiac arrest, it is very easy for medication errors to occur.

The EMS community has given much attention over the past 10 years to medication errors in the pediatric population and to addressing calculation errors in high-stress situations. Devices such as syringes with graduated stops, color coding, and other engineering controls have been designed to prevent calculation and administration errors, and smartphone apps are available to help guide and calculate pediatric dosing.

Look-Alike, Sound-Alike Medication Errors

One type of medical error that has been specifically targeted in recent years is prescribing and dispensing errors related to look-alike, sound-alike (LASA) medications. The Joint Commission highlighted the potential for LASA medication errors in a Sentinel Event Alert. As part of the effort to avoid such errors, hospitals are expected to maintain a list of these LASA medications. The Institute for Safe Medication Practices (ISMP) maintains a reference table of these drugs. In addition, the ISMP recommends the following processes to help avoid LASA errors:

- Use both the brand name and the generic name on prescriptions and labels.
- Note the medication’s purpose on prescriptions.
- Configure selection options on computer screens so that look-alike names do not appear consecutively.
- Change the appearance of look-alike names to highlight their differences. For example, use tall-man, or mixed-case, lettering (eg, DOPamine versus DoBUTamine).

Additional recommendations include focusing on prescription legibility through improved handwriting or the use of electronic prescribing, and physically separating LASA medications in different storage areas.

Wrong Patient Identification/Wrong-Side Procedures

Wrong patient identification is a potentially serious problem in health care that can easily lead to a medication administration error. Most commonly, this problem involves a nurse accidentally administering an intended medication to the wrong patient. Practice recommendations to rectify this error include always using multiple patient identifiers. Providers administering medications at the bedside should always use two patient identifiers, such as the patient’s name and date of birth.

The confirmation of patient identity is particularly important for EMS crews picking up a patient for an interfacility transport or transport home. While the 9-1-1 EMS call for a single patient yields one obvious patient in most cases, it is entirely possible for a crew to pick up the wrong patient at a hospital or health care facility. This kind of error has occurred on several occasions, illustrating why a transport agency must employ the same safety measures, such as two patient identifiers, that the hospitals use.

Few medical errors are as terrifying as those related to surgery involving the wrong site, wrong patient, or wrong procedure. In the literature, this type of error is termed a **never event**, meaning it should never occur and indicates serious underlying safety problems. Fortunately, this type of event is exceedingly rare. Efforts to combat its occurrence include developing redundant mechanisms for identifying the correct site, procedure, and patient through initiatives where surgeons (and sometimes the patient) mark the site prior to the patient’s arrival in the operating room.

Other protocols created to combat this problem focus on a **universal time-out**. The time-out is a planned pause before the beginning of a procedure that improves communication among all personnel in the room; it allows time for everyone to review important aspects of the procedure. This time-out concept has been proposed for the EMS environment as well. Examples include implementing an "EMS time-out" for trauma and other critical patients on EMS arrival so no key information is lost. While most 9-1-1 calls lead to procedures that are emergent, such that a pause is not feasible, an interfacility transport usually affords enough time for ensuring certainty.

Errors During Transitions of Care and Handoffs

Transitioning care is an integral part of care in an ED and prehospital care of a patient. Multiple handoffs may occur between various providers, including physicians, nurses, medics, and support staff, and errors during handoffs can easily occur.

Standardized approaches to transitions in care help prevent handoff errors. One method integrated in multiple health systems is the **situation, background, assessment, and recommendation (SBAR)** technique. This technique has become best practice in health care, effortlessly structuring critical information. The US Navy developed it as a communication technique for use in nuclear submarines, and it was introduced into health care in the 1990s.

The SBAR technique allows for a brief, yet concise and expected, handoff of information. Through this method, everyone involved in a handoff has a shared mental model, which improves the safety of these handoffs and transitions in care. The elements of the SBAR technique are summarized in **TABLE 3-3**.

TABLE 3-3 Situation, Background, Assessment, and Recommendation (SBAR) Technique

Situation	Briefly describe the current situation. Give a clear, succinct overview of the pertinent issues.
Background	Briefly state the pertinent history. What got us to this point?
Assessment	Summarize the facts and give your best assessment. What is going on? Use your best judgment.

Recommendation	Which actions are you asking for? What do you want to happen next?

Many EMS systems have implemented a standardized format for the handoff from the EMS crew to the hospital to ensure the transfer of critical information and completeness. One such format, used for trauma patients, is MIST—an acronym that stands for Mechanism of injury, Injuries/Inspection, vital Signs, and Treatment. A study published in *Prehospital Emergency Care* in 2020 demonstrated an improved handoff experience between nurses and paramedics when using MIST; however, data on error reduction with this technique are limited.

Why Do Health Care Errors Occur?

Various factors have contributed to the epidemic of medical errors. One commonly cited problem is the decentralized and fragmented nature of the health care delivery system. Medicine has traditionally treated errors as a failure on the part of one person, reflecting inadequate knowledge or skill. Governmental agencies, which set the standards for much of US health care, no longer use this terminology; they believe that errors reflect the functioning of the entire health care system.

Systems Approach

The systems approach suggests that most human errors occur in the context of a poorly designed system. For example, lapses in human tasks may occur secondary to long work hours, and predictable mistakes occur when inexperienced staff members face complex cognitive decisions. Instead of punishing the person, the systems approach seeks to identify those situations that give rise to human error and remedy the underlying problem. This approach acknowledges the reality that most major accidents result from multiple, smaller mistakes in environments with serious underlying system flaws.

Swiss Cheese Model

A British psychologist, James Reason, pioneered the modern field of systems analysis and introduced the **Swiss cheese model** to address errors. In this model, people make errors that result in consequences because of flawed systems—the holes in the cheese. Imagine several slices of Swiss cheese lined up next to one another; usually the holes do not all line up. If you tried to thread a string through the holes in all the slices, one or more slices would probably act as a barrier to the string's passage. However, sometimes all the holes might line up, leading to catastrophic error **FIGURE 3-1**.

Description

Reason also introduced the concepts of latent and active errors to distinguish between human and system errors. An **active error** usually involves frontline staff and occurs at a contact point between a staff member and some aspect of a larger system. A **latent error** is a mistake that is likely to occur secondary to organizational or design failures that allow the inevitable active errors to cause harm.

Another way to think about latent and active errors is to envision the sharp and blunt ends of something. The sharp end refers to an active error, such as when a frontline staff member makes an error in patient care—for example, a surgeon performing the wrong procedure. Active errors can further be classified as slips and mistakes. A **slip** refers to a lapse in concentration that occurs in the face of distractions, fatigue, or stress. An example of a slip would be if a CCTP accidentally pushed the wrong button on a piece of equipment or, because of a memory failure (lapse), failed to administer a medication. A **mistake** is when an action occurs as intended but is the wrong action; such an event often occurs secondary to lack of experience, insufficient training, or negligence. The blunt end refers to a latent error, which may be attributable to the complexity of the health care system and to those not in direct contact with patients who set policy and manage the overall system.

Handling Serious Errors

A **sentinel event** or **serious adverse event (SAE)** is a patient safety event in which an error reaches a patient and results in death, permanent harm, or severe temporary harm with interventions required to sustain life. Examples include wrong-site procedure, wrong procedure, retained foreign body, or medication error resulting in death. These events are considered sentinel because they trigger the need for immediate investigation and response by the health care system. Careful investigation of these events and corrective action plans can help to reduce further risk and prevent patient harm in the future. When such an event occurs, most hospitals activate a serious adverse event response system that includes a formalized notification chain and immediate huddle, shortly followed by a debriefing and root cause analysis (discussed in detail later in this chapter), with senior leadership endorsement and support of this process **TABLE 3-4**.

TABLE 3-4 | **Example of a Serious Adverse Event Response System**

	Huddle	Debriefing	Interview	RCA
Objective	Determine what happened Stabilize patient Address staff concerns Secure all equipment	Clarify timeline of event Assess ongoing safety risks Determine need for emotional support to staff, patient/family	Further investigation to obtain information/ details not uncovered via debriefing	Determine root causes of event Use tools to depict standard process and redesigned process Determine system versus individual culpability
When?	Immediately (within 24 hours)	24–72 hours after event	Post debriefing, in preparation for root cause analysis	Within 2 weeks of event
Who participates?	Staff directly involved in event	Staff directly involved in event	Interviewer and staff involved in event	Frontline staff and local leadership *not* directly involved in event CMO Risk/QM content experts
Who leads?	Most-senior local staff members *(typically RN unit managers)*	CMO	Trained interviewer (typically QA/RM staff)	CMO or vice president/director for risk management
Training	RN unit managers, *or* supervisors, night/evening administrators Conducted internally by each facility	SAE workgroup to facilitate "cross-pollination" of expertise among CMOs	QA/RM QI nurses Conducted centrally by a risk management organization	SAE workgroup to facilitate "cross-pollination" of expertise among CMOs/RM

Abbreviations: CMO, chief medical officer; OR, operating room; QA, quality assurance; QI, quality improvement; QM, quality management; RCA, root cause analysis; RM, risk management; RN, registered nurse; SAE, serious adverse event
Prepared in accordance with New York State Public Heath Law 2805 j through m; New York State Education Law 6527; & Federal Law 109-4.

Description

Effective communication to discuss patient safety events such as a sentinel event is vital to those participating in the aftermath of an event. Communicating effectively helps groups navigate competing priorities, overcome issues related to human factors, and reduce error. A **huddle** is a communication technique and event that often takes the form of a structured, short meeting in which patient care teams come together to talk about a patient, procedure, or situation. It can also be called on an ad hoc basis when a medical team needs to regroup and share concerns, discuss resource allocation, anticipate outcomes, and create contingency plans. After a serious adverse event, the medical team is advised to huddle and discuss the event that occurred (including the stabilization of the patient and situation), determine the facts of what happened, mitigate any ongoing harm, address staff safety concerns, secure equipment or materials, and alert others as deemed necessary by the senior staff member leading the huddle. The huddle is crucial to ensure that actual events, sequences, and timing are accurately recorded to aid in further analysis and corrective actions related to the situation. It is also the only opportunity to sequester equipment in the actual state when the incident occurred; for example, a problem caused by a faulty ventilator or intravenous (IV) pump cannot be properly analyzed if the settings are changed or the equipment is returned to use.

Shortly after a serious adverse event or sentinel event happens, a debriefing also occurs. The **debriefing** is a powerful inquiry tool in which a concise exchange occurs to identify what happened, what was learned, and what can be done better in the future. A member of senior leadership usually leads the debriefing. The focus of this meeting is to learn what occurred from staff who were involved and to hear their thoughts on what could or should have been done differently. The debriefing does not focus on system changes, as that is the role of the root cause analysis. During this meeting, it is important to obtain a timeline of the event. Additionally, the senior leadership should use the debriefing to provide emotional support to staff and/or family, determine reporting obligations, and perhaps visit the event site. Ideally, a debriefing is a nonjudgmental, nonpunitive investigation to determine what happened, looking at the process and system, and should not be used for disciplinary purposes.

The next step after an SAE or sentinel event is to complete a **root cause analysis (RCA)**. The RCA is a systematic approach to understanding the causes of an SAE and identifying system flaws that can be corrected to prevent future harm. During the RCA, a team of mixed professionals from different specialties, who were not involved directly with the event, meet and discuss the event with senior administrative leadership.

There are six steps in most RCAs:

- **Step 1: Identify what happened.** This step is occasionally completed using a flowchart to depict each step accurately and completely.
- **Step 2: Determine what should have happened.** A flowchart can also be used in this step to identify the proper steps that should have been taken.
- **Step 3: Determine the cause.** In this step, the group members ask why the error occurred. When doing so, they should consider patient characteristics, task factors, individual staff members, team factors, work environment, organizational and management factors, and institutional context.
- **Step 4: Develop a causal statement.** In this step, a statement is made about the cause, the effect, and the event.
- **Step 5: Generate a list of recommended actions to prevent recurrence of the event.** These recommendations consist of suggested action plans that the group believes will help prevent the error from occurring in the future. Action plans are created to help eliminate or significantly reduce the likelihood of an SAE from happening again, control the root cause, or limit vulnerability. They vary widely, but can include actions such as standardizing equipment, educating staff, or developing new policies.
- **Step 6: Summarize the results.** A summary document is created reviewing all steps and action plans.

Under a system of just culture, an algorithm is applied during the RCA to determine if a similar person under similar conditions could or would take the same actions. If so, the event must be treated as a system failure and not as an individual failure **FIGURE 3-2**. Under a just culture, persons who demonstrate reckless or malicious behavior are still punished, but persons who engage in unintentional at-risk behaviors are coached and given additional training.

Description

Tools to Identify Errors

Many hospitals and transport services expect staff to report near misses and medical errors. Such reporting systems are designed to reduce future risks for all patients, trigger improvements in weak areas of care processes, alert other providers to possible vulnerabilities and gaps, and contribute to planning and strategies to prevent harm. One example of an error-reporting system used by EMS agencies is the EMS Voluntary Event Notification Tool (EVENT). The National Association of Emergency Medical Technicians (NAEMT) launched EVENT in 2012 to provide a confidential, anonymous means for providers to report events without fear of punishment. Another such system is the US Food and Drug Administration's (FDA's) Adverse Event Reporting System (FAERS), which is used to report adverse medication reactions or device malfunctions. For example, if a defibrillator failed to charge or deliver a shock during a call, the provider or agency could report the event directly to the FDA. Alternatively, they could report the incident to the manufacturer, which is required to then notify the FDA.

In 2013, the National Highway Traffic Safety Administration (NHTSA), EMS for Children, and ACEP published "Strategies for a National EMS Culture of Safety." This document discusses the need for a secure national database to report and catalog adverse events in EMS in a way that could identify best practices and enhance patient safety nationally. Such a system could leverage the National EMS Information System database, which includes a wide array of data but lacks some specific information that would be useful in identifying and mitigating patient and provider harm. To encourage voluntary reporting of near misses and adverse events, organizations must support a just culture and exhibit other traits of an HRO so that both patients and providers can trust that the outcomes of that reporting will be fair. An HRO focuses on managing its inevitable failures, so that a failure does not affect the patient or the customer.

According to the Institute for Healthcare Improvement, the use of *triggers* has reduced hospitals' reliance on employees' voluntary reporting:

> The use of "triggers," or clues, to identify adverse events (AEs) is an effective method for measuring the overall level of harm from medical care in a health care organization. Traditional efforts to detect AEs have focused on voluntary reporting and tracking of errors. However, public health researchers have established that only 10 to 20 percent of errors are ever reported and, of those, 90 to 95 percent cause no harm to patients. Hospitals need a more effective way to identify events that do cause harm to patients, in order to select and test changes to reduce harm.

Trigger tools define events or rates of error that prompt a further evaluation of processes to improve error prevention.

A 2018 study by Howard et al. adapted the IHI Global Trigger Tool to an EMS system, with the researchers calling their adapted version the EMS Trigger Tool. Interestingly, they found that three events accounted for 93% of the triggers in the analysis: change in systolic blood pressure (BP) by greater than 20%, temperature greater than 38°C without reduction, and oxygen saturation of less than 94% without oxygen or less than 85% without assisted ventilation.

In addition to use of trigger tools, some organizations have developed specific quality measures for EMS. One organization, Ground and Air Medical Quality in Transport, looks specifically at performance and quality metrics across the industry and facilitates benchmarking against other services. Another organization, the National EMS Quality Alliance, has published specific quality metrics for EMS relating to topics such as pediatrics, trauma, stroke, and safety.

Strategies to Avoid Errors

Many strategies and techniques that have been used successfully in the manufacturing industry are now being applied to health care, along with safety techniques that have proven useful in aviation, such as checklists. Two of the most popular of these strategies are Six Sigma and Lean.

Six Sigma

Six Sigma is a disciplined, data-driven approach and methodology for eliminating defects in any process—from manufacturing to transactional processes, and from products to services. It was first introduced by Bill Smith while working at Motorola in 1986 and was a central tenet of Jack Welch's strategy at General Electric in the 1990s. Its name is derived from its goal of achieving reliability within six standard deviations between the mean and the nearest specification limit for the process to which Six Sigma is applied. Few industries have been capable of reaching Six Sigma reliability, which would result in a 99.99% nonfailure rate. Perhaps most notably, the aviation industry has achieved this goal.

Lean

Lean was developed by Toyota engineers in the mid-1990s. The Lean strategy looks at all processes and attempts to reduce waste and ensure all activities add value. It relies on a pull system and ideas such as just-in-time manufacturing to reduce waste. Lean focuses on the frontline worker and the work space (*gemba* in Japanese) to see all the steps involved. Once the process is fully understood, the team creates "standard work"—that is, the one standard way that all workers perform this task so as to reduce waste and the chance for error. These principles are being applied to health care; indeed, several hospitals and hospital systems have become "Lean hospitals" in the sense that they apply Lean culture to all aspects of hospital operations.

Crew Resource Management

In health care, one of the major sources of error is lack of effective communication and teamwork. The enormous risk associated with such problems became painfully apparent in the aviation industry in 1977: In Tenerife in the Canary Islands, two fully loaded 747 planes collided on the runway, resulting in the deadliest collision in aviation history; 583 people were killed. Analysis of this collision led to several alarming discoveries. The KLM captain involved in the collision was one of the most senior pilots in the company and had thousands of hours flying the aircraft. While the captain mistakenly believed the flight was cleared for takeoff, the first officer and flight engineer did not; however, they were unwilling to question the captain because the prevailing wisdom and culture at the time asserted that the captain knew best and was the ultimate authority. In that culture, it was considered wrong and detrimental to one's career to question a captain. This collision triggered major changes in the aviation industry, including the development of **crew resource management (CRM)**. CRM emphasizes a culture of mutual support, teamwork, and the expectation and requirement that any crew member can and should voice a concern regarding the safe operation of the aircraft.

Many industries have adopted these lessons, including the military, nuclear industry, and now health care. The US Department of Defense, along with AHRQ, developed a program for health care providers and facilities called **TeamSTEPPS** (team strategies and tools to enhance performance and patient safety) that embraces the principles of CRM. TeamSTEPPS is being taught and employed across a wide variety of high-risk health care settings, such as the operating room, labor and delivery, and EDs. This course teaches tools and methods by which team members can safely raise concerns, challenge orders that are unclear, and if necessary "stop the line." Many malpractice insurance carriers are now encouraging or requiring their client hospitals to implement team training programs such as TeamSTEPPS.

Simulation Training

Another area of emphasis in team building is the rapidly expanding role of **simulation** training. Use of simulation allows health care providers to hone their skills in a safe environment without risk of patient harm and to work in teams to practice both procedures and communication skills. For example, it provides an opportunity to safely train for so-called HALO (high-acuity, low-occurrence) events such as surgical cricothyrotomy and needle decompression, and it enables the safe simulation of equipment failures (eg, ventilators, monitors) much in the same way that a flight simulator allows for pilot training.

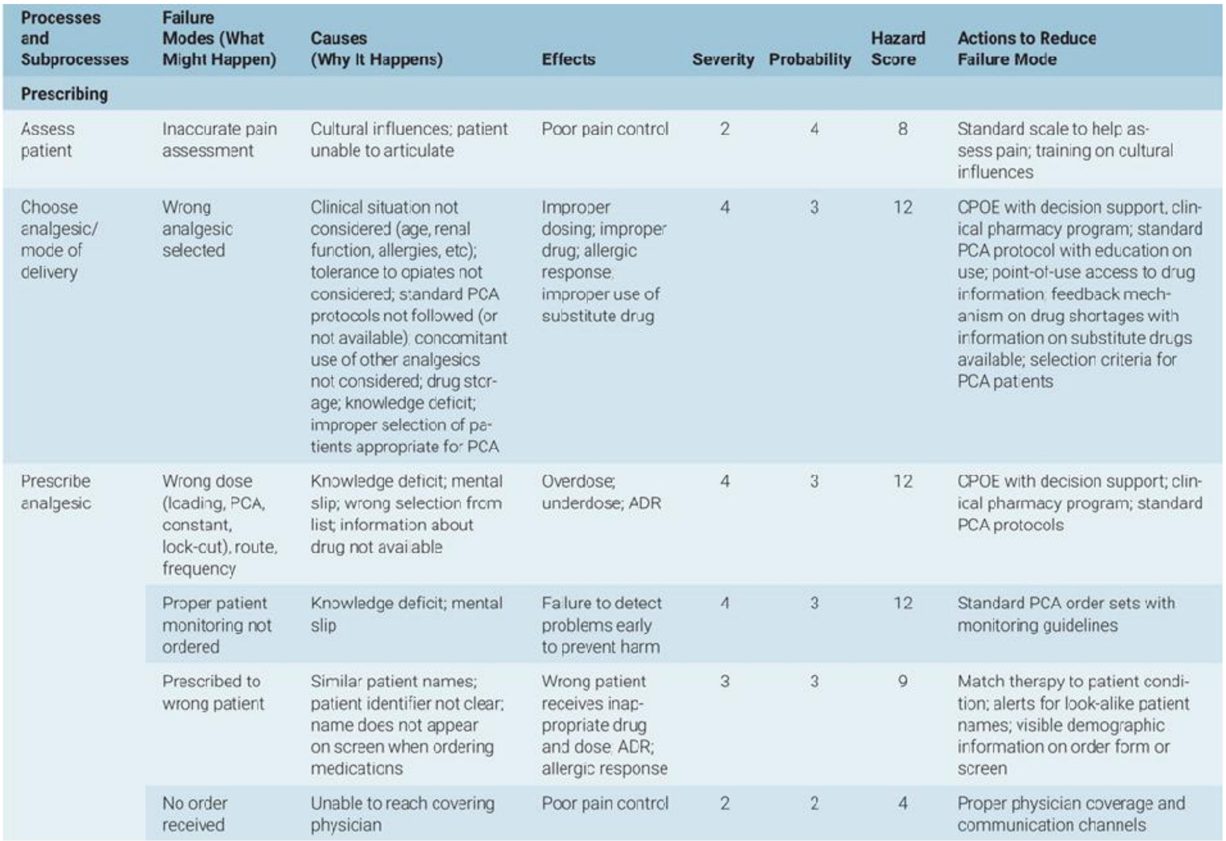
Simulation training has been growing in popularity in many medical settings, such as trauma, obstetrics and gynecology, and ED care. In EMS, simulation training can range from very simple task trainers, such as cardiopulmonary resuscitation (CPR) manikins to full-scale, high-fidelity simulation manikins that can simulate numerous life-threatening situations and allow EMS providers to practice procedures and management techniques in a safe environment. For example, rhythm simulators are commonly used to practice management of the crashing cardiac patient. Simulation is also used in EMS driver training and retraining, as the emergency response environment can be simulated and hazards presented in a safe setting.

Failure Mode and Effect Analysis

An additional tool that is helpful in analyzing potential sources of error or patient harm is **failure mode and effect analysis (FMEA)**. This process was developed by military engineers in the 1940s and further refined and used by NASA engineers working on the Mercury, Gemini, and Apollo space programs. More recently, this process has been applied to analyze the potential for health care failures.

To use FMEA, one constructs a risk matrix for each potential failure that incorporates the likelihood of that failure, the ability to detect the failure, and the potential harm, and assigns a risk score to the event. An example is provided in **TABLE 3-5**. This process can help identify priorities in risk mitigation and process redesign.

TABLE 3-5 **Sample Failure Mode and Effect Analysis: Analysis for Patient-Controlled IV Analgesia**



Processes and Subprocesses	Failure Modes (What Might Happen)	Causes (Why It Happens)	Effects	Severity	Probability	Hazard Score	Actions to Reduce Failure Mode
Prescribing							
Assess patient	Inaccurate pain assessment	Cultural influences; patient unable to articulate	Poor pain control	2	4	8	Standard scale to help assess pain; training on cultural influences
Choose analgesic/ mode of delivery	Wrong analgesic selected	Clinical situation not considered (age, renal function, allergies, etc); tolerance to opiates not considered; standard PCA protocols not followed (or not available); concomitant use of other analgesics not considered; drug storage; knowledge deficit; improper selection of patients appropriate for PCA	Improper dosing; improper drug; allergic response; improper use of substitute drug	4	3	12	CPOE with decision support, clinical pharmacy program; standard PCA protocol with education on use; point-of-use access to drug information; feedback mechanism on drug shortages with information on substitute drugs available; selection criteria for PCA patients
Prescribe analgesic	Wrong dose (loading, PCA, constant, lock-out), route, frequency	Knowledge deficit; mental slip; wrong selection from list; information about drug not available	Overdose; underdose; ADR	4	3	12	CPOE with decision support; clinical pharmacy program; standard PCA protocols
	Proper patient monitoring not ordered	Knowledge deficit; mental slip	Failure to detect problems early to prevent harm	4	3	12	Standard PCA order sets with monitoring guidelines
	Prescribed to wrong patient	Similar patient names; patient identifier not clear; name does not appear on screen when ordering medications	Wrong patient receives inappropriate drug and dose, ADR; allergic response	3	3	9	Match therapy to patient condition; alerts for look-alike patient names; visible demographic information on order form or screen
	No order received	Unable to reach covering physician	Poor pain control	2	2	4	Proper physician coverage and communication channels

Description

Quality in EMS Settings

Methods for understanding and measuring patient safety and quality in the EMS environment are in their infancy, with only limited studies of these techniques having been conducted to date. Recently, greater interest has arisen in promoting patient safety concepts and quality measurements in EMS, with several organizations (eg, NAEMSP, ACEP, NHTSA, EMS Chiefs of Canada) leading the call for enhanced patient safety in EMS. The environment and conditions in which prehospital care is provided create significant safety challenges. More specifically, EMS care is often provided in a high-stress, limited-time situation in less than ideal conditions, such as low light, moving vehicles, noisy aircraft, or extremes of temperature. Many providers work long hours, sometimes for 24 hours straight, and often have more than one job, leading to fatigue, often compounded by disturbances of their circadian rhythm. Given these factors, EMS care is potentially more dangerous and less controlled than the same care provided in an inpatient environment or ED, yet patient safety strategies and team training are only now being incorporated into the EMS system. In addition, as the Patient Protection and Affordable Care Act matures, many hospitals are organizing into large hospital systems with site-specific specializations. This trend of consolidating hospital systems and specializations has greatly accelerated in the last few years, and the rate of critical care transports has increased proportionally.

One problem with assessing adverse events during EMS care and transport, and patient safety in EMS in general, is the lack of standard data definitions and event categories. Several organizations are currently working to create standard data definitions and data sets that will enable meaningful comparison across systems.

For example, in 2012, Bigham et al. conducted a systematic literature review on patient safety in EMS. Seven themes emerged across the articles they found in the literature:

- Clinical judgment
- Adverse events and error reporting
- Communications
- Ground vehicle safety
- Aircraft safety
- Interfacility transport
- Field intubation

These themes are helpful in understanding potential pitfalls and focusing safety efforts for providers and agencies. Field intubation is discussed in detail in Chapter 6, *Respiratory Emergencies and Airway Management*.

Clinical Judgment

Several studies have examined clinical decision making by EMS personnel and looked at paramedics' determination of medical necessity for transport, appropriate cancelation of advanced life support (ALS) calls, the effectiveness of paramedics' scope of practice, and other clinical issues. Collectively, they suggest that perhaps EMS providers are being asked to make decisions that they are not trained to make. Moreover, as procedures and tasks have been added to these providers' duties, a sort of "scope creep" may lead to providers making decisions that could harm their patients. While these observations point to an increased potential for error due to increasing demands on EMS providers' skills and decision making, no concrete recommendations have been proposed to remedy this problem. Nevertheless, it would seem likely that additional training in complex decision making; low-frequency, high-risk skills; and advanced equipment will be needed, as well as additional real-time support from medical control physicians.

Error Reporting

As stated previously, only limited data are available on adverse events, medication errors, and reporting in the EMS environment. There appear to be patterns of both underreporting and nonreporting of events, which survey data suggest may be due to both a fear of reporting and a lack of recognition of near-miss events and their significance.

Communications

Communications is another major theme in patient harm and the focus of considerable patient safety efforts in the hospital environment. Numerous studies of prehospital communications have examined handoffs between EMS and ED or hospital staff. This line of research has generally demonstrated a loss of key clinical information during these handoffs, such as changes in vital signs (eg, transient hypotension), medications administered, and changes in ventilator settings, which may sometimes lead to direct patient harm.

Vehicle and Provider Safety

The transport environment is associated with the unique requirement of preventing vehicular harm to both the patient and the provider. While a full discussion of vehicle safety practices, such as those covered in emergency vehicle operation course (EVOC) training and other operational safety programs, is beyond the scope of this chapter, the CCTP should be mindful of basic safety techniques when riding in the passenger compartment. Whenever possible, the provider should remain seated and secured during transport, and should ensure that all equipment is secured to minimize the risk of injury from loose equipment in the event of a collision. Transport agencies should establish policies and procedures to help the CCTP ensure maximal safety in the patient compartment.

Air Transport Safety

The air transport crew has an especially arduous task in ensuring safety. Given the noise level, limited space, and poor lighting in most rotor-wing aircraft, identifying adverse events is more difficult in this environment than in other patient care settings. The air transport crew needs to minimize risk (maximize risk reduction) by optimizing the patient's condition prior to flight and ensuring adequate monitoring equipment is in place. Additionally, using excellent CRM skills and making appropriate go/no-go decisions are critical to the safety of the patient and the crew.

Interfacility Transport

Adverse Events During Interfacility Transport

While critical events occur across all EMS settings, adverse events associated with interfacility transfers have recently drawn closer scrutiny. A recent Canadian study suggests that the event rate is lower when transports are staffed with specially trained CCTPs than with EMT-P personnel. Overall, the data indicate that 1 in 15 patients experienced one of several adverse events during transport, including hypotension, initiation of vasopressor therapy, and respiratory events. An analysis showed that hemodynamic instability requiring intervention such as fluids or vasopressors was by far the most common adverse event, followed by respiratory instability or hypoxia. Additionally, in-transit critical events were independently associated with mechanical ventilation and baseline hemodynamic instability.

Some problematic events have been identified in relation to specific types of transports. For pediatric transports, the most common adverse events noted were hypothermia, drug errors, tachycardia, procedure error, loss of IV access, and cyanosis. Of interest, the adverse event rate was lower in this population when specialized teams performed the transport.

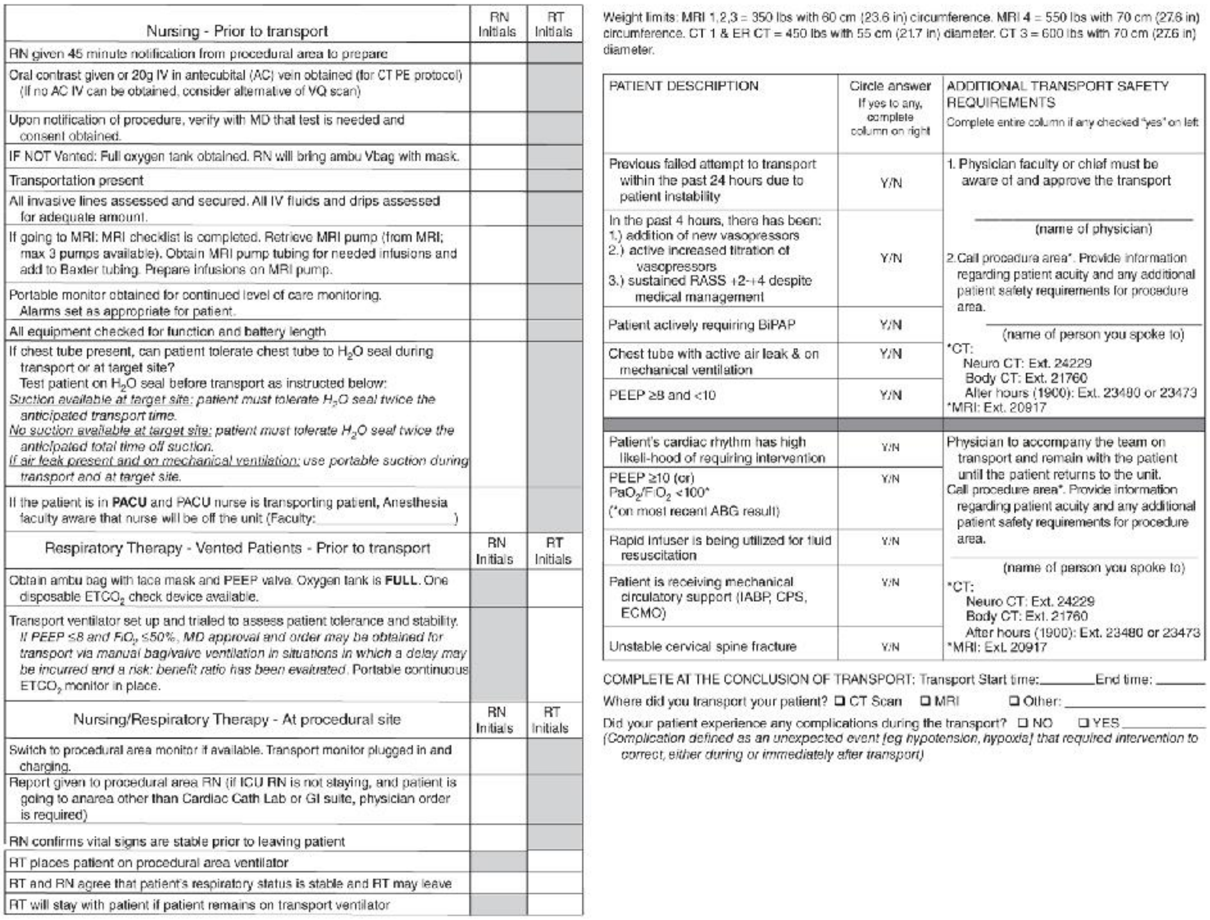
Currently, there is no mandatory regulatory oversight for transport teams. The Commission on Accreditation of Medical Transport Systems is the only accrediting body, but accreditation is voluntary, and a recent study showed that only 20% of specialty teams have received accreditation. Nevertheless, the importance of specialty-trained teams in interfacility transport of complex cases is increasing as newer and more advanced therapies become more widely employed during transport, such as inhaled nitric oxide and extracorporeal membrane oxygenation.

Mitigation Strategies for Adverse Events During Interfacility Transport

While no large-scale trials have been conducted that demonstrate a clear benefit from the guidelines proposed by some organizations, many of these strategies have shown benefit in small observational studies or are recommended as expert opinion. In a review of adult transports, Ligtenberg et al. found that 70% of adverse events could have been avoided by better preparation prior to transport, communication between the sending and receiving facilities, and the use of checklists and protocols.

One of the best ways to mitigate the risk of adverse events en route is to ensure the correct crew configuration is available for the transport. While in most cases a single CCTP may be sufficient for stable patients, additional personnel should be considered as needed, such as a critical care nurse, respiratory therapist, or physician for more complicated transports, or advanced equipment such as an intra-aortic balloon pump or extracorporeal membrane oxygenation.

Additionally, specific checklists with sections for ventilator, IV pumps, and other equipment have been shown to decrease the risk of adverse events and errors of omission **FIGURE 3-3**. One study demonstrated a decrease in the overall rate of adverse events from 36% to 22% and a decrease in the serious adverse events rate from 9% to 5% with the use of checklists.



Nursing - Prior to transport	RN Initials	RT Initials
RN given 45 minute notification from procedural area to prepare		▨
Oral contrast given or 20g IV in antecubital (AC) vein obtained (for CT PE protocol) (If no AC IV can be obtained, consider alternative of VQ scan)		▨
Upon notification of procedure, verify with MD that test is needed and consent obtained.		▨
IF NOT Vented: Full oxygen tank obtained. RN will bring ambu Vbag with mask.		▨
Transportation present		▨
All invasive lines assessed and secured. All IV fluids and drips assessed for adequate amount.		▨
If going to MRI: MRI checklist is completed. Retrieve MRI pump (from MRI; max 3 pumps available). Obtain MRI pump tubing for needed infusions and add to Baxter tubing. Prepare infusions on MRI pump.		▨
Portable monitor obtained for continued level of care monitoring. Alarms set as appropriate for patient.		▨
All equipment checked for function and battery length		▨
If chest tube present, can patient tolerate chest tube to H_2O seal during transport or at target site? Test patient on H_2O seal before transport as instructed below: *Suction available at target site: patient must tolerate H_2O seal twice the anticipated transport time.* *No suction available at target site: patient must tolerate H_2O seal twice the anticipated total time off suction.* *If air leak present and on mechanical ventilation: use portable suction during transport and at target site.*		▨
If the patient is in **PACU** and PACU nurse is transporting patient, Anesthesia faculty aware that nurse will be off the unit (Faculty: ____________)		▨
Respiratory Therapy - Vented Patients - Prior to transport	RN Initials	RT Initials
Obtain ambu bag with face mask and PEEP valve. Oxygen tank is **FULL**. One disposable $ETCO_2$ check device available.	▨	
Transport ventilator set up and trialed to assess patient tolerance and stability. *If PEEP ≤8 and FiO_2 ≤50%, MD approval and order may be obtained for transport via manual bag/valve ventilation in situations in which a delay may be incurred and a risk: benefit ratio has been evaluated.* Portable continuous $ETCO_2$ monitor in place.	▨	
Nursing/Respiratory Therapy - At procedural site	RN Initials	RT Initials
Switch to procedural area monitor if available. Transport monitor plugged in and charging.		▨
Report given to procedural area RN (if ICU RN is not staying, and patient is going to anarea other than Cardiac Cath Lab or GI suite, physician order is required)		▨
RN confirms vital signs are stable prior to leaving patient		▨
RT places patient on procedural area ventilator	▨	
RT and RN agree that patient's respiratory status is stable and RT may leave		
RT will stay with patient if patient remains on transport ventilator	▨	

Weight limits: MRI 1,2,3 = 350 lbs with 60 cm (23.6 in) circumference. MRI 4 = 550 lbs with 70 cm (27.6 in) circumference. CT 1 & ER CT = 450 lbs with 55 cm (21.7 in) diameter. CT 3 = 600 lbs with 70 cm (27.6 in) diameter.

Description

Another consideration is availability of appropriate equipment that has been properly maintained and checked. For example, IV pumps and ventilators have battery backup power supplies, and it is critical to ensure that all devices are in good working order with fully charged batteries prior to initiation of patient transport. Waveform capnography is critical for monitoring intubated patients during transport and must be considered a minimum standard of care. Likewise, monitor alarms are critical for alerting providers to unexpected changes in the patient’s condition. Alarm limits and volumes must be set correctly prior to transport to ensure the CCTP is immediately made aware of any parameters that move out of range.

Summary

Patient safety and quality have become a major focus of both health care organizations and regulatory agencies such as The Joint Commission. While enhanced patient safety techniques and team-training skills are becoming standard in the hospital environment, EMS systems have only recently begun to address these issues. The ultimate goal is to ensure application of one high standard of care and quality across the health care setting. In this environment, both the CCTP and the transport agency are critical links in the patient safety chain from admission to discharge. Hospitals are organizing into large hospital systems with site-specific specializations, and the CCTP is being called on to carry out increasingly frequent and complex transfers. Ensuring the safety of these transfers is paramount for the CCTP.

CASE STUDY

Your critical care ground transport crew is called late in the afternoon to a rural hospital for a 37-year-old patient with suspected sepsis, hyperglycemia, and new-onset atrial fibrillation. This patient needs transport to a tertiary medical center where she can receive a higher level of care.

You arrive to find the patient in the ED appearing moderately ill. She presented to the hospital in the early morning with gastrointestinal distress, protracted vomiting, and fever. The ED providers administered fluids and antiemetics; obtained blood, urine, and sputum cultures; and obtained chest and abdominal radiographs, a 12-lead ECG, and chemistry and hematology lab studies. Empiric antibiotics and acetaminophen were also started.

The patient has a history of poorly controlled diabetes, hypertension, and obesity. She denies allergies and confirms the hospital note that she is currently taking an angiotensin-converting enzyme (ACE) inhibitor for BP control and uses both insulin glargine (Lantus) and insulin aspart (NovoLog) but often has wide swings in her blood sugars. She denies any cardiac history and has never experienced palpitations or been told that her ECG was abnormal.

Lab studies were all normal except for a white blood count of 14,500 cells/mm^3, a serum lactate level of 4 mmol/L, and a serum glucose of 295 mg/dL. The patient's initial 12-lead ECG showed uncontrolled atrial fibrillation with a rate of 185 beats/min and no evidence of ischemia. The chest radiograph showed consolidation in the left lower lobe. The abdominal films were unremarkable. The patient's BP has remained normal to slightly elevated, and her fever has decreased from 102.8°F (39.3°C) on initial presentation to 99.5°F (37.5°C) 30 minutes prior to your arrival. Her heart rate did not decrease significantly with the lower temperature, so an infusion of diltiazem (Cardizem) was initiated at 5 mg/h, then decreased to 3 mg/h once her heart rate dropped to 100 beats/min. The patient's blood glucose continued to climb, so an insulin infusion was started and titrated to lower blood glucose to 150 mg/dL. The ED staff report that they turned the insulin infusion off 30 minutes prior to your arrival because the finger-stick blood glucose was 90 mg/dL.

While your partner finishes obtaining the report and copies of the transfer paperwork, you move the three IV pumps to your ambulance stretcher. You note that three medication bags are hanging: insulin, diltiazem, and piperacillin–tazobactam (Zosyn). The pump labeled insulin is on standby, the pump labeled diltiazem is running at 8 mg/h, and the pump labeled piperacillin–tazobactam is running at 12.5 mL/h, which you recognize will deliver the antibiotic over the usual 4-hour period. A cursory set of vital signs matches those taken by the ED staff 30 minutes earlier, except that the patient's heart rate has climbed from 105 beats/min to 148 beats/min. You note the rhythm remains atrial fibrillation, and you increase the rate on the diltiazem pump to 10 mg/h as you wheel the patient to the ambulance. The patient is alert and oriented and does not appear to be in acute distress. You talk with her family about the transfer plan, and they indicate that they will meet you at the receiving hospital.

Once in the ambulance and under way, you obtain a finger-stick glucose of 20 mg/dL and note that the patient is slightly obtunded. Her heart rate continues to climb despite your earlier increase in the diltiazem infusion rate. You decide to trace each of the infusions from the peripheral IV sites at which they are connected to back to the medication bags. All three are labeled at the tubing ends where they connect to the IVs and the pumps match the labels on the tubing. When you reach the medication bags, you discover that the diltiazem tubing and pump are actually infusing a bag of insulin and the insulin pump (currently on standby) is connected to a bag of diltiazem. You stop the pump labeled diltiazem, begin an infusion of 10% dextrose, and hang a new bag of diltiazem with new tubing on the diltiazem pump.

On arrival at the receiving facility, the patient's blood glucose has increased to 110 mg/dL, her heart rate has dropped to 120 beats/min with a 3 mg/h rate for the newly hung diltiazem drip, and the 10% dextrose infusion has been discontinued. The patient is alert and oriented.

1. How common are medication errors in critical care transport?
2. What were the causal factors that gave rise to this error?
3. What should the role of staff be with regard to reporting adverse events, and how should employers encourage and support reporting?
4. Which actions, including discipline, are appropriate in this case?

Analysis

Medication errors account for a significant percentage of medical errors. While there is little information specific to CCT medication errors, the literature suggests that at least 2% of hospitalized patients experience a medication error. Many safety professionals and risk managers believe the incidence of medication errors in hospitalized patients is significantly underreported and potentially unrecognized. Given the austerity of the CCT environment, the lack of independent double-checks, and the lack of the barcode technology used to reduce errors in the inpatient setting, the risk of medication errors during transport is probably significantly higher than that in the hospital setting.

The CCTPs reported this medication error using their service incident reporting system. The transport service risk managers categorized the error as an SAE, and an RCA was conducted. It was determined that both the diltiazem and insulin infusion bags ran out nearly simultaneously. The nurse caring for the patient ordered additional bags of both infusions in advance from the pharmacy, scanned them individually, and then proceeded to hang both bags, inadvertently connecting the insulin to the diltiazem tubing and the new bag of diltiazem to the insulin tubing. While the insulin was a high-alert medication, requiring an independent double-check by a second registered nurse, the transferring facility had in excess of 55 medication infusions on its high-alert list. Nurses merely scanned the badge of a coworker without actually conducting the independent double-check because they perceived the frequency of this process to be an annoyance.

The CCTP examined all three medication bags, confirming that they contained the medications and concentrations expected. He also examined the pumps but failed to follow the tubing from each medication bag to the corresponding pump and to the label on the distal end of the tubing. Had this been done with each infusion, the error would have been discovered prior to initiating transport. While hindsight is often 20:20, there was arguably a failure to carefully consider potential causes for the patient’s increasing heart rate and decreasing blood glucose level.

Many employers expect team members to report adverse events in an effort to reduce future risk for all patients, trigger improvements in weak spots in processes of care, alert other providers to possible vulnerabilities and gaps, and contribute to planning and strategies to prevent harm. To encourage reporting, organizations must support a just culture and exhibit other traits of an HRO. When team members sense that reporting may result in disciplinary actions or a perceived lack of concern or even incompetence from their supervisors, they may downplay adverse events or fail to report them at all.

Using a systems approach and considering the just culture system, it is very likely that this error was a result of a poorly designed system rather than being caused by people. Within a just culture, if a similar person under similar conditions could or would take the same actions, the event must be treated as a system failure, rather than as an individual failure. Looking at the history of both the nurse and the CCTP, neither had similar experiences in the past, and neither seemed to exhibit reckless behavior. Both seemed to have made honest mistakes. The behavior of the nurse in bypassing the independent double-check was an action called **normalization of deviance**, in which a shift away from policies and practices becomes normative behavior. Both the nurse and the CCTP were able to learn from this experience. Neither was punished, but changes were made to policies and practices in an effort to prevent a recurrence of the same error in the future.

PREP KIT

Ready for Review

- The complexity inherent in an EMS system provides many opportunities for process failures, errors, and adverse outcomes.
- A series of reports published by the Institute of Medicine not only captivated the medical community, but also caused the media and general public to become aware of the issue of safety in health care and put this concern on the national agenda.
- The CCTP likely encounters more critically ill patients and more complex patient care scenarios than does a 9-1-1 responder, so the likelihood of errors may be significantly greater in the CCT environment than in the usual EMS setting.
- Quality goals suggest that health care should be safe, effective, patient centered, timely, efficient, and equitable; these quality aims may be difficult to achieve in an EMS environment owing to its time-limited nature and the critically ill nature of patients.
- Many definitions of patient safety have been proposed, including the World Health Organization’s definition of freedom from unnecessary harm or potential harm associated with health care.
- Not all errors will reach patients and cause harm, but it is essential for organizations to study these errors and look for opportunities to improve the processes that allow them to happen before any true patient harm results.
- Errors that lead to serious patient harm are rarely the result of just one error involving one person, but rather usually involve a series of errors or breakdowns in processes.
- Breakdowns in communication that almost lead to errors or harm are referred to as near misses or close calls. They may occur many times before an actual harmful incident occurs.
- Many transport services expect staff to report near misses through a reporting system to reduce future risks for all patients,

trigger improvements in weak spots in processes of care, alert other providers to possible vulnerabilities and gaps, and contribute to planning and strategies to prevent harm.

- A medical error is the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. Such errors may generally be categorized as adverse drug events, wrong-site surgeries, falls, burns, pressure ulcers, and mistaken patient identities.
- A safety culture encompasses several key features: (1) acknowledging that organizations engage in high-risk activities and determining the importance of consistent safe operations to counteract these activities; (2) supporting a blame-free environment where errors can be reported without fear of punishment; and (3) maintaining organizational commitment to address reported errors and safety concerns.
- A just culture focuses on blamelessly identifying issues that lead to errors or unsafe behaviors, while still maintaining individual accountability for reckless behavior.
- Highly reliable EMS organizations focus on managing failures, so that a failure does not affect the patient.
- Among the most notable errors in health care are medication and prescription errors. Other, less-common errors include wrong patient identification, transfusion errors, preventable suicides, falls, burns, wrong-side procedures, and errors in transition of care or handoffs.
- The process of a patient receiving a medication is complex and fraught with opportunities for error, including prescribing, dispensing, administering, and monitoring errors.
- Practice recommendations to rectify wrong-patient errors include always using multiple patient identifiers.
- The concept of the universal time-out has been proposed for the EMS environment, such as implementing an EMS time-out for trauma and other critical patients on EMS arrival to ensure that no key information is lost during handoff.

- Transitioning care is an integral part of the ED and prehospital care of a patient. The situation, background, assessment, and recommendation (SBAR) technique allows for a brief, yet concise and expected, handoff of information.
- The systems approach suggests that most human errors, including those in health care, occur in the context of a poorly designed system.
- In the Swiss cheese model, errors made by people result in consequences related to flawed systems.
- Active errors occur at a contact point between a staff member and some aspect of a larger system; latent errors are mistakes that are likely to occur secondary to organizational or design failures that allow the inevitable active errors to cause harm.
- Active errors can be further classified as slips and mistakes: A slip is a lapse in concentration; a mistake is when an action occurs as intended but is the wrong action.
- A sentinel event or serious adverse event is a patient safety event in which an error reaches a patient and results in death, permanent harm, or severe temporary harm, such that interventions are often required to sustain life. It triggers the need for immediate investigation and response by the health care system.
- When a sentinel event occurs, most hospitals activate a serious adverse event response system that includes a formalized notification chain and immediate huddle, followed shortly by a debriefing and a root cause analysis, with senior leadership endorsement and support of the process.
- Many strategies and techniques that have been successful in the manufacturing industry, such as Six Sigma, Lean, and crew resource management (CRM), are now being applied to health care, along with safety techniques that have proved useful in aviation, such as checklists.
- EMS care is potentially more dangerous and less controlled than the same care provided in an inpatient environment or ED, yet

patient safety strategies and team training are only now being incorporated into the EMS system.

- Key issues related to quality in EMS settings include clinical judgment, adverse event and error reporting, communications, ground vehicle safety, aircraft safety, interfacility transport, and field intubation.
- In some cases, EMS providers are being asked to make decisions that they are not trained to make; scope creep in their responsibilities may also lead to providers making decisions that could harm the patient.
- Underreporting and nonreporting of error events in the EMS setting may be due to both a fear of reporting and a lack of recognition of near-miss events and their significance.
- During the handoff between EMS and either ED or hospital staff, the loss of key clinical information may sometimes lead to direct patient harm.
- Whenever possible, the provider should remain seated and secured during transport, and should ensure that all equipment is secured to minimize the risk of injury from loose equipment in the event of a collision.
- The air transport crew needs to maximize risk reduction by optimizing the patient’s condition prior to flight and ensuring adequate monitoring equipment is in place.
- One of the best ways to mitigate the risk of adverse events en route is to ensure the correct crew configuration is available for the transport.
- Prior to transport, appropriate equipment should be properly maintained and checked. Specific checklists with sections for ventilators, IV pumps, and other equipment have been shown to decrease the risk of adverse events and errors of omission.

Vital Vocabulary

active error An error that almost always involves frontline staff and occurs at a contact point between a staff member and some aspect of a larger system.

adverse drug event (ADE) An adverse reaction caused by taking a medication.

crew resource management (CRM) A safety-oriented program that emphasizes a culture of mutual support, teamwork, and the expectation and requirement that any team member can and should voice a concern regarding the safe operation of the team.

debriefing A powerful inquiry tool in which a concise exchange occurs to identify what happened, what was learned, and what can be done better in the future.

error A preventable adverse event in the delivery of care, whether or not it is evident or harmful to the patient.

failure mode and effect analysis (FMEA) A process that helps identify priorities in risk mitigation and process redesign.

harm Unintended physical injury resulting from or contributed to by medical care.

highly reliable organization (HRO) An organization that focuses on managing its inevitable failures, so that a failure does not affect the patient or the customer.

huddle A communication technique and event that often takes the form of a structured, short meeting in which patient care teams come together to talk about a patient, procedure, or situation.

just culture A system of beliefs and practices that focuses on blamelessly identifying issues that lead to errors or unsafe behaviors, while still maintaining individual accountability for reckless behavior.

latent error A mistake that is likely to occur secondary to organizational or design failures that allow the inevitable active error to cause harm.

Lean A strategy that looks at all processes and attempts to reduce waste and ensure all activities add value.

medical error The failure of a planned health care action to be completed as intended, or the use of a wrong care plan to achieve an aim.

mistake A situation in which an action occurs as intended but is the wrong action; it often occurs secondary to lack of experience, insufficient training, or negligence.

near miss An unplanned event that did not cause an injury, illness, or damage, but had the potential to do so; it is indistinguishable from a full-fledged adverse event in all but the outcome.

never event An event that should never occur and indicates a serious underlying safety problem.

normalization of deviance A process in which a shift away from acceptable policies and practices becomes the behavioral norm.

patient safety According to the World Health Organization, freedom from unnecessary harm or potential harm associated with health care.

root cause analysis (RCA) A systematic approach to understanding the causes of a serious adverse event and identifying system flaws that can be corrected to prevent future harm.

safety culture In an EMS organization, a system of beliefs and practices that includes acknowledging that organizations engage in high-risk activities and determining the importance of consistent safe operations to counteract these activities, supporting a blame-free environment where errors can be reported without fear of punishment, and maintaining organizational commitment to address reported errors and safety concerns.

sentinel event A patient safety event in which an error reaches a patient and results in death, permanent harm, or severe temporary harm such that interventions are required to sustain life.

serious adverse event (SAE) A sentinel event.

simulation A training technique that allows health care providers to hone their skills in a safe environment without risk of patient harm and to work in teams to practice both procedures and communication skills.

situation, background, assessment, and recommendation (SBAR) A technique that allows for a brief, yet concise and expected, handoff of information.

Six Sigma A disciplined, data-driven approach and methodology for eliminating defects in any process.

slip A lapse in concentration that occurs in the face of distractions, fatigue, or stress.

Swiss cheese model A model in which errors made by people result in consequences related to flawed systems.

TeamSTEPPS Team strategies and tools to enhance performance and patient safety; a program that embraces the principles of crew resource management and teaches tools and methods by which team members can safely raise concerns, challenge orders that are unclear, and if necessary “stop the line.”

universal time-out A planned pause before the beginning of a procedure that improves communication among all personnel in the room; it allows time for everyone to review important aspects of the procedure.

OBJECTIVES

After completing this chapter, you will be able to:

1. Briefly discuss the emphasis of the air medical role in facilitating critical care transports (pp 74–75).
2. Describe the composition of the atmosphere (p 75).
3. List the three physiologic zones in the atmosphere (pp 76–77).
4. Discuss the primary gas laws affecting flight physiology (pp 77–81).
5. Summarize the advantages and disadvantages of the use of rotor-wing aircraft (pp 81–82).
6. Summarize the advantages and disadvantages of the use of fixed-wing aircraft (p 82).
7. Summarize the advantages and disadvantages of pressurized and nonpressurized aircraft (p 82).
8. Recognize the physical and physiologic effects of rapid cabin decompression (p 82).
9. List the primary stressors of flight and their physiologic impacts (pp 82–90).
10. Define the factors affecting tolerance of the stressors of flight (pp 90–92).
11. Define the effective performance time and the time of useful consciousness (pp 92–93).
12. Define the four types of hypoxia (pp 93–95).
13. Describe the four stages of hypoxia as they relate to altitude (pp 95–96).
14. Recognize the signs and symptoms of altitude-induced hypoxia and the appropriate treatment (p 97).
15. Identify different dysbarisms and trapped gas disorders (p 97).
16. Explain the role of the Commission on Accreditation of Medical Transport Systems and the concepts of visual flight rules, instrument flight rules, and a sterile cockpit (pp 99–100).
17. Discuss the concept of flight following (pp 100–101).

18. List standards created to enforce aircraft safety (pp 103–104).
19. Describe causes of air medical crashes, including human errors and risk factors (pp 102–103).
20. Summarize crew resource management (pp 104–106).
21. Summarize the Federal Aviation Administration guidelines that pertain to air medical transport (p 106).
22. Explain the importance of taking safety precautions as part of air medical programs (p 107).

Introduction

Many critical care transport professionals (CCTPs) will work in the aircraft environment in the course of their duties. Some CCTPs may be permanently assigned to an aircraft, whereas others may rotate to aircraft as part of their staffing assignments. The CCTP needs to be familiar with both rotor-wing (helicopter) and fixed-wing (airplane) operations. In the air medical environment, crew safety is always the top priority. Providers must never forget that safety is the most important part of patient care and an absolute requirement for successfully completing the mission.

The air medical environment is both complex and extremely dynamic. A thorough knowledge of flight physiology is essential to keep the flight crew airworthy and to prevent transport-related complications in critically ill and injured patients. CCTPs frequently encounter patients with comorbidities and patients who have experienced multiple traumas and are already in a severely compromised condition. Many of these patients' conditions will be exacerbated by changes in the barometric pressure that occurs at higher altitude. Likewise, the forces experienced during flight can have a significant effect on disease pathophysiology. For all these reasons, CCTPs must have a strong understanding of the effects of altitude on the body.

A number of gas laws are pertinent to flight medicine, and several common problems can occur as the result of changes in oxygen levels and barometric pressure during air transport. In addition to these issues, this chapter discusses the advantages and disadvantages of pressurized and nonpressurized aircraft and the effect of decompression at altitude. CCTPs must have a solid understanding of the potential catastrophic consequences that can be experienced with rapid cabin decompression.

Further, CCTPs must be aware of the primary stressors related to flight on the flight crew members and appreciate the factors that can affect tolerance of those stressors. Aircrew members need to be familiar with different illusions of flight and spatial disorientation, which can have disastrous consequences on flight operations. Some types of spatial disorientation can have negative effects on patients as well and can precipitate serious medical conditions.

Even providers whose responsibilities pertain almost exclusively to ground-based services must still have a comprehensive knowledge of flight physiology. They will frequently prepare patients for air transport and receive patients who have been flown to their destination. For this reason, they must have a thorough understanding of how flight dynamics affect their patients. Knowledge of flight physiology involves not only recognition of barometric maladies, but also (and more importantly) the prevention of such problems.

The Air Medical Role

The basic role of an air medical service is to rapidly transport CCTPs to a patient, stabilize the patient’s condition, and transport that patient to a tertiary care center as quickly as possible. The patients who benefit most from air medical transport are those who are critically ill or injured or who would have a negative outcome with a prolonged transport.

Although air transport offers many benefits, as a CCTP you must weigh the potential advantages for the patient against the risks associated with the specific mode of transport. Before selecting this mode of transportation, patients should be evaluated and assessed for the effects of altitude and other forces that might adversely alter their condition en route. For example, patients who have cardiac conditions for which activity-sensing pacemakers have been implanted may experience severe complications if the pacemaker malfunctions because of flight vibrations.

Air medical transport may be relatively contraindicated for patients with the following conditions, requiring a careful risk–benefit analysis:

- Severe anemia
- Hemoglobinopathy
- Myocardial infarction (MI) within 10 days or complications in the 5 days before the flight (with the exception of a patient with an acute MI being flown to the catheterization lab, which is done routinely)
- Uncontrolled arrhythmia
- Pregnancies past 24 weeks’ gestation
- Recent eye surgery affecting the globe
- Nonacute hypovolemia

If air medical transport is undertaken in such cases, special considerations, such as flying at a lower altitude than usual, may need to be taken to optimize the patient’s outcome. Although patient conditions and possible complications must always be considered, the terrain, weather, and geographic location of the closest facility must also be factored into the decision-making process. In addition, it is important to recognize the transport crew’s capabilities and to ensure crew members’ safety.

Although there are certainly some drawbacks associated with air medical transport, history has shown that air medical transports decrease mortality rates and allow patients to have access to more specialized tertiary care facilities. Air medical transports may facilitate more rapid entry into the health care system, especially for patients who live in otherwise inaccessible areas. Such programs can be a major source of support for community hospitals and rural areas when they are confronted with critically ill or injured patients.

The Atmosphere

The **atmosphere** extends from the surface of the earth to an altitude of about 6,200 miles, which is the beginning of space **FIGURE 4-1**. This chapter focuses primarily on the components of the lower atmosphere, in which all aviation except space exploration occurs. The atmosphere varies with time of day, season of the year, and latitude. Because of these variables, only averages are discussed in this chapter.

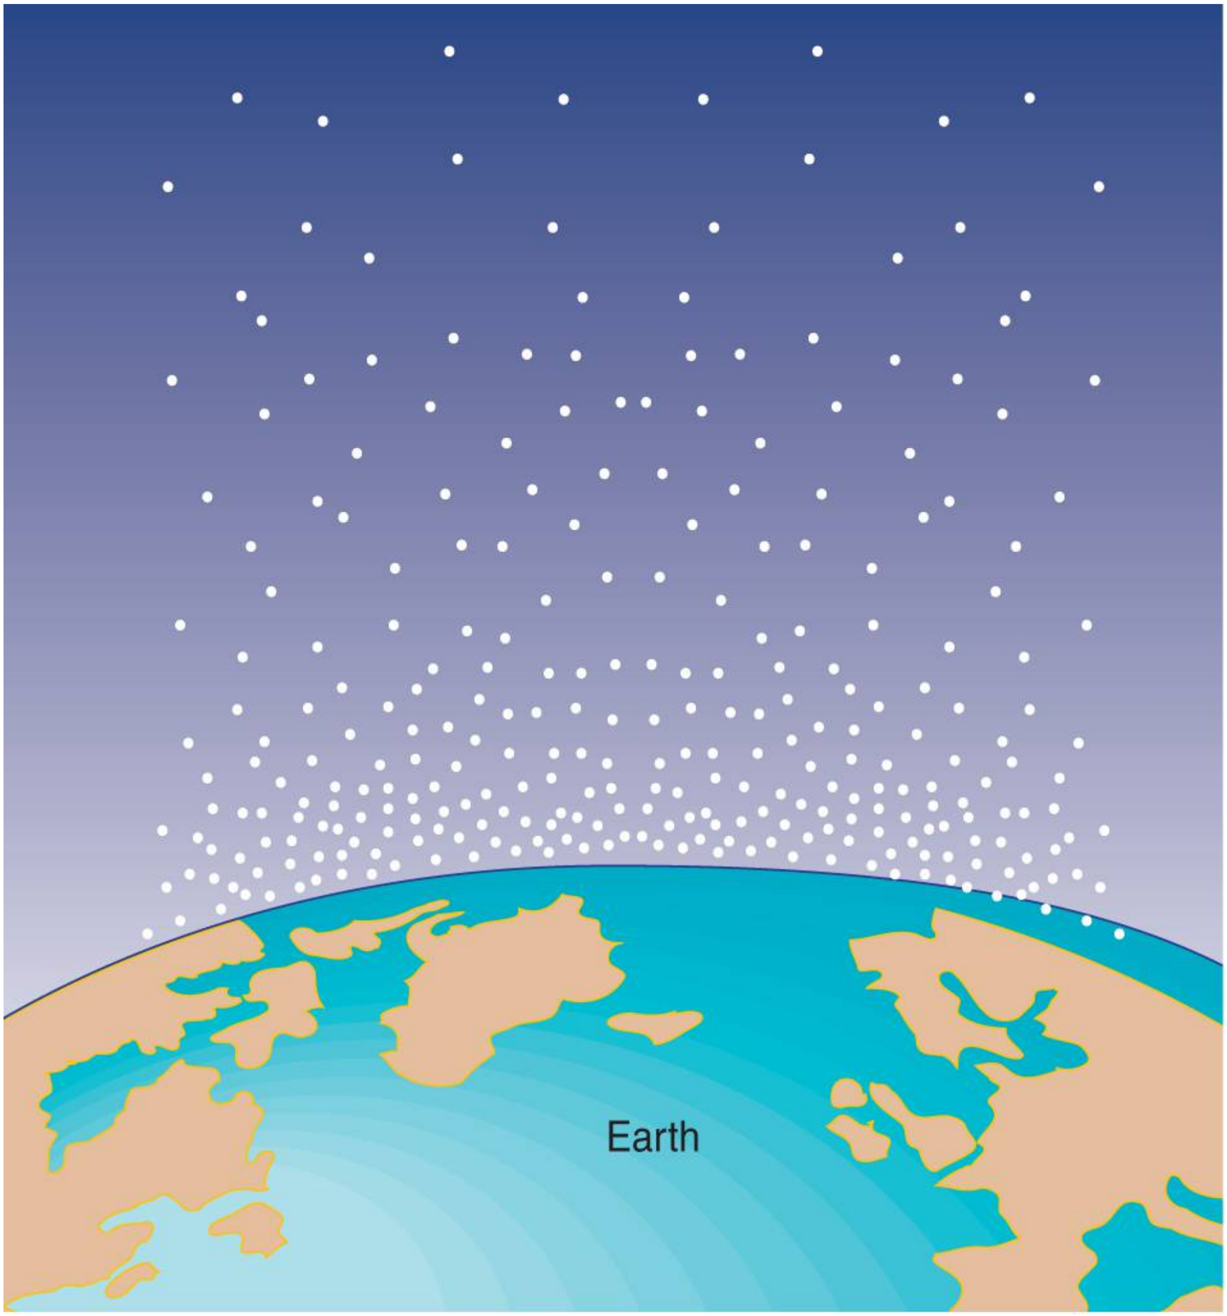

FIGURE 4-1 The density of the atmosphere decreases the farther you are from sea level.

© Jones & Bartlett Learning.

Atmospheric Composition

The composition of the atmosphere is constant and is defined in terms of percentages of gases. Although the percentage of gases is constant, the density of the atmosphere and its constituent gases vary with the altitude. Three gases—oxygen, nitrogen, and argon—constitute almost 99% of the atmosphere, which remains constant from the surface to altitudes of 250,000 feet.

- Oxygen makes up 21% of the atmosphere's volume. A by-product of photosynthesis, it is the most critical gas needed to sustain life.
- Nitrogen is the most abundant gas in the atmosphere, accounting for 78% of the total volume. This inert gas is odorless, colorless, and tasteless. While not readily used by humans, nitrogen is a critical element for life. It is present in the human body in abundant quantities and can be responsible for evolved gas disorders at altitude or after rapid ascent while scuba diving.
- Argon constitutes approximately 0.93% of the atmosphere's volume.

Other gases found in the atmosphere in trace amounts include carbon dioxide, neon, helium, methane, krypton, and hydrogen.

No matter the altitude, the percentage of the atmosphere consisting of oxygen will always be roughly 21%. During an ascent to higher altitude, the molecules of gases, including oxygen, spread out and become less numerous in each breath. This is why it can be difficult for human beings to breathe at high altitudes, such as at the top of Mount Everest.

Layers of the Atmosphere

Five distinct layers of the atmosphere have been identified based on thermal characteristics (temperature changes), chemical composition, movement, and density. The density of the atmosphere decreases with height because the weight of the molecules actually compresses its component gases near the earth's surface.

The first layer of the atmosphere is called the **troposphere**. The troposphere extends from sea level to about 26,000 feet (5 miles) over the poles and to nearly 52,000 feet (10 miles) above the equator. Virtually all weather occurs in the troposphere because of the presence of water vapor and strong vertical currents there. In this layer, clouds form, rain falls, wind blows, and humidity varies depending on the climate. The strong jet stream is located above 35,000 feet, with maximum winds in the jet stream averaging 200 mph at about 30° latitude north or south. The troposphere is also the densest portion of the atmosphere. Temperature in this layer varies from 62.6°F (17°C) to minus 68.8°F (minus 56°C) and decreases proportionately with increases in altitude.

The **tropopause** is the layer between the troposphere and the stratosphere, which is the next layer. The tropopause ranges in height from 30,000 feet at the poles to more than 60,000 feet at the equator. More solar energy is received by the earth near the equator, causing the air there to heat and expand. This expansion of rising air increases the height of the tropopause. Conversely, the cool air at the poles results in contraction and shrinkage of the air, resulting in a lesser height of the tropopause at these locations. The tropopause and the troposphere are collectively known as the lower atmosphere.

The layers above the tropopause include the stratosphere, stratopause, mesosphere, thermosphere, and exosphere, in that order. Critical care transports do not occur at these altitudes. **FIGURE 4-2** shows the layers of the atmosphere and indicates how they compare with the zones of the atmosphere (discussed next).

Description

Physiologic Zones of the Atmosphere

The atmosphere is divided into three distinct zones that directly correlate to a human's response to hypoxia: the physiologic zone, the physiologically deficient zone, and the space equivalent zone.

Physiologic Zone

The **physiologic zone** is the area of the atmosphere that contains the oxygen and barometric pressure needed for a normal, healthy person to live. This zone extends from sea level to 10,000 feet. In this zone, the barometric pressure falls from 760 mm Hg at sea level to 523 mm Hg at 10,000 feet. The pressure at 10,000 feet is still enough to maintain an adequate **partial pressure of oxygen (arterial) (Pao$_2$)** without the use of supplemental oxygen, pressurization, or protective equipment. Nevertheless, at 10,000 feet, many healthy people will begin to experience very mild effects of **hypoxia** (oxygen deprivation), such as a mild headache, and almost all patients with comorbidities will be hypoxic at this altitude. As will be discussed in more detail later, air medical transport providers are subject to Part 91 and/or Part 135 under Title 14 of the Code of Federal Regulations (14 CFR), often referred to as the Federal Aviation Regulations (FARs). Part 135.89 states that commercial pilots must use supplemental oxygen when flying at altitudes greater than 10,000 feet.

Physiologically Deficient Zone

The area from 10,000 to 50,000 feet is called the **physiologically deficient zone**. Above 10,000 feet, barometric pressure begins to decrease to levels that will result in hypoxic hypoxia (a state of oxygen deficiency caused by a decrease in the amount of oxygen in the blood), which is discussed later in this chapter. Barometric pressure at this level ranges from 523 mm Hg at 10,000 feet to 87 mm Hg at 50,000 feet. At these altitudes, the effects of trapped gases become more pronounced, and protective equipment, supplemental oxygen, and pressurized aircraft are necessary for transports.

Space Equivalent Zone

The **space equivalent zone** extends from 50,000 feet to 120 miles. At this point in the atmosphere, 100% supplemental oxygen is no longer adequate because of the minimal barometric pressure. Pressure suits and sealed cabins are also required. Two additional hazards can be present. First, exposure to atmospheric conditions could result in the boiling of body fluids as the fluids turn to a vapor. Second, personnel might be exposed to increased levels of radiation from the sun in this zone. Currently, no commercial aircraft used for air medical transport operate in this zone.

Barometric Pressure

Barometric pressure, also called atmospheric pressure, is a direct result of the weight of air. Barometric pressure varies with time and location because the amount and weight of air above the earth vary with time and location. This pressure is also related to the density of the air, which reflects the air temperature and height above the earth's surface. Thus, **barometric pressure** is the weight per unit area of all the molecules of the gas above the point at which the measurement was taken, with temperature and humidity as variables. It is also one of the most important factors that determines weather.

Barometric pressure is reported in a variety of units. Inches of mercury is the unit most commonly used in the United States, but millibars is used in most countries that use the metric system, such as most of Europe. It may also be measured in atmospheres (atm), although different scientific definitions of the atmosphere exist. The two most prevalent definitions are the US Standard Atmosphere and the International Standard Atmosphere. The US Standard Atmosphere has been recognized for the longest time, but the International Standard is now more widely recognized around the globe.

Gas Laws

CCTPs must have a thorough knowledge of the applicable gas laws as they relate to both flight and hyperbaric medicine (ie, medicine involving one or more gases at a greater than normal pressure). The various gas laws have an important role not only in patient care, but also in the overall safety of the flight crew. Several gas laws, some of which are interdependent, are integral to flight physiology.

Boyle's Law

Robert Boyle studied the relationship between the volume of a dry gas and its pressure. Boyle found that when he increased the volume of the gas, the pressure decreased. Conversely, a decrease in volume resulted in an increase in pressure. A practical example of this law's application is that as altitude increases, the atmospheric pressure decreases.

Boyle's law has numerous implications for aviation medicine. For example, any gas trapped in the chest, such as in a pneumothorax, will expand approximately 35% when going from sea level to 8,000 feet **FIGURE 4-3**. At 18,000 feet, a given volume of gas will expand to twice its size at sea level.

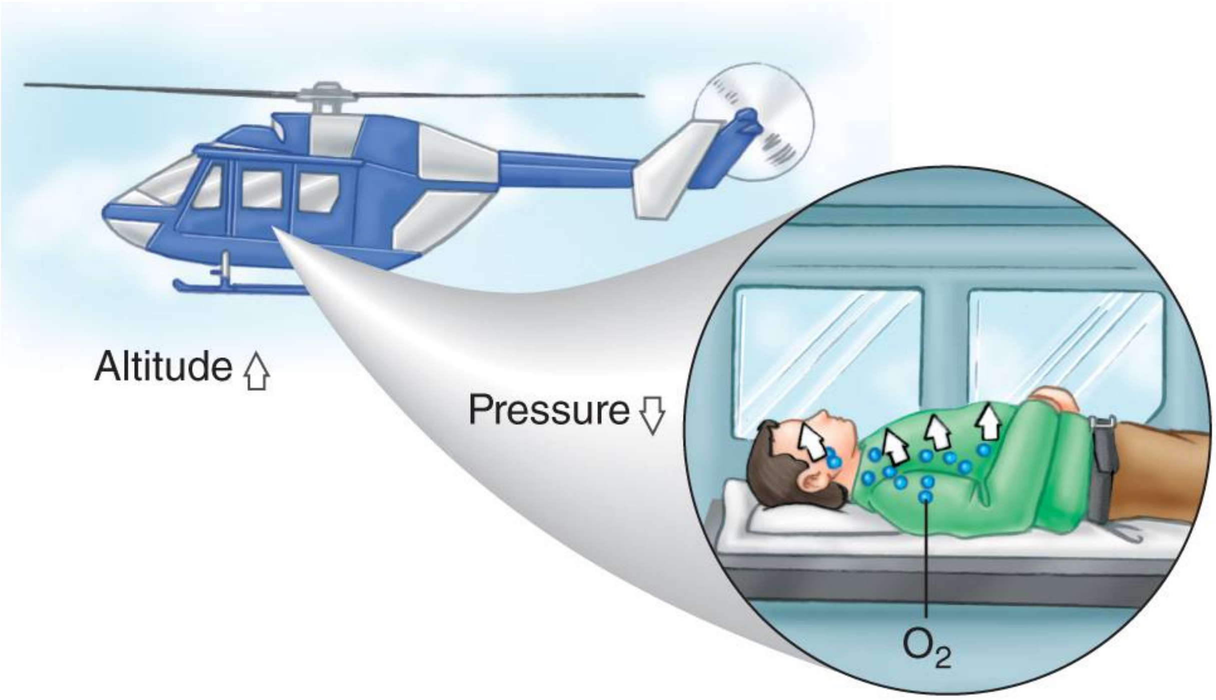

FIGURE 4-3 Boyle's law. As altitude increases, atmospheric pressure decreases, and gases inside the body expand.

Abbreviation: O_2, oxygen

© Jones & Bartlett Learning.

Description

Several disease processes can have drastic effects with increasing altitude. An injury such as a pneumothorax can quickly become a tension pneumothorax as altitude increases. Patients with an open skull fracture are at risk for **pneumocephalus** because air becomes trapped inside the skull and expands with altitude, causing a significant increase in intracranial pressure. Patients with **pneumoperitoneum** (a collection of air within the peritoneum) or **pneumomediastinum** (a collection of air within the mediastinum) are also susceptible to worsening of their condition with increasing altitude. Although these disease processes might not cause a high-tension event within the body, they create significant discomfort for the patient.

Boyle's law also applies to the expansion of any trapped gas within the body, such as in the middle ear, sinuses, stomach, and intestines.

Many pieces of medical equipment are also exquisitely sensitive to an increase or decrease in barometric pressure. The cuffed balloon on endotracheal tubes, for example, can double in size with a change in altitude from 5,000 feet to 10,000 feet, causing the balloon to rupture or triggering tissue necrosis if the balloon is allowed to remain hyperinflated for a significant length of time. Therefore, cuffed balloons should be filled with saline before flights planned at altitudes greater than 6,000 feet, or cuff pressure should be monitored and adjusted.

All patients who have a nasogastric or orogastric tube inserted should be transported on aircraft with the tube open or frequently vented. Patients with colostomy bags should frequently have the built-up gas “burped” to prevent overpressurization and failure of the colostomy bag.

Charles’s Law

Discovered in 1787 by Jacques Charles, **Charles’s law** states that the volume of a gas is directly proportional to the temperature, with the pressure remaining constant **FIGURE 4-4**. The practical application of this law is that as the air heats up, the volume increases, allowing the molecules to spread out and making the air less dense. Helicopters fly more easily in cold weather because gas molecules are more compressed and allow more lift as the rotor blades spin. In contrast, gas molecules are farther apart in hot weather and provide less lift. Therefore, a helicopter or airplane is able to carry a smaller amount of weight on a hot, humid day than on a cold, dry day.

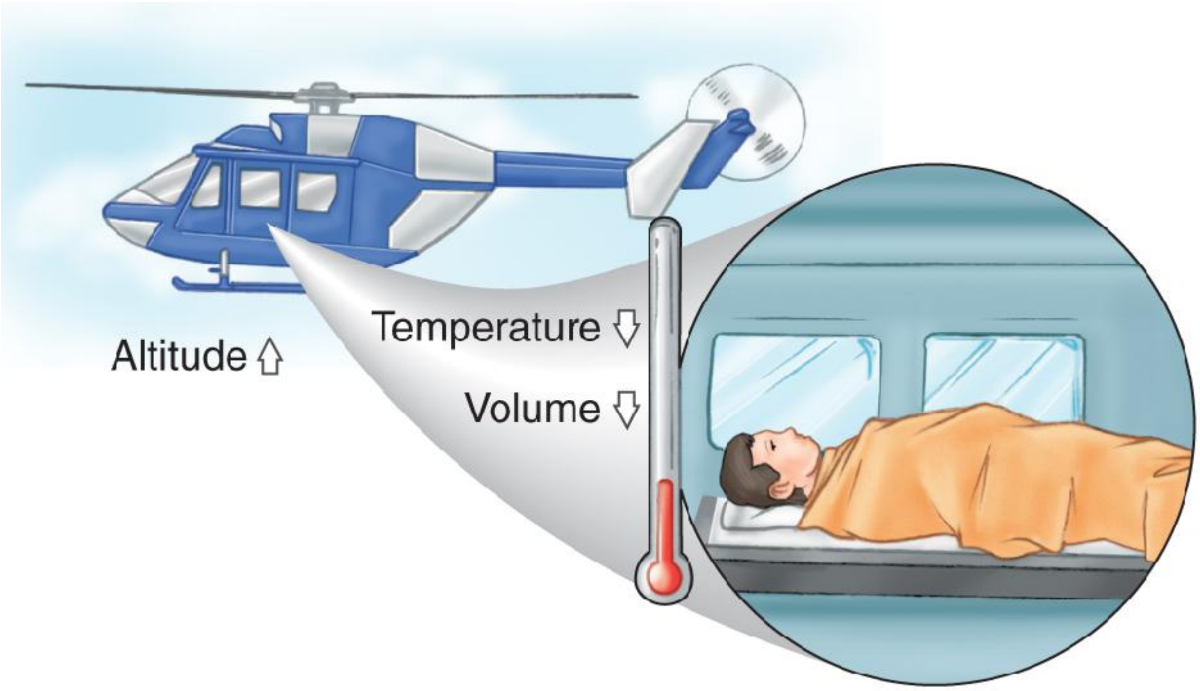

FIGURE 4-4 Charles's law. The volume of a gas is directly proportional to the temperature, with the pressure remaining constant.

Description

Dalton's Law

In 1800, John Dalton postulated **Dalton's law**, which states that the total pressure of a gas mixture is the sum of the individual pressures. Simply put, all of the parts equal the whole. This law is also referred to as the law of partial pressures, where a partial pressure is the pressure of a single gas in the mixture.

Dalton's law illustrates that increasing altitude results in a proportional decrease in the partial pressures of the gases found in the atmosphere. Although the percentage concentrations of gases remain stable with increasing altitude, their partial pressure decreases in direct proportion to the total barometric pressure. Dalton's law is extremely important in critical care medicine because when supplemental oxygen is given, this law can be used to calculate the expected partial pressure of oxygen (Po_2) that should be obtained when arterial blood gas values are checked **FIGURE 4-5**.

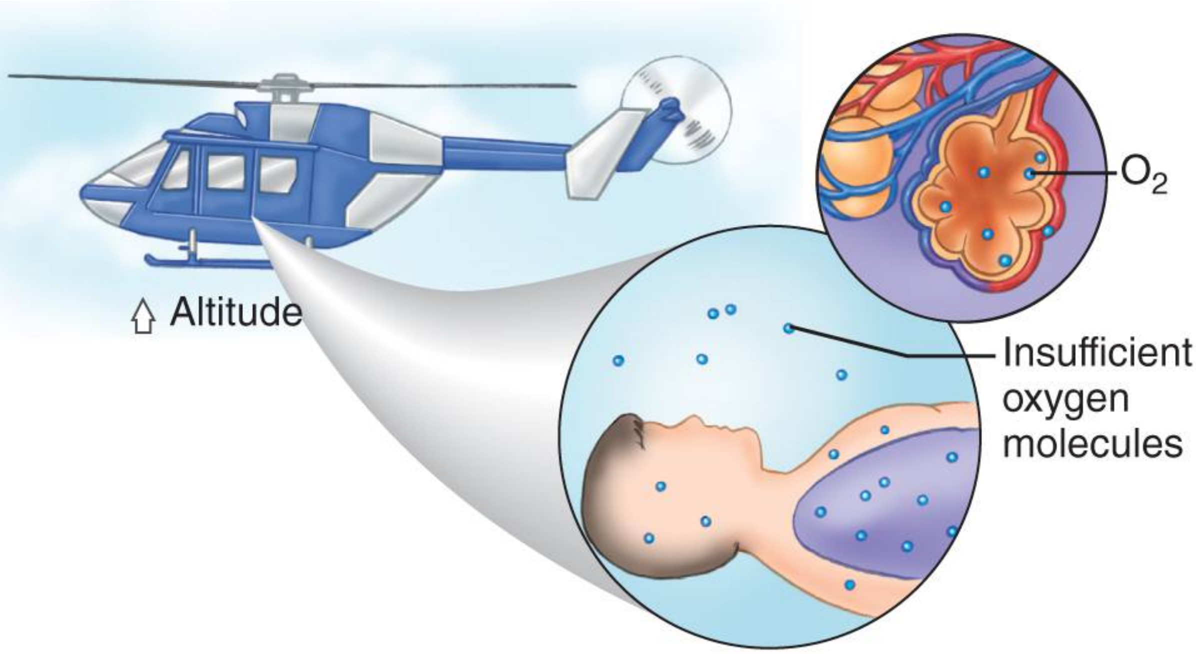

FIGURE 4-5 Dalton's law. The total pressure of a gas mixture is the sum of the individual pressures. Insufficient oxygen (O_2) molecules can lead to hypoxia.

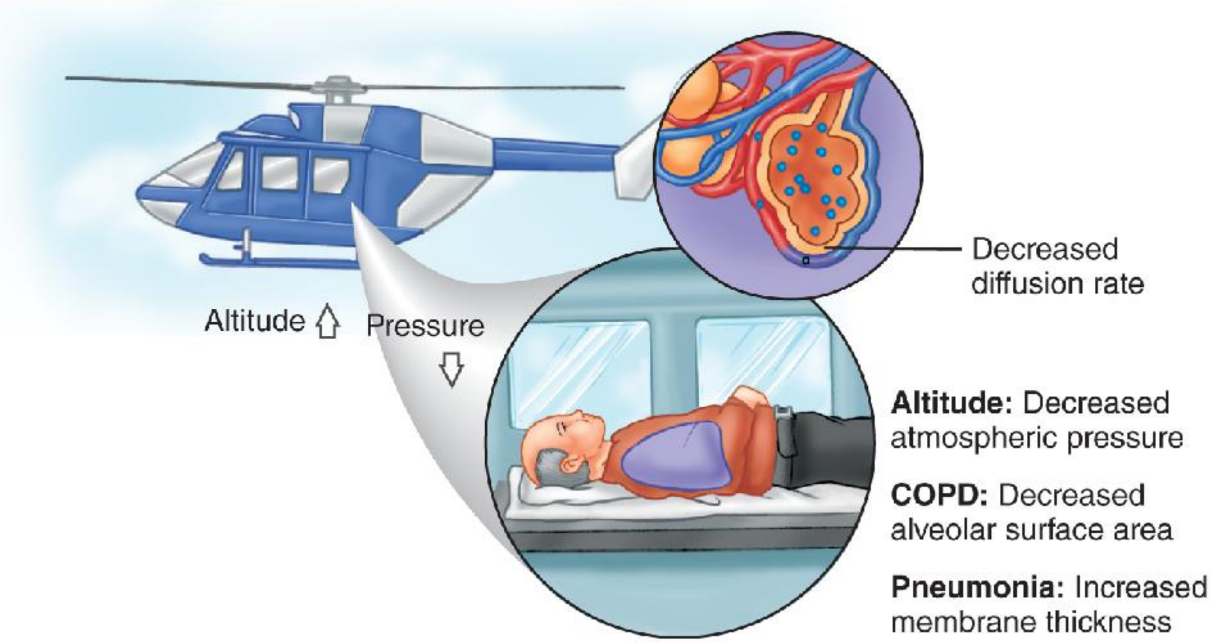
Description

Fick's Law

Fick's law, established by Adolph Fick in 1855, states that the diffusion rate of a gas is (1) proportional to the difference in partial pressure, (2) proportional to the area of the membrane, and (3) inversely proportional to the thickness of the membrane **FIGURE 4-6**. In practical terms, the rate of diffusion is affected by atmospheric pressures, the surface area of the membrane, and the thickness of the membrane. Fick's law is the primary gas law governing the diffusion of oxygen across the alveolar membrane. For example, an older adult with chronic obstructive pulmonary disease (COPD) who also has pneumonia will have decreased gas exchange at altitude because of the decreased partial pressure of oxygen at altitude, coupled with the decreased surface area of the alveoli and the increased membrane thickness secondary to the disease processes.



Decreased diffusion rate
Altitude ⇧ Pressure ⇩
Altitude: Decreased atmospheric pressure
COPD: Decreased alveolar surface area
Pneumonia: Increased membrane thickness

FIGURE 4-6 Fick's law. The diffusion rate of a gas is affected by atmospheric pressures, the surface area of the membrane, and the thickness of the membrane. A patient with chronic obstructive pulmonary disease (COPD) and pneumonia will have decreased gas exchange.

Description

Henry's Law

In 1800, J. W. Henry postulated **Henry's law**, which states that the amount of a gas in a solution varies directly with the partial pressure of a gas over the solution. In other words, as the pressure of a gas over a liquid decreases, the amount of gas dissolved in the liquid will also decrease.

The effect of Henry's law in the body is seen in decompression sickness, which is discussed later in this chapter. In this case, inert gases in the body tissue (primarily nitrogen) are maintained in equilibrium with the partial pressures of the same gases in the atmosphere. As barometric pressure decreases, the partial pressure of nitrogen in the atmosphere decreases as well. As the body attempts to establish a new equilibrium, nitrogen comes out of solution in the form of gas bubbles and travels in the venous blood system to the lungs **FIGURE 4-7**.

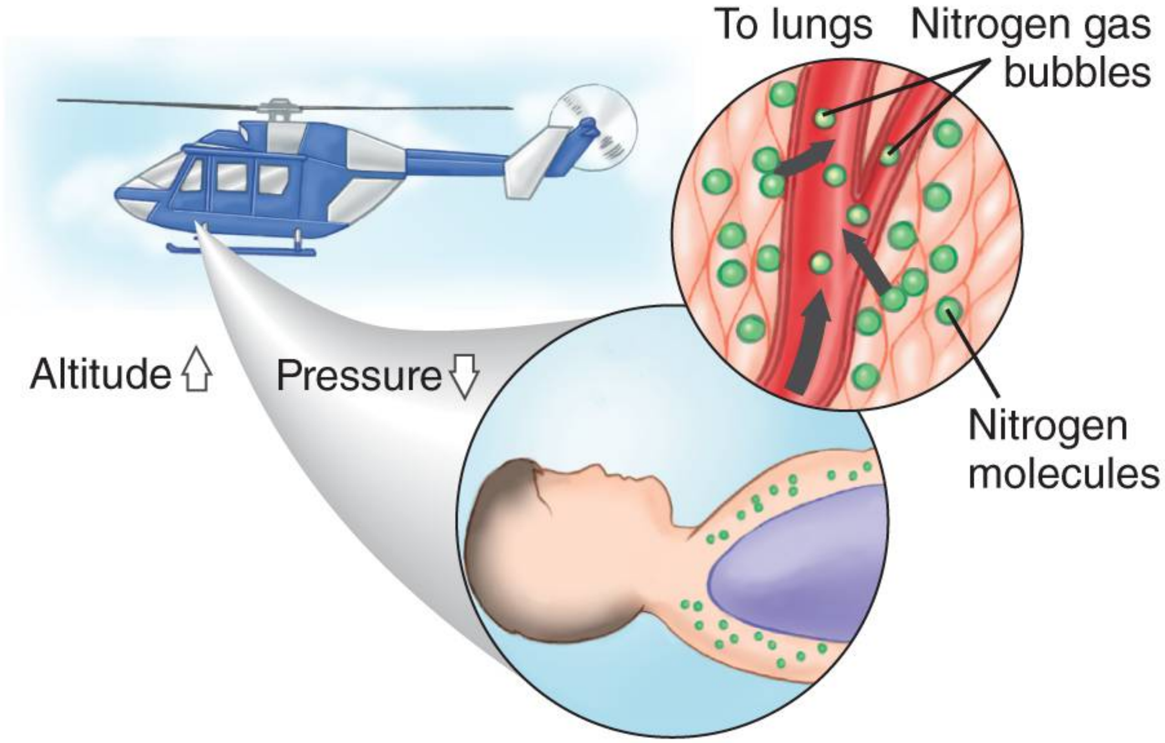

FIGURE 4-7 Henry's law. As the pressure of gas over a liquid decreases, the amount of gas dissolved in the liquid will also decrease. In decompression sickness, nitrogen saturates the tissues, then forms gas bubbles that travel to the lungs.

Description

Gay-Lussac's Law

In 1809, the French chemist Joseph Louis Gay-Lussac found that there is a correlation between the pressure and the temperature of a gas when its volume is constant. Gay-Lussac's law can be expressed as a ratio: If pressure increases, temperature increases, and vice versa **FIGURE 4-8**. As an example, think of a room full of people (molecules). As the room becomes smaller (pressure increases), people will bump into each other, creating friction that will generate heat. As the room gets larger (pressure decreases), people no longer bump into each other and no heat is generated; thus, the room is cooler. Two other commonly cited examples of Gay-Lussac's law are the drop in measured tire pressure seen when an automobile sits outdoors overnight in a very cold environment and the increase in pressure observed in an oxygen cylinder when it is left out in very warm sunlight.

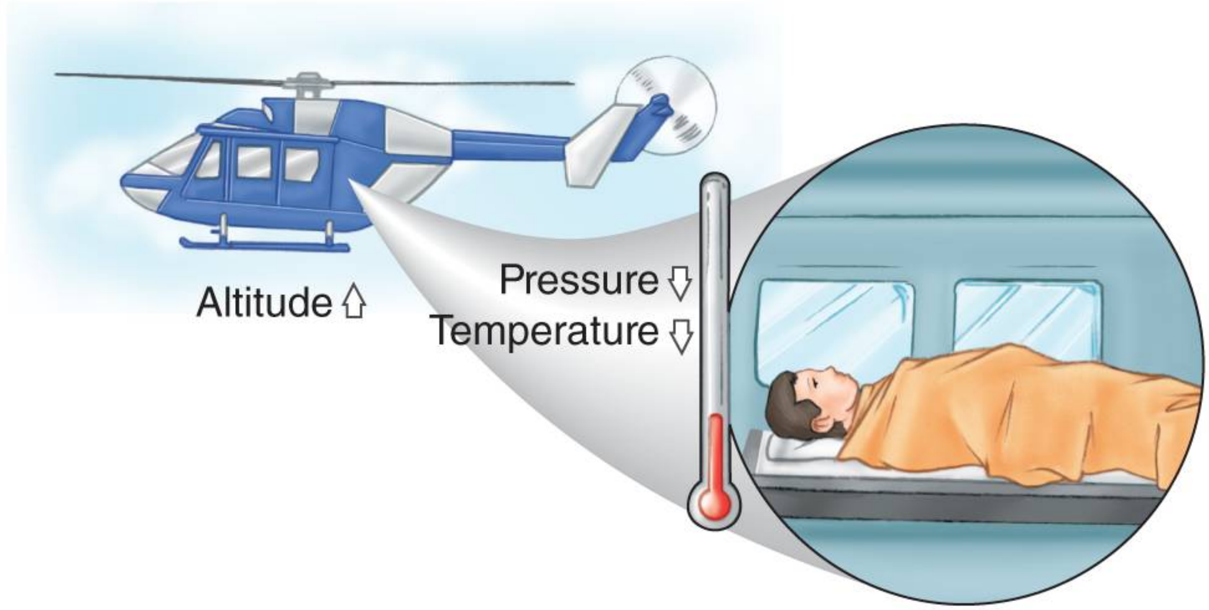

FIGURE 4-8 Gay-Lussac's law. As pressure decreases, temperature decreases, so remember to keep your patients warm.

Description

Graham's Law of Gaseous Diffusion and Effusion

Graham's law, formulated by the Scottish physical chemist Thomas Graham, states that the rate at which a gas moves through a small hole (effusion), avoiding interaction with other particles along the way, is inversely related to the square root of the mass of one mole of its molecules. In comparison, diffusion refers to particles moving from an area of high concentration to one of low concentration. When a gas is dissolved in liquid, its relative rate of diffusion is directly proportional to its solubility in the liquid. Both the effusion and diffusion concepts come into play when discussing the movement of oxygen and carbon dioxide between the alveolus and its capillary network.

A practical example of Graham's law is the ongoing process of diffusion of oxygen and carbon dioxide in the blood and transfer of oxygen from blood into the cells. Carbon dioxide molecules are much more massive than oxygen molecules (which would initially suggest a higher rate of effusion on the part of oxygen). However, carbon dioxide also has 22 times the solubility of oxygen, which mathematically means that carbon dioxide's diffusion rate is much faster than that of oxygen.

At altitude, with a lower barometric pressure and a greater overall volume of gas (particularly oxygen) in the atmosphere, the gas is less dense (ie, less concentrated) and the gradient for movement across the alveolar capillary membrane is altered. These dynamics can ultimately affect cellular respiration, leading to a reduction in movement of both oxygen and carbon dioxide. In short, oxygen is present, but there is not enough pressure to keep the molecules close enough together that a person can draw a meaningful breath. The CCTP must understand and remain mindful of this key concept **FIGURE 4-9**.

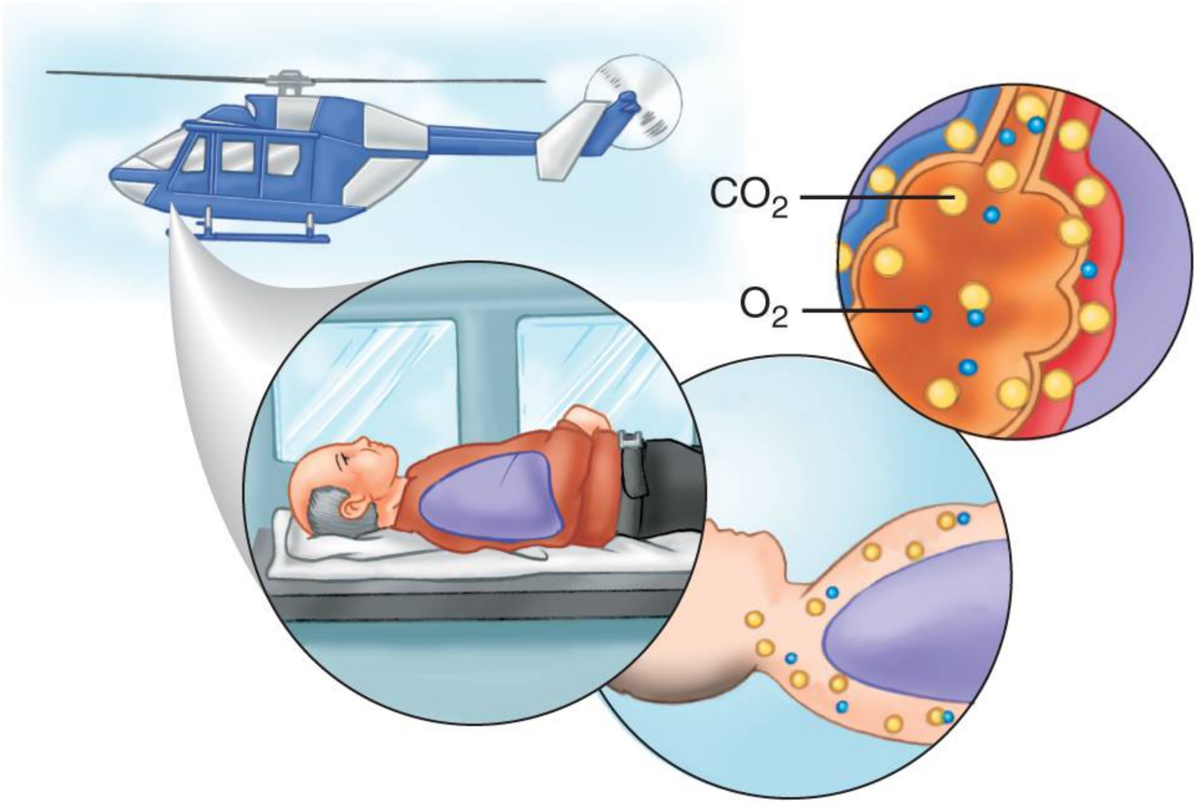

FIGURE 4-9 Graham’s law. The rate at which a gas moves through a small hole is related inversely to the square root of the mass of one mole of its molecules. Diffusion of a gas in solution (eg, blood) is directly proportional to its solubility. Carbon dioxide (CO_2) diffuses more readily into the bloodstream than does oxygen (O_2) due to its higher solubility.

Description

Formulas Based on the Gas Laws

The following formula, based on Henry’s law, is used to determine how much additional oxygen will be needed to compensate for the altitude and barometric pressure changes. Fraction of inspired oxygen is indicated by F_{IO_2}.

$$\frac{\text{Initial } FIO_2 \times \text{Initial Barometric Pressure}}{\text{Baraometric Pressure at Cruising Altitude}} = \text{Adjusted } FIO_2$$

If the barometric pressure is 760 mm Hg at sea level and 600 mm Hg at 6,000 feet above sea level, and if the patient's initial FIO_2 is 70%, the adjusted FIO_2 would be calculated as follows:

$$\frac{70\% \text{ Initial } FIO_2 \times 760 \text{ mm Hg}}{600 \text{ mm Hg}} = 88.7\% \text{ Adjusted } FIO_2$$

To ensure that the patient continues to receive 70% FIO_2, the ventilator would need to be adjusted to 88% FIO_2.

Medical Transport Aircraft

As a CCTP, you need to be familiar with both rotor-wing (helicopter) and fixed-wing (airplane) operations. Transports via both types of aircraft have advantages and disadvantages. Nevertheless, they share many commonalities, including the four primary forces that constantly act on the aircraft in flight: **lift**, **thrust**, **weight** (gravity), and **drag** **FIGURE 4-10**. Lift counteracts weight, and thrust opposes drag. Essentially, greater amounts of thrust and lift allow an aircraft to take off. Conversely, greater amounts of drag and weight must exist for an aircraft to land. In straight and level flight, thrust equals drag and lift equals weight.

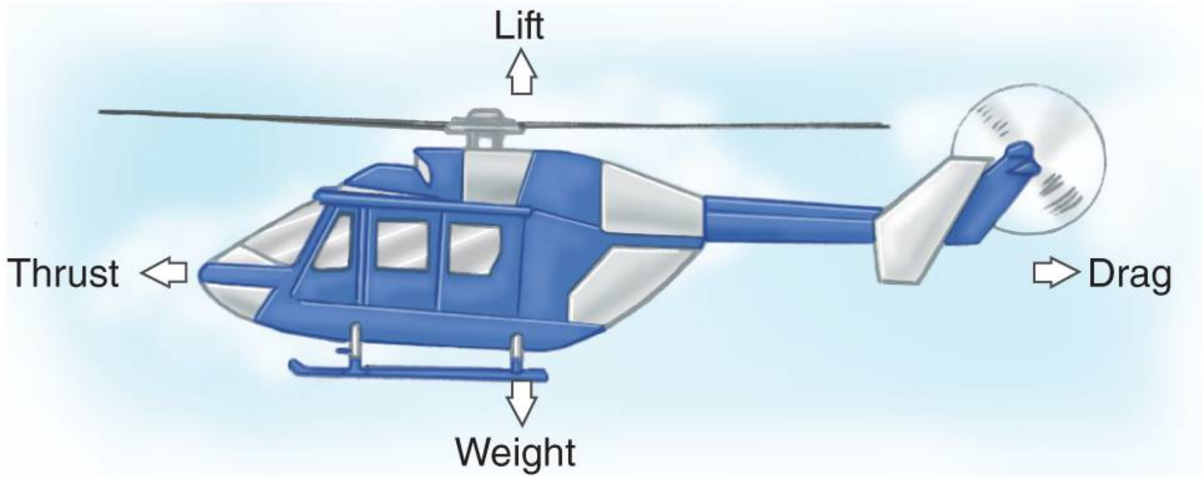

FIGURE 4-10 The forces of flight: weight, lift, drag, and thrust.

Description

Rotor-Wing Transport

Rotor-wing transport, the means of transport that facilitates **helicopter emergency medical service (HEMS)**, has the distinct advantage of vertical takeoff and landing, allowing the helicopter access to areas that may be inaccessible by ground vehicles or fixed-wing aircraft **FIGURE 4-11**. Rotor-wing aircraft generally have sustained speeds in excess of 150 mph, can operate at altitudes of less than 2,000 feet, and can move from point to point. (Depending on the local terrain, the altitude at which an aircraft will be able to fly may vary and is always at the discretion of the pilot-in-command.) Air medical providers who use such aircraft serve all types of population bases, from dense urban locations to extremely rural areas. A relatively small number of helicopters can serve a large population because of the quick turnaround time for most flights and their ability to cover distances quickly.

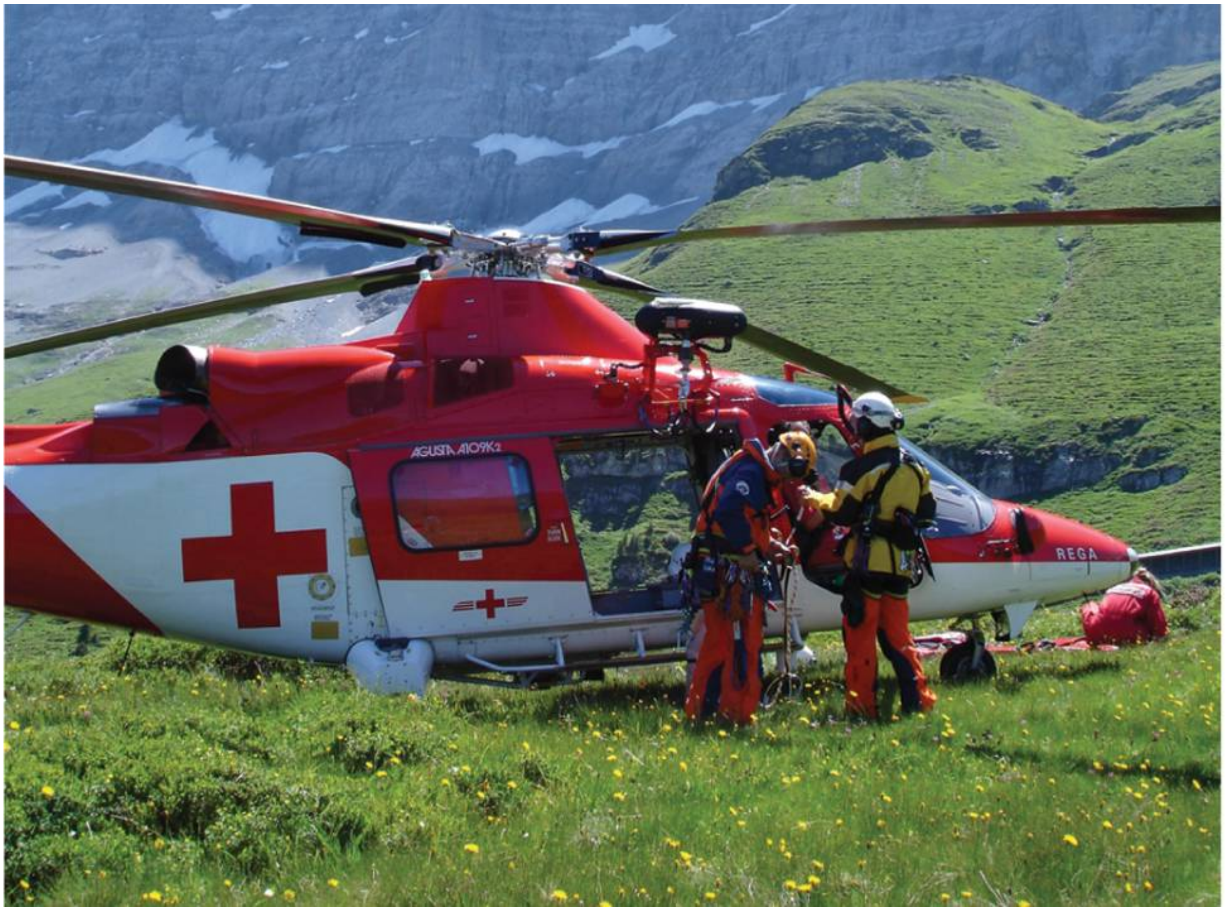

FIGURE 4-11 Helicopters can access locations that ground vehicles and fixed-wing aircraft cannot, making them ideal for certain situations.

Courtesy of Rega, Swiss Air-Rescue.

Rotor-wing transport has some disadvantages. Helicopters are more restricted than fixed-wing aircraft regarding weather limitations. They also have more stringent interior space limitations, which often make it difficult to perform complex patient-care procedures in the aircraft. For example, because of space constraints, when being transported by HEMS, a patient may be inaccessible from the waist down, or there may not be enough space behind the patient's head to allow intubation. These situations can have major ramifications for patient care.

Another limiting factor is the expense of helicopters compared to ground transport vehicles. A used helicopter may cost $2 million, and a new one may be closer to $20 million. There must be justification for the necessity of the helicopter to offset its increased costs relative to ground transport. HEMS is considerably more expensive than ground transport, averaging almost seven times the cost of an ambulance transport. (See Table 1-1 for further comparison of the advantages and disadvantages of different transportation modes.)

Helicopter transport is also subject to weight limitations. This concern becomes more problematic in the summer when the air is less dense, decreasing the amount of lift that the blades can achieve (ie, lift capacity). (Remember Charles's law?)

Fixed-Wing Transport

As a general rule, transport by fixed-wing aircraft is safer than transport by rotor-wing aircraft. Fixed-wing aircraft use established landing areas (airports) and fly at designated cruising altitudes that minimize their risk of colliding with human-made objects. The vast majority of fixed-wing air medical aircraft are certified to follow instrument flight rules (discussed later in the chapter) and fly with a two-pilot crew, further increasing safety.

Fixed-wing aircraft offer several advantages for medical transport. Two of their greatest advantages are their high speeds, ranging from 250 to 600 mph, and their ability to travel over greater distances. Some fixed-wing aircraft can carry multiple patients, ranging from two on smaller aircraft to hundreds on large military air medical aircraft.

There are usually no weight limitations regarding patient size, and the aircraft can carry multiple medical crew members with a variety of equipment.

Nevertheless, fixed-wing aircraft have some distinct disadvantages, including the high cost of obtaining an aircraft for air medical purposes. Many air medical providers do not purchase or lease their own aircraft, but instead contract with various executive aircraft services to provide aircraft as needed. The cost of patient transport by fixed-wing aircraft can exceed $10,000 or more for short-distance flights and can exceed $100,000 for international flights. Most fixed-wing services secure reimbursement from patients or insurance companies prior to initiating a flight because of the high costs involved.

Fixed-wing aircraft must use maintained landing fields, and restrictions on runway length may apply, depending on the size of the aircraft. In addition, fixed-wing aircraft require hangars to house them on the ground, which increases their overall operating costs.

Pressurized Versus Nonpressurized Aircraft

The most effective method of protecting people from the physiologic effects of reduced barometric pressure is to pressurize the aircraft. This pressurization is accomplished by increasing the barometric pressure in the aircraft above the ambient pressure outside the aircraft. Two primary methods are used for pressurizing aircraft: the isobaric system and the differential control method for pressurization. The majority of civilian and military aircraft use isobaric systems for pressurization. The differential control (also known as conventional or isobaric-differential) method is designed primarily for military aircraft and has an aircraft cabin pressure that fluctuates with altitude.

Decompression at altitude is categorized as either slow or rapid. Rapid cabin depressurizations are dramatic events. With a loud explosion and numerous master caution warning horns sounding in the cockpit, it is quickly obvious to everyone that a major emergency has occurred. When rapid cabin depressurization occurs, the occupants of the aircraft are immediately exposed to the dangers of hypoxia, decompression sickness, gastrointestinal expansion, and hypothermia. Commercial pilots are extensively trained and tested on rapid decompression and emergency descent procedures.

A slow decompression, in contrast, can occur when a small leak develops in a pressurized aircraft. This type of decompression is dangerous because of its insidious onset and the undetectable loss of oxygen, which can lead to hypoxia and death if uncorrected.

If a loss of cabin pressure occurs, a descent must be made immediately to a level at which cabin altitude can be maintained at or below 10,000 feet. In addition, all occupants must use oxygen until the pilot-in-command indicates it is no longer necessary. As described later in this chapter, rapid cabin depressurization also dramatically affects the effective performance time and the time of useful consciousness, reducing these times by as much as one-half.

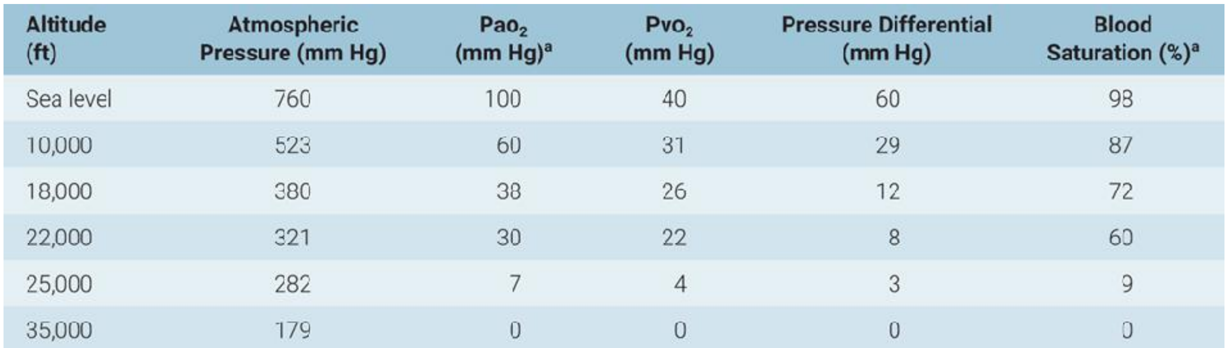
Primary Stressors of Flight

Flight crew members will experience many stressors during their career; however, some stressors may cause catastrophic outcomes. When flying in a fixed-wing or rotor-wing aircraft, all personnel will inevitably experience rapid altitude changes. When the body is exposed to significant altitude changes without the proper precautions, adverse outcomes may occur as the body attempts to maintain homeostasis.

Decreased Levels of PO_2

Decreased levels of PO_2 can quickly cause hypoxia in both the flight crew and passengers. At 15,000 feet, the barometric pressure is 429 mm Hg, and average values for a healthy patient would include an oxygen saturation of 80% (the body requires 87% to 97%) and a PaO_2 of 44 mm Hg (the body requires 60 to 100 mm Hg) **TABLE 4-1**. Remember that these values are averages for a healthy person; they are not representative of the patients who require critical care.

TABLE 4-1 Partial Pressures of Oxygen at Various Altitudes



Altitude (ft)	Atmospheric Pressure (mm Hg)	PaO_2 (mm Hg)[a]	PvO_2 (mm Hg)	Pressure Differential (mm Hg)	Blood Saturation (%)[a]
Sea level	760	100	40	60	98
10,000	523	60	31	29	87
18,000	380	38	26	12	72
22,000	321	30	22	8	60
25,000	282	7	4	3	9
35,000	179	0	0	0	0

[a] These are average measurements for a healthy patient.

Abbreviations: PaO_2, partial pressure of oxygen (arterial); PvO_2, partial pressure of oxygen (venous)

Description

Barometric Pressure Changes

The greatest pressure change in an aircraft takes place from sea level to 5,000 feet. Therefore, problems associated with pressure must be considered even in nonpressurized aircraft that are not flying at altitudes requiring supplemental oxygen or cabin pressurization. During daylight hours for nonpressurized aircraft, 10,000 feet of altitude is the ceiling at which crew members must begin to use oxygen. Because the loss of night vision is one of the first symptoms of hypoxia, the ceiling drops to 8,000 feet for nighttime flight operations that exceed 1 hour in length. The alveolar Po_2 at 10,000 feet is approximately 61 mm Hg, which produces the maximum acceptable degree of hypoxia allowed. The upper limit for the indifferent stage of hypoxia (discussed later in this chapter) is 10,000 feet. However, deviation by only a few thousand feet for a short time will have little difference. For this reason, certain military operations are allowed at 13,000 feet as long as the duration of the flight is less than 3 hours.

In addition to causing hypoxia and malfunctioning pacemakers, ambient pressures and increasing altitudes can cause discomfort in air-trapped organs and sinuses (eg, the ears and gastrointestinal system).

Thermal Changes

Flight crew members are subjected to a variety of thermal extremes, ranging from the very cold to the very hot. Temperature changes increase the body's demand for oxygen and make the body less tolerant of the effects of hypoxia. Such changes can also cause the effects of hypoxia to become evident at lower altitudes than would normally be expected.

Temperature decreases as altitude increases. Specifically, temperature decreases by 3°F to 5°F per 1,000-feet gain in altitude, depending on the humidity. (At altitudes from 35,000 to 99,000 feet, the temperature remains relatively constant at minus 32°F [minus 50°C].) If the air conditioner cannot keep the cabin cool because of high ambient temperatures, rotor-wing aircraft may have the option to ascend and take advantage of the cooler temperatures at higher altitudes.

Flight personnel are often subjected to a wide range of ambient temperatures because of the geographic range of their aircraft. For example, flight crew assigned to rotor-wing aircraft may experience a temperature of 80°F (26.7°C) at their base but fly less than 1 hour into mountainous areas where the temperatures can be less than 40°F (4.4°C). Crews assigned to fixed-wing aircraft may see an even broader range of temperatures as they start in a northern climate in the snow and end in the hot sun in a southern climate.

A secondary hazard is the greenhouse effect, which results from radiant solar heat. This effect can increase the temperature in the cockpit or cabin of a small aircraft by as much as 50°F to 59°F.

Given the potential for such temperature changes, flight crews must be cognizant of the potential for heat stress. Core body temperatures that exceed 100°F (37.8°C) result in decreased short-term memory, degradation of motor skills, and a general decrease in performance. Heat stress also causes increased irritability and poor judgment, increases the propensity for motion sickness and hypoxia, and potentiates the effects of gravitational forces, which are discussed later in this chapter.

Vibration

Vibration is noted in all helicopters, most propeller-driven aircraft, and, minimally, jet-engine aircraft. Studies have found that vibrations between 1 and 12 Hz can cause significant effects on the body. Low-frequency vibrations can cause body discomfort, pain (usually in the abdomen or chest), decreased vision, and, most notably, fatigue. Excess vibration is an issue that must be addressed with aircraft mechanics and manufacturers. Nevertheless, some modifications can be made to reduce the effects of vibration. Increasing the cushioning on seats is one of the most important modifications, as is proper use of shoulder and lap belts, which reduces the transmission of vibrations.

Prolonged effects of vibration can increase the core body temperature as the body constantly tries to fight the effects of vibration and movement. As just mentioned, one of the most notable effects of vibration is fatigue. As the body becomes fatigued with prolonged exposure to vibration, it becomes more susceptible to the effects of vibration, which perpetuates the cycle.

To combat crew fatigue due to vibration, the amount of time a crew is allowed to fly on any given shift before resting is subject to restrictions. Preventive measures include prohibiting medical crew members from leaning against the airframe (to decrease vibration) and providing extra padding for patients so they are not leaning against the airframe.

Decreased Humidity

Humidity is the degree of moisture (water vapor) in the air; it is expressed as a percentage. The level of humidity is related to temperature: As temperature increases, so does humidity. Conversely, as temperature falls, so does the relative humidity. Because temperature falls with altitude, so does humidity. Given the relatively low altitudes at which they fly, rotor-wing and propeller aircraft tend to have higher humidity levels compared to jet aircraft. The air in a pressurized jet aircraft is also constantly being recirculated through filters, and any moisture is drawn off by the system. In high-speed, high-altitude, long-range flights, less than 5% humidity remains after 2 hours of flight and less than 1% remains after 4 hours of flight.

During a long flight, the dry air in the aircraft can cause dry, cracked mucous membranes, chapped lips, and sore throats; it can also lead to dehydration. This lack of humidity is why many people feel fatigued or jet-lagged after a long commercial flight. These problems can further be compounded in injured or ill patients, so it is important to consider patient hydration status before and during the flight **FIGURE 4-12**.

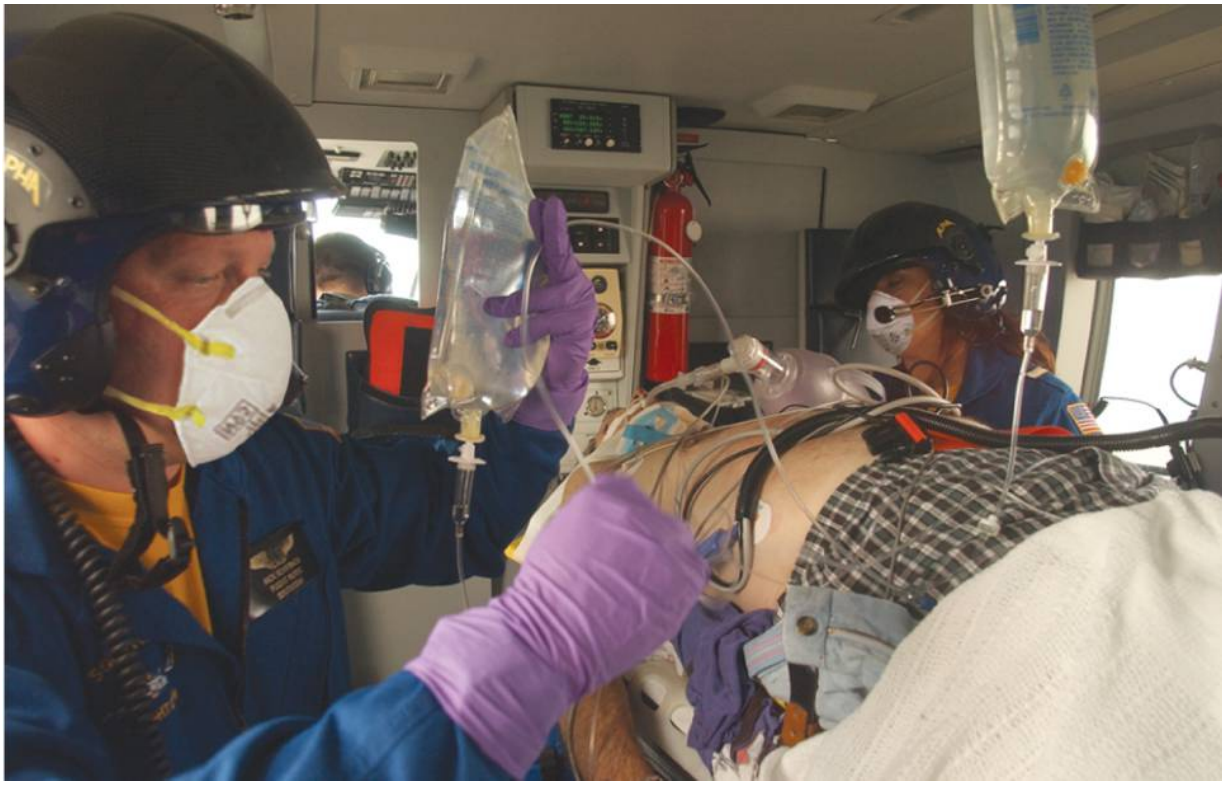

FIGURE 4-12 Proper hydration should be provided for all patients transported by air.

© Mark C. Ide.

Patients who are receiving supplemental oxygen are at twice the risk of becoming dehydrated. If available, humidified oxygen should be used during air transports. The dry air in the aircraft can also cause drying of the cornea in unconscious or intubated patients if their eyes are not protected by taping or using artificial tears. In addition, owing to the relatively dry environment, consideration should be given to increasing the rate of intravenous (IV) fluids or providing additional oral hydration, if possible. To combat the effects of decreased humidity, crew members are encouraged to increase their fluid intake.

Noise

Noise is defined as any unwanted sound. Long exposure to noise can damage the soft tissues of the inner ear. The cells and nerves in the inner ear may be completely destroyed by continuous exposure to loud sounds. If enough cells are damaged, hearing is permanently damaged.

One of the biggest problems with damage caused by noise involves the subtle symptoms of hearing loss. Hearing loss usually manifests as feelings of pressure or fullness in the ears, muffled speech, or ringing in the ears. These symptoms may go away within minutes, hours, or days after the exposure or, depending on the damage, may never go away.

To determine how noise will affect hearing, three factors must be considered: loudness, pitch, and duration of exposure. It was once thought that only extremely high sound levels produce hearing loss; however, cumulative exposure to levels around 70 decibels from A-weighted noise-monitoring equipment (dBA) without protection have been shown to lead to irreversible hearing loss **TABLE 4-2**. Sound at 140 dB causes pain and indicates danger of immediate hearing loss.

TABLE 4-2 | Noise Exposure Without Hearing Protection That Leads to Irreversible Hearing Loss

Sound	Decibel Level (dBA)[a]	Time of Exposure
Whispering	20	No limit
Normal conversation	60	No limit
Car	70	No limit
Diesel truck, jackhammer	100	2 h
Helicopter	105	1 h

Sound	Decibel Level (dBA)[a]	Time of Exposure
Live rock music	90–130	8 h at 90 dB, but imminent hearing loss at 130 dB
Propeller aircraft	120	7 min
Jet aircraft	140	Imminent hearing loss at any length of exposure

[a] dBA refers to noise levels from the A-weighted noise-monitoring equipment used in noise studies to filter noises so they are more similar to how they would be interpreted by the human ear.

© Jones & Bartlett Learning.

Noise in the cabin of the aircraft can make it difficult for patients and care providers to communicate, which can lead to patient anxiety. The noise also makes it difficult for CCTPs to assess heart and lung sounds. Many monitoring errors and malfunctions can be attributed to the noise and vibrations associated with air medical transport. Assessment techniques such as pulse oximetry, capnography, and hemodynamic monitoring are less affected by noise and vibrations and help enable early recognition of complications.

To preserve the hearing of patients and accompanying family members, CCTPs must remember to provide them with appropriate hearing protection for the flight. In addition, CCTPs and other flight crew members must protect their own hearing. Many employers require aircraft personnel to wear hearing protection to limit the effects of noise in the aircraft.

Crew members who work in the aircraft environment must be very attentive to the potential for hearing loss. They should be required to wear hearing protection approved by the American National Standards Institute whenever they are operating around an aircraft that is running.

All crew members working inside a rotor-wing aircraft should always wear hearing protection. Oftentimes this protection is accomplished by wearing a helmet with an internal communication system. Many crew members elect to wear soft hearing protection under their helmets as a secondary means of protection. Rotor-wing programs that do not use helmets should require use of headsets at all times. Not only do the helmets and headsets protect personnel from noise, but they also facilitate communication between crew members.

Crew members who operate on fixed-wing aircraft may or may not be required to have hearing protection inside the aircraft. Hearing protection depends on the type of aircraft (propeller versus jet) and the individual aircraft design. Generally speaking, larger aircraft will have better sound insulation and will not require the use of hearing protection inside the aircraft.

Fatigue

Fatigue involves much more than simply the lack of sleep; however, lack of sleep is the foundation for fatigue. Most physiologic problems encountered in the flight environment can cause significant fatigue, and their effects can quickly pile up when combined with a lack of restful sleep. Studies conducted by the **Federal Aviation Administration (FAA)** and the **National Transportation Safety Board (NTSB)** have noted that crew fatigue is often a contributing factor in aviation accidents and near misses.

Many flight crew members begin their shift already tired. Indeed, studies have shown that more than 50% of flight personnel are chronically fatigued because of long work hours. Air medical crew members most commonly work 12- or 24-hour shifts, but most pilots are limited by federal regulations to a maximum of 8 flight hours in any 24-hour period and are required to have at least 8 hours of uninterrupted rest. Most companies and flight crews do not rely on government agencies to police their duty time; instead, they impose more stringent requirements on themselves.

In addition to lack of sleep, three other factors contribute to crew fatigue: jet lag, vibration of the aircraft, and poor diet, which often includes missed meals due to the very nature of air medical transport. Jet lag is a factor leading to fatigue that is encountered in the fixed-wing environment, but not the rotor-wing environment. When flight crew travel across time zones, their bodies require time to adjust to the new time zone. Studies have shown that it takes 1 day for each hour of difference from the original time zone to reset the body's own circadian rhythm.

It is not uncommon for CCTPs to experience fatigue while flying, but the real challenge arises when CCTPs are required to maintain competency while caring for critically ill or injured patients during flights. Fatigue causes delayed reaction time, thereby increasing the risk of error. To minimize these risks, the Commission on Accreditation of Medical Transport Services emphasizes measures such as providing for crew rest and ensuring that duty days are not excessive. To avoid beginning another flight in a fatigued state, CCTPs should immediately request crew rest as soon as they feel fatigued. This request must be granted and typically lasts for 4 hours, occurring between flights. At the end of the 4 hours, a CCTP is reassessed to determine fitness for duty.

Gravitational Forces

The body's response to **gravitational forces** is affected by the intensity of the effect of acceleration, its direction, the length of time the body is subjected to stress, the time it takes for gravity's effects to appear, and the individual's unique physical makeup. Although this effect is termed gravitational force, it is actually rapid acceleration or deceleration, not gravity, that affects the body. One unit of gravitational force (informally referred to as *g*-force: 10*g*, for example) is equal to the weight of the object. The gravitational force experienced is multiplied by the person's weight to determine the actual force on the body. For example, a 100-pound (45.4-kg) person who experiences 10*g* will have 1,000 pounds (454 kg) of force on their body.

Two types of gravitational forces can be experienced. Negative gravitational forces result from a steep dive in an aircraft. Positive gravitational forces result from high-speed acceleration, climbs, or high-speed turns. Positive gravitational forces push blood away from the brain, whereas negative gravitational forces push blood toward the brain. Most humans can survive a greater degree of positive gravitational force than negative gravitational force.

Gravitational forces can have significant effects on the human body. The first physiologic sensation of gravitational force is the feeling of being pushed down in a seat or feeling weightless, depending on whether the aircraft is accelerating or decelerating. As the gravitational force increases, breathing becomes labored. Acceleration compresses the rib cage and lungs, making it difficult to draw in air or exhale and potentially resulting in exhaustion and air hunger. Hypoxia arises when gravitational force causes blood to leave the brain (eg, during a high-speed acceleration or turn) and move into the lower extremities. The body must then work much harder to circulate blood to the brain. Hypoxia can result in a loss of peripheral vision when the body is subjected to gravitational forces of 5*g* to 6*g*. As the gravitational force continues, tunnel vision develops, and eventually vision becomes gray (loss of color perception). Further exposure to acceleration stress will cause a person to experience blackout: a loss of all vision. During this time, the organs are displaced downward, significantly affecting blood flow. If the gravitational force continues, the flight crew member will lose consciousness (also called gravitational force loss of consciousness, or gravitational force–induced loss of consciousness). Other signs and symptoms include petechiae, rashes, and bruising; loss of consciousness with accompanying seizures, amnesia and confusion; and cardiac arrhythmias (tachycardia and bradycardia), heart blocks, and stress cardiomyopathy.

Several factors are known to decrease tolerance to positive gravitational force during acceleration. Age can play an important role in determining the extent to which a person may be affected by acceleration. People older than 60 years, for example, have a diminished tolerance for gravitational forces. Infection and illness, resulting in fever and dehydration, also increase the body’s susceptibility to the effects of gravitational forces. A person with hypoglycemia will lose consciousness, under acceleration stress, 0.5*g* earlier than someone with a higher, normal blood glucose level.

Alcohol consumption will cause a person to feel effects 0.1*g* to 0.4*g* sooner.

Spatial Disorientation and Illusions of Flight

A key concept in flight physiology is spatial orientation, which is the ability to use the senses to orient oneself to the surroundings. In flight, specific movements or situations may result in **spatial disorientation**, a condition in which the person has an incorrect understanding of their body's position with respect to the earth.

To maintain spatial orientation on the ground, three components come into play: effective perception; integration; and interpretation of visual, **vestibular**, and **proprioceptive** sensory information. Vestibular sensory information comes from the organs of equilibrium located in the inner ear. Proprioceptive sensory information is obtained from the skin, muscles, tendons, and joints. The brain recognizes changes in linear acceleration, angular acceleration, and gravity and attempts to relate them to the visual input. In flight, spatial orientation is difficult to achieve because of conflicting sensory input. When visual, vestibular, and proprioceptive sensory stimuli provide conflicting information, a sensory mismatch occurs and results in illusions and spatial disorientation.

Of all of these senses and stimuli, visual reference provides approximately 90% of the information needed to maintain spatial orientation. This dominant source of input will overpower conflicting sensations from other systems, such that people seldom realize when the brain has received contradictory information. Learning not to rely on visual reference is an important factor for pilots who are flying by instruments. Indeed, a great deal of time during instrument training is spent convincing students to trust the instruments and not their senses. The senses may provide invalid information because the brain is convinced that "down" is the bottom of the aircraft, no matter the aircraft's actual position or angle.

All of the illusions discussed in this section result from vestibular ear disorders. As a consequence, these illusions can also cause significant nausea and vomiting, further debilitating the flight crew.

According to the FAA, spatial disorientation is responsible for 5% to 10% of all general aviation crashes, and crashes resulting from spatial disorientation are usually fatal (90%).

Types of Spatial Disorientation

Spatial disorientation has been studied extensively by both military and civilian organizations. Spatial disorientation is divided into three types:

- **Type I spatial disorientation** occurs when the pilot does not notice that spatial disorientation is occurring because the senses confirm that the pilot's experience is real. A flight crew member who does not sense danger will not respond to the disorientation. This is a potentially deadly type of disorientation, because it can lead to a crash. A pilot experiencing type I spatial disorientation may fly directly toward the earth without realizing where the aircraft is headed.
- **Type II spatial disorientation** occurs when the pilot initially does not recognize the onset of spatial disorientation, but senses that something is wrong. Usually the pilot will misinterpret the problem as an instrument malfunction and trust their own senses instead of relying on the instruments. For example, during gradual banking and descent, the pilot may sense the descent but not the bank and may attempt to gain altitude. The attempt to gain altitude actually increases the rate of the bank until the aircraft spirals out of control. Fortunately, such a graveyard spiral is a rare occurrence.
- **Type III spatial disorientation** occurs when the pilot is affected by the illusion of intense movement and is unable to regain spatial awareness. Usually when one person is affected this way, the other generally is not, and the correctly oriented person (the copilot) can steer the aircraft to safety.

Since John F. Kennedy, Jr.'s fatal crash in 1999, the FAA has revised several rules regarding recognition of and training for spatial disorientation. Currently, even initial private pilot applicants must receive at least 3 hours of instrument training and be taught recovery techniques, and most instructors include the topic of spatial disorientation during recurrent training.

Visual Illusions

The visual system can give deceptive signals to the brain, especially during instrument meteorological conditions, such as when flying in clouds or low visibility. These illusions can lead to misperceptions about location, altitude, distance away from other aircraft or objects, the rate of speed as the aircraft closes in on other objects, and attitude. For example, a **somatogravic illusion** is an error in perception that occurs with acceleration, as the otolith organs are displaced rearward, similar to when a person is looking up. This perception of a nose-up altitude may cause the pilot to push the nose of the aircraft down inappropriately at night or in unlit terrain. Flight crew members need to have a good understanding of such visual illusions to prevent and recognize potentially disastrous situations. These situations are potentially lethal but extremely rare.

Third Spacing

Third spacing, loss of fluids from the intravascular space into the tissues, became a factor in aviation at the end of World War II. The German Luftwaffe encountered this phenomenon after they developed the first jet-powered aircraft. It became evident that the human body was not designed for rapid acceleration and deceleration or for high-speed turns. Third spacing becomes a factor during high-speed turns because of the addition of centrifugal force in concert with the acceleration or deceleration of the aircraft. These forces actually began to push fluids (primarily plasma) from the intravascular space into the extravascular space, causing hypovolemia and potentiating hypoxia.

To counteract the effects of third spacing, the “*g*-suit” or military antishock trousers (MAST pants) were developed. The first *g*-suits were tightly laced suits that were similar to corsets. Aviators donned these suits and then tightened the laces to help counteract third spacing. Subsequent suits were designed to recognize high-gravitational-force maneuvers and automatically inflate to apply circumferential pressure on body tissues, thereby helping prevent plasma from leaching into the extravascular space. Today, in most aircraft that will experience high-gravitational-force maneuvers, the flight team is equipped with pressure suits and trained in techniques to prevent them from experiencing third spacing.

Flicker Vertigo

Flicker vertigo is defined by the Flight Safety Foundation as “an imbalance in brain cell activity caused by exposure to low-frequency flickering (or flashing) of a relative bright light.” The effects of flicker vertigo may include nausea, vomiting, seizures, or fainting. These symptoms are usually mild and stop as soon as the source of the flickering is removed. This condition can be brought about by any bright light flickering at a frequency of 4 to 20 cycles per second (hertz [Hz]). Helicopter personnel are most often affected by flicker vertigo when natural light or reflections of anticollision strobe lights are distorted by the aircraft’s rotor blades. This same phenomenon is possible in fixed-wing propeller aircraft. A rotating beacon can also cause flicker vertigo. If the propellers are the trigger for flicker vertigo, simply changing the revolutions per minute of the engine can often eliminate the symptoms; if strobe lights while in clouds are the cause, they can be turned off until the aircraft is in clear skies.

Fuel Vapors

Flight crew members and patients alike are exposed to the noxious odors of fuel vapors during air transport. Most of this exposure occurs when the flight crew is loading or unloading a patient. The jet fuel odors can cause headaches and precipitate feelings of nausea, if prolonged. The flight crew is more susceptible to these effects than is the patient, because the crew has more prolonged exposure to them.

Weather

Weather can be an additional stressor. For example, rapidly worsening conditions or inadvertent flight into conditions that require the use of instrument flight rules cause stress. Transport programs that operate by visual flight rules (discussed in detail later) fly only in conditions that meet a visibility minimum of 3 miles (5 km) and appropriate clearance from clouds. Transport programs rated for instrument flight rules can fly in all but the worst of weather. The vast majority of rotor-wing programs operate under visual flight rules only because the pilots often must land the aircraft at unimproved sites (ie, sites that are not paved). Pilots undergo extensive training intended to ensure that they can quickly handle changing weather conditions.

Anxiety

Anxiety has a pivotal role in flight operations but is rarely addressed or discussed; it is often assumed to have been covered in the initial crew training. Several factors can cause anxiety. Numerous studies have shown that catecholamine release occurs in both flight crew members and patients during rotor-wing operations. Even among experienced flight crew members, a significant release of adrenaline, a catecholamine, occurs. This release of catecholamines can be advantageous to performance if it occurs in small quantities, but detrimental if large quantities flood the body.

For new flight nurses and paramedics, the learning curve related to air medical transport is exceptionally steep. These professionals must be adept at treating patients with the most critical conditions (traumatic and medical) and of all age ranges. Initially, all new flight crew members can be expected to have a high level of anxiety until they have gained experience transporting patients with a range of conditions during different types of flights.

Anxiety can occur in patients as well as the crew. Patients who express concern about the tight confines of the aircraft may be pretreated with anxiolytics **FIGURE 4-13**. Administration is based on individual protocols and patient presentation.

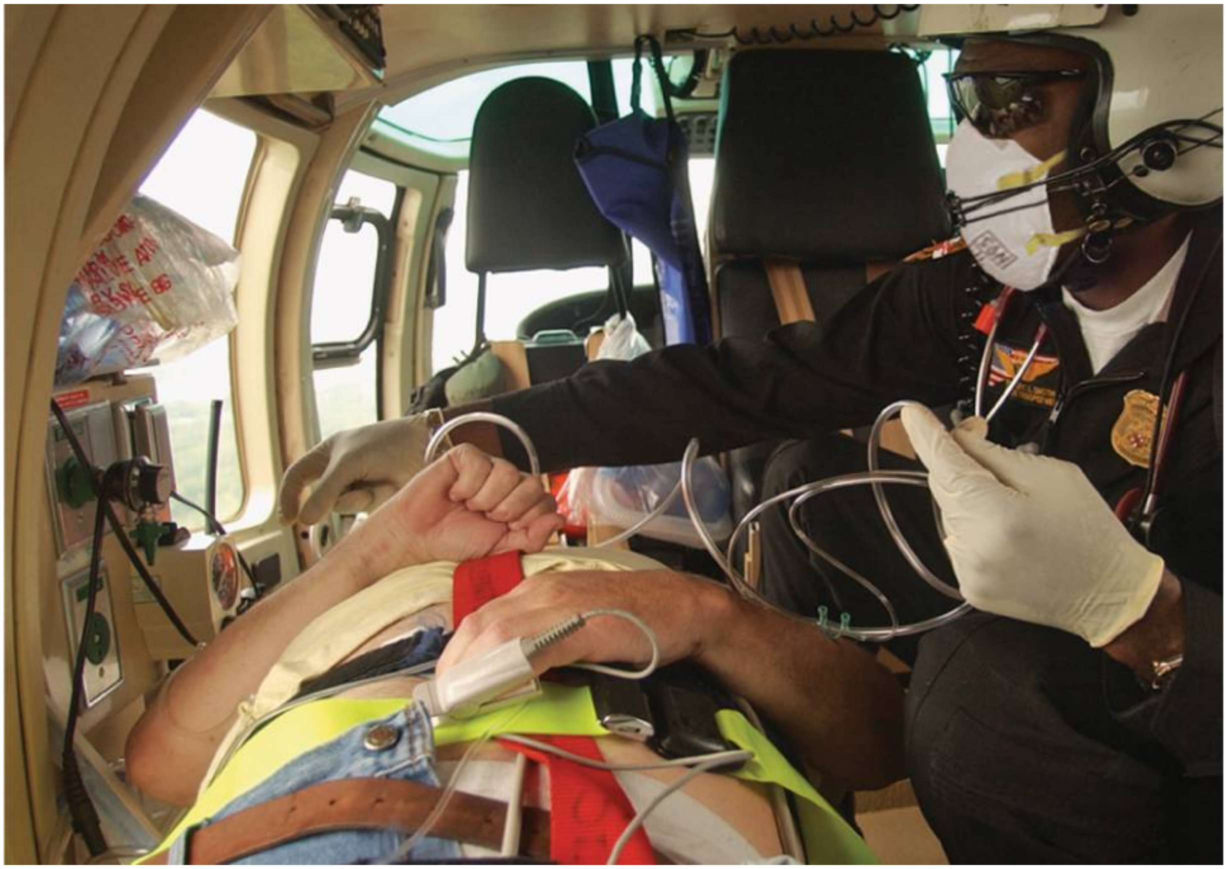

FIGURE 4-13 Aircraft cabins are very small, which can lead to anxiety on the part of patients and CCTPs.

© Mark C. Ide.

Night Flying

Crew members must be vigilant in assisting the pilot in scanning for other aircraft when able to do so, both at night and during the day. Fortunately, due to their lighting systems, aircraft are often easier to spot at night. Lights on airplanes indicate the direction of flight: From the seat of the aircraft being flown, the green light is on the right wing, the red light is on the left wing, and a white light is displayed to the rear. Because the positioning of lights on all aircraft adheres to this standard, it is easy to determine the direction of flight at night **FIGURE 4-14**. For example, when pilots in an aircraft see another aircraft with a red light on the left, a green light on the right, and a white light in the middle, they know that the aircraft is moving away.

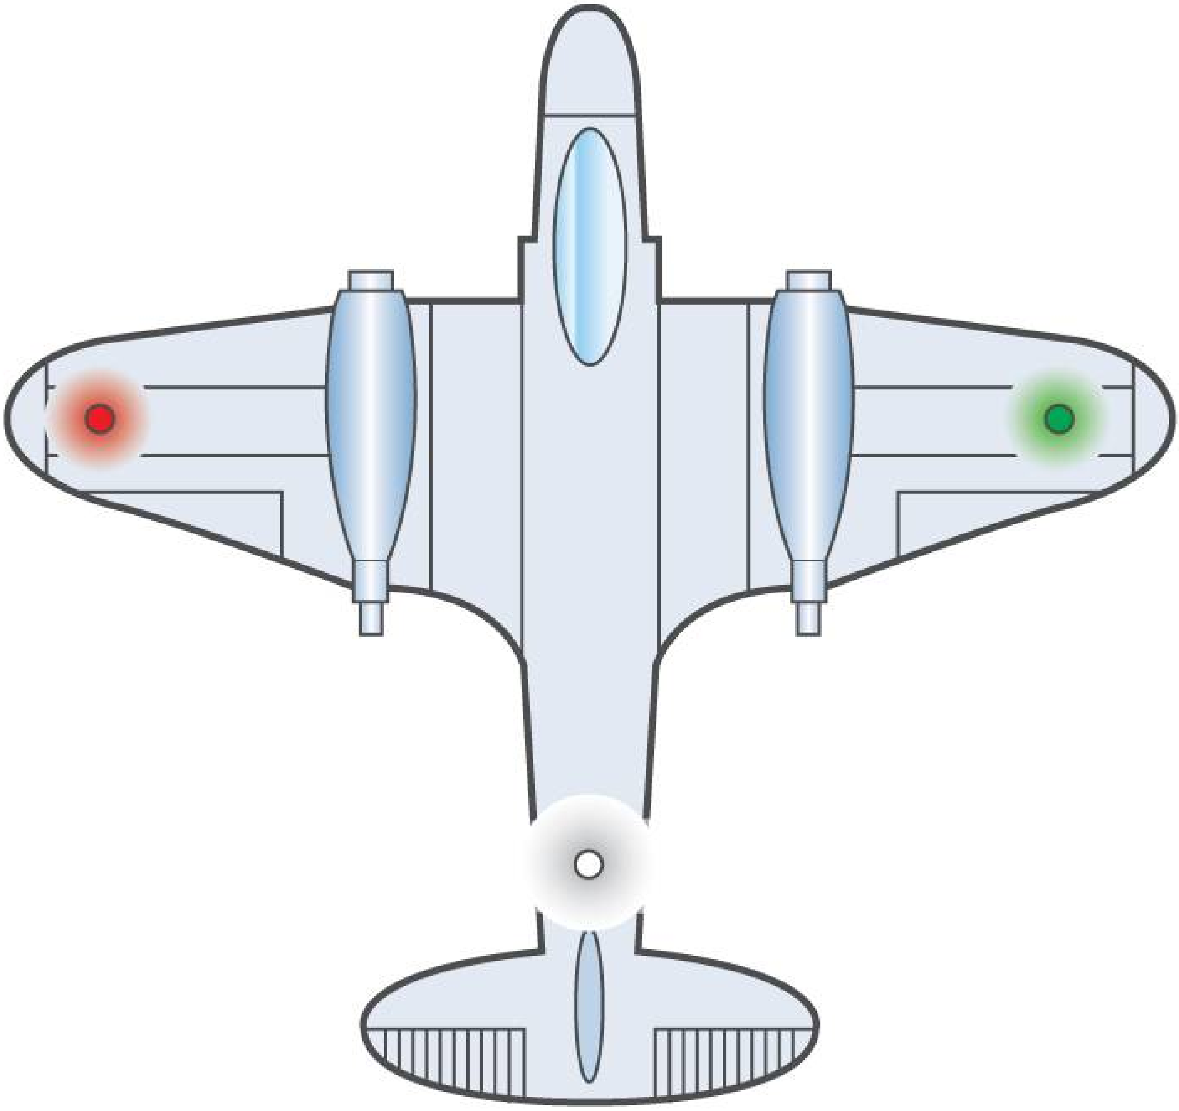

FIGURE 4-14 An aircraft's lights are set up in a standard format that makes it possible to determine the aircraft's direction of flight.

© Jones & Bartlett Learning.

Crew members should reduce use of white light that may affect the pilot's night vision. Red lighting inside the aircraft is preferred.

The pilot and crew face other challenges in night flights. For instance, the crew has severely limited outside visibility. The pilot has the following disadvantages:

- Limited field of vision (reduced by 40% due to night-vision goggles, if used)
- Added weight stress from the helmet
- Loss of depth perception
- Monochromatic vision
- A reduced sense of speed

Factors Affecting Tolerance of the Physiologic Stressors of Flight

The primary human factors affecting the provider’s tolerance of the stressors of flight can be remembered by the mnemonic IM SAFE, which stands for Illness, Medication, Stress, Alcohol, Fatigue, and Emotion. Other human factors, such as tobacco use and hypoglycemia, also affect stress tolerance and are important considerations in assessing flight fitness.

In flight medicine, there are two types of altitude: physical altitude, which is represented in feet above ground, and physiologic altitude, which is the altitude *perceived* by the body. Although incapacitation to altitude does not begin to manifest until 10,000 feet of physical altitude, the body may perceive itself as being at a much higher altitude, possibly thousands of feet higher, because of human factors. The person may function as if at this higher altitude despite the seemingly “safe” physical altitude.

Illness

Many illnesses, even the common cold, can significantly impair a crew member’s performance. Nasal congestion can lead to severe headaches, vertigo, or nausea during pressure changes, such as during a rapid descent. All flight crew members should be cleared to fly by a physician during any period of illness.

Medications

The use of medications affects the tolerance of hypoxia. Over-the-counter (OTC) medications, although frequently considered benign, can result in incapacitation when their effects are combined with the effects of hypoxia. In addition, an underlying problem might go untreated because OTC medications can mask the problem. All flight crew members should follow approved lists for OTC medications before they fly, or consult with a **flight surgeon** or a physician knowledgeable in flight medicine, such as an aviation medical examiner, before taking any medications when they are scheduled to work.

The FAA has published a list of approved prescription and OTC medications that flight crew members are permitted to use. In 14 CFR Part 61, the FAA states that pilots assume responsibility for all medications they take and that if there is any doubt about the effect of the medication on the ability to fly, they must consult with a flight surgeon before flying. All flight crew members should be strongly cautioned against taking a medication for the first time when they are working because they cannot know how their body will react to the medication.

Stress

Most pilots and flight crew cannot simply "leave stress on the ground." Everyday stresses such as work, financial, and family issues can affect performance negatively and can lead to distraction and poor judgment. If crew members are experiencing high levels of stress, they should be encouraged to discuss this situation with members of management at their program. High levels of stress can cause inattentiveness and may have adverse effects on performance, including catastrophic effects in the aviation environment. If crew members recognize high levels of stress in their coworkers, they should take action to ensure the safety and effective operation of the program.

Alcohol

Alcohol can be a toxin in the body and can result in **histotoxic hypoxia**, inhibiting the use of available oxygen by hemoglobin and delaying metabolism at the cellular level. Research indicates that the intake of 1 ounce (30 mL) of alcohol is equivalent to 2,000 feet of physiologic altitude. Simply drinking two beers can add between 4,000 and 8,000 feet of physiologic altitude. Alcohol works by depressing the central nervous system and inhibiting judgment and coordination, further amplifying the effects of altitude. Part 91 of 14 CFR clearly addresses the topic of alcohol. It reads as follows:

1. No person may act or attempt to act as a crewmember of a civil aircraft—
   1. Within 8 hours after the consumption of any alcoholic beverage;
   2. While under the influence of alcohol;
   3. While using any drug that affects the person's faculties in any way contrary to safety; or
   4. While having an alcohol concentration of 0.04 or greater in a blood or breath specimen. Alcohol concentration means grams of alcohol per deciliter of blood or grams of alcohol per 210 liters of breath.

Most aviation companies have a 12-hour "bottle to throttle" policy; however, all policies are underscored by the caveat that people who feel under the influence of alcohol, regardless of the time from the last drink, should not fly. Parts 91 and 135 of 14 CFR also state that all flight crew members are subject to random drug and alcohol tests at any time while on duty.

Regardless of whether the service's policy calls for maintaining 8 or 12 hours between drinking alcohol and flying, another significant hazard is the hangover, or post-alcohol impairment, associated with drinking. Physical and mental performance is still markedly reduced 14 to 24 hours after the blood alcohol level has returned to zero. One of the most dangerous problems during the hangover phase is the propensity for hypoglycemia and significant fatigue. Despite the frequent claims made about OTC medications, there is no simple remedy for hangovers.

Fatigue

Exhaustion and fatigue play important roles in an individual's ability to tolerate the effects of hypoxia. Shift work causes a tremendous disruption in the circadian rhythm, making it difficult for crew members to regulate their sleep at work and at home. Many air medical crew members also work second jobs during their time off and must be careful to allow for plenty of rest before the start of their flight shifts. Exhaustion can lead to errors in judgment, narrowed attention, uncharacteristic behavior, and falling asleep at work. Crew members who find that they need to use pharmacologic sleeping aids need to first have the medication approved by a flight surgeon. Frequent use of sleeping aids should be considered a flight safety issue and discussed in depth with a flight surgeon.

Emotion

Certain emotionally upsetting events, such as major arguments, a death in the family, and divorce, can significantly impair pilot and crew performance. Any pilot or crew member who experiences an intense emotional event should not fly until satisfactory resolution of that incident occurs.

Tobacco

An aviator who smokes risks incurring the effects of hypemic hypoxia, because carbon monoxide is 50 to 300 times more strongly attracted to hemoglobin than to oxygen. **Hypemic hypoxia** is caused by a decrease in the blood's oxygen-carrying capacity due to a reduced amount of hemoglobin in the blood or a reduced number of red blood cells. Research has shown that smoking 3 cigarettes in rapid succession or smoking 20 to 30 cigarettes in a 24-hour period can saturate 10% of the hemoglobin in the body. Consequently, at sea level, a regular smoker has a starting physiologic altitude of 3,000 to 8,000 feet, even before the aircraft takes off. Smoking also affects night vision; a regular smoker has already lost 20% of the night vision, even at sea level.

Hypoglycemia

A nutritious diet allows flight crew members to be much more tolerant of the effects of hypoxia. Poor diet and low blood glucose levels can cause nausea, headache, dizziness, shakiness, nervousness, and judgment errors. Also, not eating anything or eating foods high in sugar and fat or cooked in grease can precipitate the effects of motion sickness. A good way to prevent the effects of motion sickness is to eat several small meals or to regularly snack on healthy foods during the shift. A lack of food in the stomach can cause nausea and exacerbate motion sickness.

All flight team members should be encouraged to maintain a healthy weight. Obesity can cause many problems in the flight environment and can be detrimental to the overall safety and performance of the overweight flight crew member. In addition, most rotor-wing flight programs have a weight limit for crew members.

Additional Stressors

In addition to the aforementioned stressors, several others may affect crew members' effectiveness during air medical transport. Age is an important factor: As the body ages, its ability to compensate for stress declines. Good physical conditioning is also important for flight crew members. Physical exertion during flight significantly lowers the altitude at which evolved gas disorders occur. Physical exertion increases oxygen demand, increasing the risk for hypoxia. Maintaining good physical conditioning can help to increase this threshold.

Hypoxia

Hypoxia is a major hazard in aviation that can have catastrophic results. This physiologic effect can occur in otherwise healthy people at altitudes less than 10,000 feet, but can greatly affect patients with impaired pulmonary function at much lower altitudes.

A common misconception in aviation is that a person can readily recognize the early signs of hypoxia and take immediate corrective actions. This misconception is dangerous and can be deadly. In fact, one of the earliest effects of hypoxia is impaired judgment. This impaired judgment can limit flight crew members' ability to recognize hypoxia and, consequently, their ability to take immediate corrective actions. Numerous aircraft crashes have documented aircrews responding to hypoxic events with inappropriate and dangerous actions. Also, early hypoxia mimics fatigue and hypoglycemia, making it difficult to recognize. Fatigue and hunger contribute to hypoxia as well.

Effective Performance Time and Time of Useful Consciousness

There is a limit to how long a person can function with an inadequate level of oxygen. This limited span of time is called **effective performance time** **TABLE 4-3**. In contrast, the **time of useful consciousness** is the period between a person's sudden deprivation of oxygen at a given altitude and the onset of physical or mental impairment to the point that deliberate function is lost.

TABLE 4-3 **Relationship Between Effective Performance Time and Altitude**

Altitude (ft)	**Effective Performance Time (Standard Ascent Rate)**	**Effective Performance Time (After Sudden Decompression)**
18,000	20–30 min	10–15 min
22,000	8–10 min	5 min
25,000	4–6 min	1.5–3.5 min
35,000	30–60 s	15–30 s
43,000	9–12 s	5 s
> 50,000	9–12 s	5 s

Data from Federal Aviation Administration.

The times in Table 4-3 are based on experiments conducted with healthy military volunteers in a standard altitude chamber. The effective performance time and time of useful consciousness will vary for each person and depend on individual tolerances, the method of hypoxia induction, and the environment before hypoxia. Any exercise will reduce these times considerably. For example, on exposure to hypoxia at 25,000 feet, the average person has a time of useful consciousness of 3 to 5 minutes. The same person, after performing 10 deep knee bends, will have a time of useful consciousness in the range of 1 to 1.5 minutes. Also, an aircrew member who was breathing 100% oxygen before the onset of hypoxia will have a longer period of compensation than an aircrew member who was breathing ambient air.

Rapid cabin depressurization also dramatically affects the effective performance time and the time of useful consciousness. When aircraft cabin decompression occurs above 33,000 feet, oxygen flow in the alveoli is immediately reversed. A higher PaO_2 in the pulmonary capillaries occurs, causing the oxygen reserves in the blood to become depleted and reducing the effective performance time by as much as one-half. The time of useful consciousness varies from 5 minutes to 1 minute; however, if the crew is subjected to rapid depressurization, this period may last only a matter of seconds. A **rapid decompression** can reduce the time of useful consciousness by as much as 50% because of the forced exhalation of the lungs during decompression or during an extremely rapid ascent.

Another common misconception regarding hypoxia is that individuals living at higher altitudes do not require supplemental oxygen to function effectively at more extreme heights. In reality, although these individuals may have adapted to their environment to some extent, the physiologic changes in their bodies do not afford the level of protection that most assume. Living at higher altitudes causes the body to produce red blood cells at a faster rate, facilitating oxygen transport. A slight physiologic advantage exists; however, an aircrew member who, for example, lives at 5,000 feet may be able to fly 1,000 to 2,000 feet above the 10,000-feet recommended ceiling without ill effects, but this tolerance is not extended to an additional 5,000 feet.

Types of Hypoxia

Hypoxic Hypoxia

Hypoxic hypoxia (also referred to as altitude hypoxia) results from inadequate respiration or a reduction in PO_2 and is characterized by a lack of oxygen entering the blood **FIGURE 4-15**. Hypoxic hypoxia can have a variety of causes, including lung disease, right-to-left shunt in the heart, airway obstruction, a reduction in gas exchange area in the alveoli, and a low PO_2. Increased altitude also leads to hypoxic hypoxia.

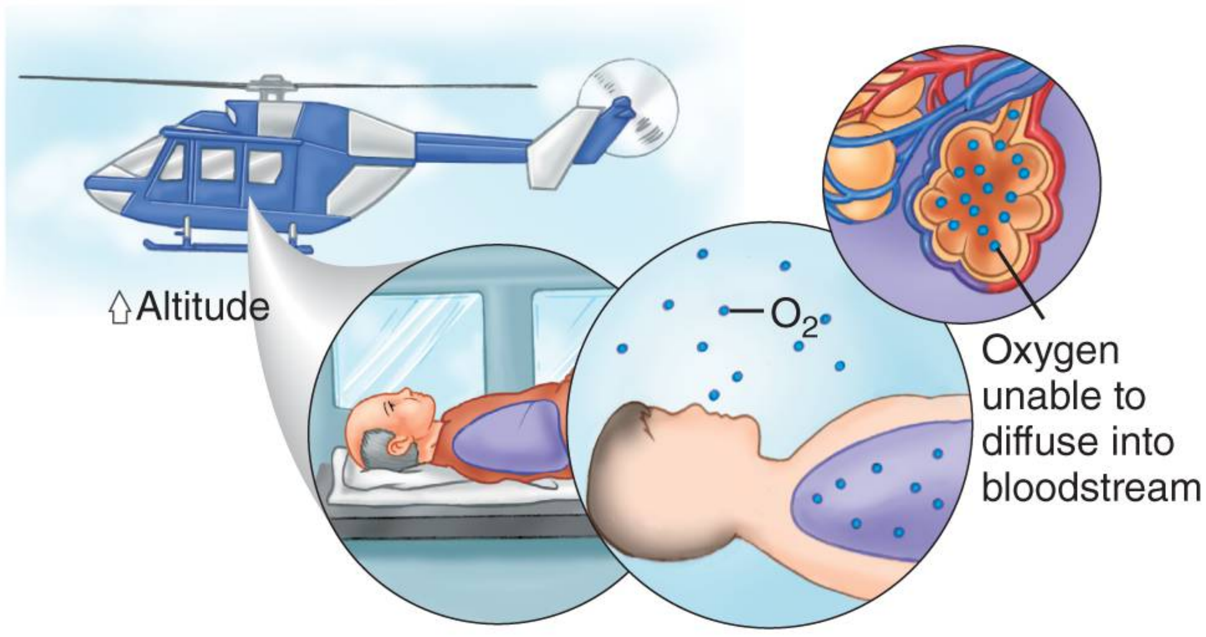

FIGURE 4-15 Hypoxic hypoxia results from a lack of oxygen or an inability of oxygen (O_2) to diffuse into the bloodstream.

© Jones & Bartlett Learning.

Description

In the air medical environment, personnel will most likely encounter this condition as a result of reduced atmospheric pressure that causes a reduced alveolar PaO_2. Simply put, there is not enough oxygen available in an inspired breath at higher altitudes owing to decreased PO_2. Clinical hypoxia actually starts to develop within a few hundred feet from the ground; however, symptoms do not begin to manifest until the aircraft reaches an altitude above 5,000 feet.

Histotoxic Hypoxia

Histotoxic hypoxia is caused by the cell's inability to adequately use oxygen because of substances in the blood such as narcotics, alcohol, chewing tobacco, and other poisons. In such a case, plenty of oxygen is available, but the tissues cannot accept it, or oxygen cannot offload from the hemoglobin **FIGURE 4-16**. During histotoxic hypoxia, the venous hemoglobin oxygen saturation is higher than normal because the oxygen is not being unloaded to the tissues, a situation that arises because the tissues are unable to metabolize the delivered oxygen. This type of hypoxia is the most frequently encountered by aircrew members in flight.

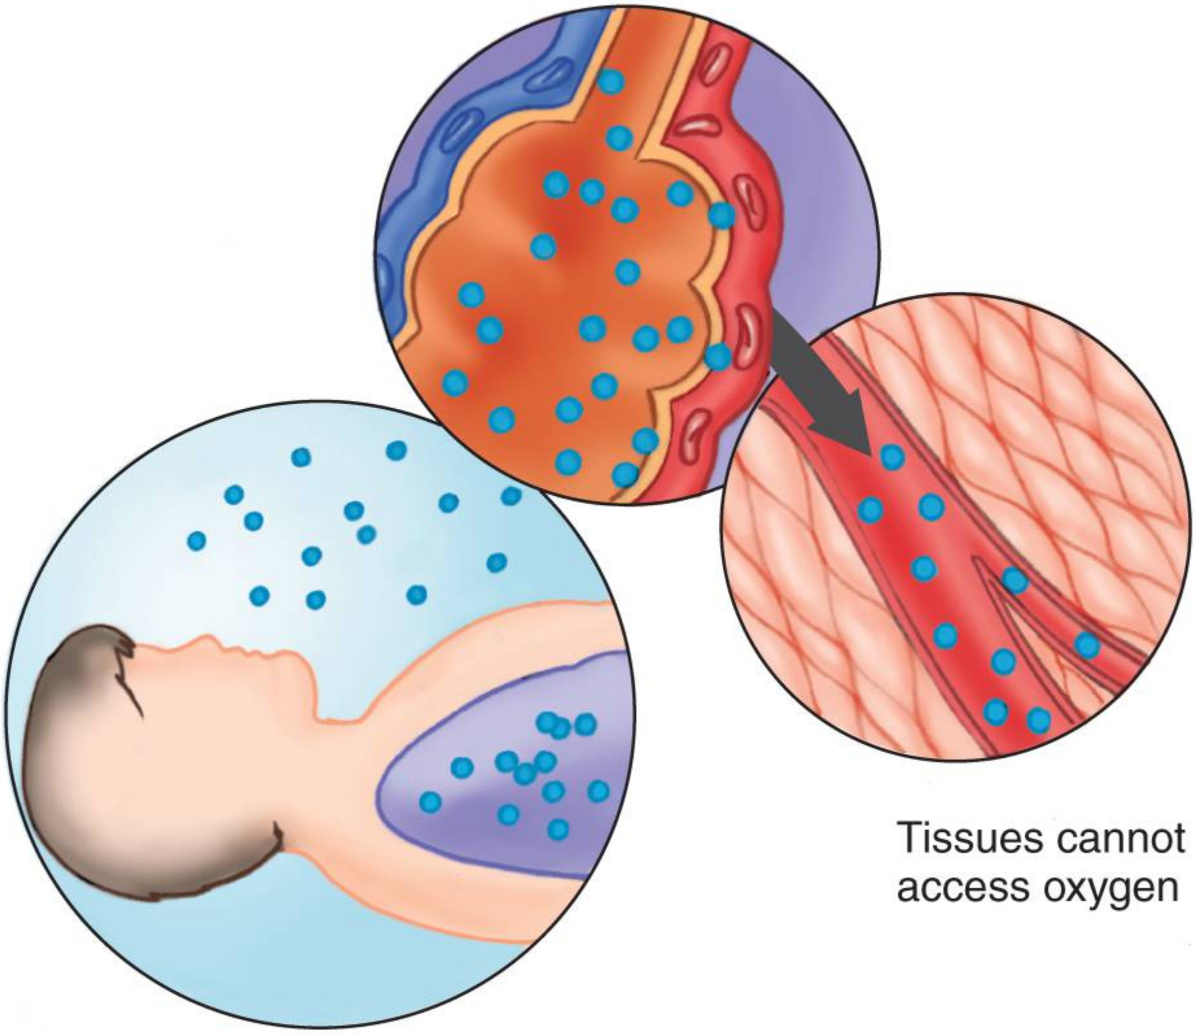

FIGURE 4-16 In histotoxic hypoxia, plenty of oxygen is available and can bind to the hemoglobin, but the tissues cannot access it.

© Jones & Bartlett Learning.

Stagnant Hypoxia

Stagnant hypoxia occurs when there is failure to transport oxygenated blood. This form of hypoxia occurs when the flow of blood is reduced, but not necessarily completely stopped **FIGURE 4-17**. Outside of the aviation environment, this condition is frequently seen in patients with heart failure and major MIs. In flight medicine, stagnant hypoxia can result from venous pooling in the patient during accelerated maneuvers, such as steep turns and other maneuvers that increase the gravitational load on the aircraft. Another practical example is blood pooling in the lower extremities of patients and crew members who sit in an aircraft for extended periods.

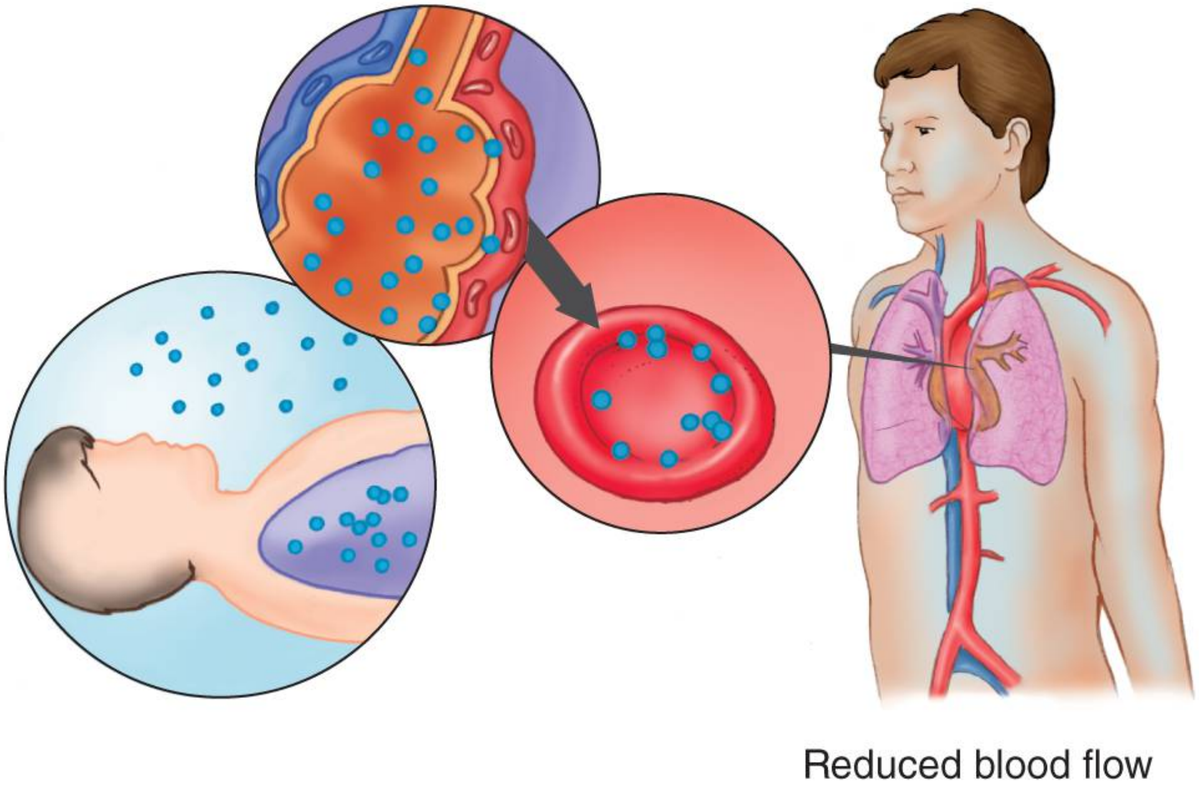

FIGURE 4-17 In stagnant hypoxia, there is a failure to transport oxygenated blood.

© Jones & Bartlett Learning.

Hypemic Hypoxia

Hypemic hypoxia (also known as anemic hypoxia) occurs when too few functional hemoglobin molecules are present (eg, with exposure to chemicals such as carbon monoxide or in sickle cell disease) or a lack of red blood cells (eg, with hemorrhage or anemia) diminishes the blood's ability to carry oxygen to the tissues **FIGURE 4-18**. In such a case, oxygen is abundant but it cannot bind to hemoglobin because the amount of functional hemoglobin is insufficient. Blood loss and anemia are the two most common causes of this condition. Excessive smoking is a major cause as well: Smokers are susceptible to hypoxia at lower altitudes compared to nonsmokers. The blood may be completely saturated with oxygen in hypemic hypoxia; however, it is insufficient to meet the metabolic demands of the body.

Special Populations

When transporting a pregnant patient by air, oxygen supplementation should always be provided at high altitudes. Even if a pregnant woman's oxygen saturation is 100% (by pulse oximetry), the fetus may still be compromised. The pregnant patient's circulatory system will shunt all richly oxygenated blood to her own vital organs, robbing the fetus and placenta of much-needed oxygen. A normal fetal PaO_2 level is approximately 45 mm Hg (in a pregnant patient with 90% to 100% PaO_2). If a pregnant patient's PaO_2 level decreases as a result of hypoxia, the oxygen status of the fetus can quickly become compromised, because the fetus has only limited reserves.

Four Stages of Hypoxia as They Relate to Altitude

The symptoms of hypoxia can be divided into four stages directly related to the altitude, approximate barometric pressure, and the oxygen saturation of the blood: the indifferent stage, the compensatory stage, the disturbance stage, and the critical stage **TABLE 4-4**. Symptoms of hypoxia are listed in **TABLE 4-5**.

TABLE 4-4 Stages of Hypoxia

	Indifferent Stage	Compensatory Stage	Disturbance Stage	Critical Stage
Altitude (ft)	0–10,000	10,000–15,000	15,000–20,000	20,000–25,000
Oxygen saturation (%)	98–90	89–80	79–70	69–60
Symptoms	Decrease in night vision	Drowsiness Poor judgment Impaired coordination Impaired efficiency	Impaired flight control Impaired handwriting Impaired speech	Circulatory failure

Description

TABLE 4-5 Symptoms of Hypoxia

Confusion/altered mental status

Fatigue

Headache

Changes in vision acuity
- Tunnel vision
- Blurred vision and/or inability to focus
- Difficulty focusing from near to far
- Loss of night vision

Euphoria

Tingling in the hands and feet

Feelings of air hunger

Tachypnea

Cyanosis of the skin

Irregular heart rhythms

Short-term memory loss

Decreased muscular coordination

Loss of hearing

Diminished sense of pain

Diminished sense of touch and feel

Difficulty speaking; stammering

Loss of self-criticism

Overconfidence

Overly aggressive behavior

© Jones & Bartlett Learning.

Indifferent Stage

The **indifferent stage** is so named because of its minor physiologic effects on the body. This stage is typically experienced between sea level and 10,000 feet, but in some people it may manifest at altitudes as low as 5,000 feet. The mild hypoxia associated with the indifferent stage can cause night vision to deteriorate at altitudes above 5,000 feet. Recognizing this problem, the military requires fighter pilots to breathe oxygen from the ground up during night-flight operations. In addition, electrocardiographic changes have been known to occur at altitudes as low as 5,000 feet. Tachycardia is common in the indifferent stage, as is a slight increase in alveolar ventilation. Oxygen saturation in this stage varies from 98% to 87%.

Compensatory Stage

In the **compensatory stage**, the body is able to provide short-term physiologic compensation to counteract the effects of hypoxia. The extent of this compensation depends on the flight crew member's physical shape, physical activity level, and duration of exposure. In this stage, the respiratory rate and depth may increase and cardiac output increases. The compensatory stage is experienced between 10,000 feet and 15,000 feet (between 39,000 feet and 42,000 feet if breathing 100% oxygen). Hemoglobin saturation in this stage varies from 87% to 80%.

Disturbance Stage

In the **disturbance stage**, which is experienced between 15,000 and 20,000 feet, the body's tissues can no longer depend on the physiologic compensatory mechanisms for sufficient oxygen supply. Hemoglobin saturation in this stage varies from 79% to 70%. This stage is characterized by subjective and objective symptoms of hypoxia. During altitude testing, some subjects did not experience the subjective symptoms before becoming unconscious from hypoxia. In the disturbance stage, the following aspects of body functioning can be affected by hypoxia: the respiratory system, senses, mental processes, manifestations of personality, and psychomotor functions.

Senses

Vision, hearing, and sense of touch are affected during the disturbance stage. Visual ability decreases as the eye muscles become weak and uncoordinated. Sensations of touch and pain become diminished and eventually are lost. Weakness and loss of muscular coordination are experienced and become worse with a greater degree of hypoxia. This loss of muscle coordination, in conjunction with confusion, quickly becomes a deadly combination.

Cognition

One of the most dangerous hallmarks of hypoxia is the early impairment of intellect that makes it impossible for people to comprehend their own disabilities. As the cerebrum becomes hypoxic, the victim loses the ability to make coherent judgments and calculations. Reaction time becomes slower, and short-term memory is severely impaired. All of these impairments prevent the person from recognizing the ongoing effects of hypoxia.

Personality Manifestations

Hypoxia can cause the emergence of symptoms similar to those a person may exhibit while under the influence of alcohol. These symptoms include the following:

- Aggressiveness
- Euphoria
- Irritability
- Overconfidence
- Depression

Psychomotor Functions

As hypoxia is induced, muscular coordination decreases. As hypoxia progresses, muscle coordination deteriorates to levels that are incompatible with coordinated activity. The first problems manifested are speech difficulty, illegible handwriting, and poor coordination in flying the aircraft. As the degree of hypoxia increases, delicate and fine muscular movements become impossible, and gross motor movements become significantly impaired. It is interesting to note that stammering and illegible handwriting are two of the hallmark signs of typical hypoxic impairment.

Critical Stage

The last stage of hypoxia, called the **critical stage**, occurs at 20,000 feet and above (44,800 feet and above with the use of 100% oxygen). Within 3 to 5 minutes of hypo-oxygenation, judgment and coordination deteriorate to the point of inadequate or inappropriate function. In this stage, mental confusion is quickly followed by incapacitation, unconsciousness, and death, if uncorrected. Hemoglobin saturation in the critical stage drops to less than 65%.

Hyperventilation Versus Hypoxia

Hyperventilation symptoms mimic those of hypoxia, so it is critical to first address the possibility of hypoxia before assuming that the problem is caused by hyperventilation. Hyperventilation and hypoxia result in confusion, poor judgment, and inappropriate corrective maneuvers.

Hyperventilation may be caused by the subconscious reaction to a stressful situation. This reaction is manifested by an abnormal increase in the volume of inspiratory and expiratory air and by tachypnea, which results in respiratory alkalosis as the carbon dioxide is blown off. This aberration in blood gases can have serious consequences. Normal control of respiration is mediated reflexively through the chemoreceptors in the aorta and the carotid artery by arterial oxygen deficiencies. In healthy people without a hypoxic drive, ventilation rate and depth are controlled by carbon dioxide and the acid–base balance of the blood circulating through the respiratory center in the medulla. Cellular activity, in turn, is dependent on proper acid–base balance. When the pH of the blood falls out of normal range, homeostasis is interrupted in the cell, and cellular activity quickly declines or stops.

Hyperventilation leads to several important physiologic changes that begin a cascade of events. As the minute volume (tidal volume × rate) increases, the partial pressure of carbon dioxide decreases, leading to an increase in the pH of the blood. The cerebral blood vessels respond to the decreased carbon dioxide pressure by demonstrating vasoconstriction, resulting in decreased cerebral perfusion. Unconsciousness quickly follows the induction of prolonged or significant hypoxia into cerebral tissues.

Hyperventilation can cause assorted symptoms, including the following:

- Light-headedness
- Feelings of suffocation
- Drowsiness
- Tingling in the extremities
- Painful muscle spasms
- Ataxia
- Disorientation
- Unconsciousness

One of the most disastrous effects of hyperventilation is that it produces panic in the person with this condition.

Recognition and Treatment of Altitude-Induced Hypoxia

The key to quickly recognizing altitude-induced hypoxia is a thorough knowledge base and understanding of basic flight physiology. As previously mentioned, many aviators have erroneously believed that they can recognize hypoxia as it is occurring and immediately correct the problem. To be sure, recovery from hypoxia is rapid when sufficient oxygen is supplied. People who are on the precipice of unconsciousness can regain their full mental abilities within 15 seconds after receiving high-flow oxygen. In fact, studies show that a hypoxic person who rapidly breathes in 100% oxygen may experience sudden dizziness, which is quickly resolved, followed by complete restoration of function.

Prevention is the key to treatment, and avoidance of hypoxia is the key to safety. If hypoxia is detected, the flight crew must immediately use supplemental oxygen and descend to an altitude below 10,000 feet. Hypoxia in crew members is a valid reason to declare an emergency with air-traffic control (ATC).

Supplemental Oxygen Requirements

Part 135.89 of 14 CFR governs the use of supplemental oxygen by pilots and provides rules for both pressurized and nonpressurized aircraft. In nonpressurized aircraft (including helicopters), at altitudes from 10,000 to 12,000 feet, each pilot must use oxygen continuously if the duration of flight at this altitude is longer than 30 minutes. Pilots must use oxygen at all times above 12,000 feet. In a pressurized aircraft when the cabin altitude exceeds 10,000 feet, the same rule applies. At altitudes from 25,000 to 35,000 feet, each pilot must use continuous oxygen unless the aircraft is equipped with an approved quick-donning–type mask. Pilots must wear an oxygen mask continuously above 35,000 feet. More stringent rules regarding oxygen use as altitude increases are mandated because of the dramatic decrease in time of useful consciousness as distance above sea level increases; above 35,000 feet, pilots will have mere seconds to respond to a sudden loss of cabin pressure.

Passengers must be provided with supplemental oxygen as well, in accordance with 14 CFR Part 91.211. At cabin altitudes above 15,000 feet, all occupants must be provided with supplemental oxygen. In a pressurized aircraft, a 10-minute supply of oxygen must be available for each occupant if the aircraft will operate above

25,000 feet. These rules for supplemental oxygen apply to crew and nonpatient passengers only: A sick or injured patient will likely need supplemental oxygen at all altitudes to prevent hypoxia.

Dysbarism and Evolved Gas Disorders

Several disorders are directly related to altitude. Barotrauma, for example, can result from gases expanding and contracting in the body, which causes pain, usually in the digestive tract, sinuses, teeth, middle ear, or lungs. Some illnesses, such as decompression sickness, are associated with symptoms that are not fully understood. Other illnesses, such as **dysbarism**, are directly related to the effects of altitude as described by the various gas laws. Dysbarism is a syndrome resulting from a difference between the barometric pressure and the pressure of gases within the body. As gases expand at altitude, they can cause pain in closed cavities.

Barotitis Media

Barotitis media affects the middle ear and is one of the most common trapped-gas problems. A flight team member who flies with a head cold can experience substantial pain. Barotitis media results from failure of the middle ear space to equalize pressures when going from low to high atmospheric pressure. In this situation, pressure in the middle ear becomes increasingly negative, and a partial vacuum is created. As the pressure increases, the tympanic membrane is depressed inward and becomes inflamed, and a petechial hemorrhage develops. Blood and tissue fluids are drawn into the middle ear cavity. The eardrum may rupture if the pressure does not equalize.

As the barometric pressure in the aircraft cabin decreases during ascent, the air trapped in the middle ear begins to expand, pushing the eustachian tube open **FIGURE 4-19**. Air escapes through the nasal passages, and the pressure is equalized. Normally, the eustachian tubes can be opened by swallowing, yawning, tensing the muscles in the throat, or pinching the nose and attempting to blow through the nostrils. On ascent, expanding trapped air usually escapes easily, with the eardrums equalizing the pressure, which is typically felt as popping in the ears. On descent, however, it becomes much more difficult for the negative pressure inside the middle ear to equalize. As the negative pressure continues to build, the affected individual experiences loss of hearing and pain. Any type of respiratory infection can make equalization in the eustachian tube difficult or impossible. If the eustachian tubes cannot equalize pressure on descent, profound pain may be felt, and hemorrhage may occur, indicating that the eardrum is about to burst or has already ruptured. To relieve the symptoms, the pilot should ascend until the pain is relieved and equalized, then take a very slow descent so the ears can slowly equalize.

Description

Barosinusitis

Another risk to persons exposed to ambient pressure changes is **barosinusitis**, an inflammation of one or more of the paranasal sinuses resulting from a pressure gradient between the sinus cavity and atmosphere. Barosinusitis is relatively uncommon, generally affecting the frontal sinuses, and is not usually seen in children because the frontal sinus cavities are not fully mature until adolescence. Patients and providers with upper respiratory tract infections are at greater risk for barosinusitis because secretions associated with the infection tend to block the sinus ostia, interfering with pressure equalization.

The clinical presentation of barosinusitis manifests during or very shortly after exposure to barometric pressure changes as unilateral sharp facial pain and headache. A pressure like sensation may be felt in the sinuses, and occasionally individuals exhibit epistaxis.

Treatment includes pain management and decongestants. Topical decongestants such as phenylephrine nasal spray or oral decongestants such as pseudoephedrine are effective. Antihistamines should be avoided, as they tend to dry the nasal mucosa and secretions, although if the underlying cause is poorly controlled allergies, antihistamines may have a preventive value.

Barodontalgia

Like barotitis media and barosinusitis, **barodontalgia** (“flyer’s toothache”) results from ambient pressure changes. The rarest of the three conditions, barodontalgia may be caused by gas bubbles trapped below the gums during restorative dental treatments, by periodontal cysts, or by abscesses. Symptoms include pain and pressure in or surrounding a tooth and usually resolve on return to sea level. Barodontalgia is most commonly seen among scuba divers and military pilots who experience extremely rapid changes in pressure. Most cases seem to be associated with dental disease and may be considered a symptom of such disease.

Decompression Sickness

Although **decompression sickness** is not the most frequently encountered dysbarism, it is the most widely recognized. Decompression sickness is explained by Henry’s law: It occurs when inert nitrogen gas bubbles form at one or more locations in the body. The symptoms manifested depend on the location in the body in which the nitrogen bubbles form. This scenario is much more common in deep-water diving.

The tissues and fluid of the body typically contain approximately 1 to 1.5 L of dissolved nitrogen, depending on the barometric pressure of the atmosphere. As altitude decreases, nitrogen leaves the body in an attempt to reestablish equilibrium. Normally, the excess nitrogen diffuses into the capillaries in solution and is eliminated through the venous circulation. If a human body is subjected to a rapid decrease in atmospheric pressure, however, the capillaries become supersaturated and nitrogen begins to leave as a gas instead of in a solution. In that case, nitrogen bubbles form in the tissue and blood. Fat is able to dissolve nitrogen five to six times more readily than blood can, so those tissues having the highest fat content are more likely to become saturated with nitrogen.

Decompression sickness can cause circulation problems and, in severe cases, even death because of the potential for nitrogen bubbles in the arterial circulation to cause an arterial gas embolism. Symptoms of decompression sickness are listed in **TABLE 4-6**.

Operational Issues Related to Medical Transport

Communications

The **Commission on Accreditation of Medical Transport Services (CAMTS)** is a program dedicated to ensuring high-quality patient care and safety within ground, rotor-wing, and fixed-wing medical transport services. CAMTS has established many communication standards to help improve the overall safety of most critical care transport systems. Much of its effort has focused on rotor-wing and fixed-wing divisions because proper communication procedures within the cockpit are important for ensuring the safety of both patients and crew.

Sterile cockpit is a term used by the pilot-in-command to describe the mode of operation during takeoffs, landings, and any other critical phase of flight. During this time, communication should be restricted to only what is necessary for the safety of the flight so as not to distract the pilot-in-command. Air carrier standards state that a sterile cockpit should be enforced at all altitudes less than 10,000 feet; however, most helicopters fly only between 2,000 and 5,000 feet. In such situations, the sterile cockpit times are determined by the pilot-in-command, but will always include takeoff, approach, and landing. Sterile cockpit times should be clearly defined by the pilot-in-command prior to flights. Once the rotor-wing aircraft has reached its cruising altitude and speed, the pilot-in-command will typically permit crew members to take part in casual conversation unless this interferes with other communications such as monitoring or discussing flight operations with ATC. Communications with operation centers and dispatchers should also be permitted during this phase of the flight process. The rule of thumb should be that communications to operation centers, such as those that give lift-off time and estimated time of arrival (ETA), should be relayed prior to lift-off, after the aircraft reaches its cruising altitude, or after the pilot declares a nonsterile cockpit.

Sterile cockpit procedures also apply to communications among the medical crew about patient care and communications with the patient. Most pilots have the option of “isolating” crews; that is, by flipping a switch in the cockpit, the pilot can take the crew out of the communication loop with ATC and ground units.

If, during flight, the pilot-in-command experiences a mechanical issue, it may be necessary to land short of the original destination. In most cases, when mechanical issues arise, the pilot-in-command seeks out the closest airport as a landing site. The crew should also be alert at all times for potential mechanical malfunctions such as smoke in the patient care area, abnormal odors, unusual vibrations not reported by the pilot, abnormal sounds, or fluids leaking into the patient bulkhead. Pilots may also choose to declare an emergency to ATC. This should immediately result in a sterile cockpit.

Instrument Flight Rules Versus Visual Flight Rules (Fixed-Wing and Rotor-Wing Operation)

In the aviation industry, all parties must be familiar with the two possible modes of flight: visual flight rules and instrument flight rules.

Visual flight rules (VFR) describe a mode of flight used when weather conditions are good, meaning there is generally good visibility and minimal cloud cover. A pilot can fly VFR in many areas without being in contact with ATC and is responsible for keeping the aircraft clear of clouds; however, in populated areas such as large cities, the pilot must be in contact with ATC even when flying VFR.

Instrument flight rules (IFR) describe a mode of flight used when minimum cloud clearance and visibility requirements cannot be met. During these conditions, the pilot may not be able to see outside the aircraft (eg, owing to clouds or fog) and must rely on the instruments inside the cockpit to maintain control and navigation of the aircraft **FIGURE 4-20**. A pilot flying IFR must receive an ATC clearance prior to takeoff and maintain contact with ATC during the flight, which will ensure the aircraft maintains the proper distance from other air traffic.

FIGURE 4-20 Cockpit with electronic instruments.

© Pavel L Photo and Video/Shutterstock.

Initiating a Flight and Flight Following

A critical care transport is initiated when the communications center receives a request for service from an authorized agency such as local police, fire, emergency medical services (EMS), or a referring hospital and then passes that request on to the flight team. The flight team then either accepts or declines the mission after reviewing the relevant factors, such as the weather, terrain, and nature of the patient's injury or illness. Some programs require that the pilot make the decision without any knowledge of the patient. This prevents pilots from being influenced by patient characteristics and taking on extra risk—for example, deciding to transport a pediatric patient when it is actually not safe to do so. Once the aircraft launches, the communications center and/or ATC remains in contact with the aircraft throughout the flight.

When a pilot is flying IFR, ATC is legally mandated to stay in contact with the aircraft to ensure it maintains a safe distance (ie, separation) from other IFR aircraft. When a pilot is flying VFR, a type of monitoring called **flight following**, or radar advisory service, may be provided by an authorized ATC facility **FIGURE 4-21**. This service consists of a controller notifying the aircraft about traffic in the area when the controller is available to do so.

FIGURE 4-21 Flight following occurs when an air-traffic control center stays in contact with a pilot.

© Photodisc/Alamy Stock Photo.

When a pilot is flying VFR, it is good practice to maintain constant contact with other local traffic and ATC facilities in proximity of the aircraft. When a pilot is flying IFR, a filed flight plan, flight clearance, and ATC contact are mandatory.

When a pilot is flying VFR in a helicopter, contact is maintained with one of two entities: ATC and a communications center. If the pilot-in-command decides not to flight follow with ATC, the flight must be tracked by a communications center, either by a commercial flight-tracking system or by real-time radio contact with a communications center, with an update provided every 15 minutes.

Identifying Flight and Scene Locations

It is critical that the flight-following center use global positioning system (GPS) technology so that it can constantly track the aircraft's movement even when the pilot is not in radio contact with the center. Several commercial flight-tracking programs are available that use a GPS signal sent from the aircraft and received by the center. In the event of an in-flight emergency requiring an emergency landing, the center can use this signal to immediately determine the aircraft's last known position.

The flight-following center also needs to have computer software available that can allow for a physical address to be input and converted to GPS coordinates. In the rotor-wing environment, responders to the scene frequently use handheld GPS devices to obtain coordinates for the geographic location. These devices are extremely accurate: If the coordinates are properly read and relayed, they will lead the aircraft to within a few hundred yards of the scene. To prevent inaccuracies in the relayed coordinates, at least two sets of coordinates should be obtained for all scene flights.

Air Medical Safety

Air medical transport has inherent hazards but is rich with rewards. Providers working in this setting encounter a complex myriad of hazards. They are expected to launch quickly after a request has been made, placing stress on the flight crew to rapidly become airborne. Subsequently, their aircraft often lands at chaotic scenes where a hasty landing zone has been established and where a variety of emergency personnel are operating in close proximity to the landing zone. Air medical providers are also called to situations where patients are facing catastrophic injury or illness, requiring the flight crew to give maximum attention and apply expert decision-making abilities to treat the patient. Frequently the aircraft is called because the patient's condition is so serious that it has exceeded the capabilities of the medical personnel on the ground, putting additional stress on the aircrew. Finally, the aircraft environment is physically demanding and can induce heat illness, dehydration, motion sickness, and physical and mental exhaustion in air medical personnel after extended operations.

Air Medical Crashes

Annually, more than 1,000 helicopters are used to transport an estimated 400,000 patients in the United States. These numbers have been growing steadily since the inception of air medical flights, and as the total number of medical flights has increased, so has the total number of air medical crashes. From 1999 to 2018 in the United States, 206 EMS helicopter crashes occurred, representing about 10% of all helicopter crashes in that time. However, when analyzed according to crashes per 100,000 flight hours, rates have been declining in that time.

An unfortunate trend in EMS medical flight crashes continues to be the high fatality rates. Despite the overall improving safety of medical flights, when a crash occurs it has a far greater likelihood of being fatal when compared to non-EMS flights. From 1999 to 2018, in the United States, only 14% of non-EMS helicopter crashes involved at least one fatality, whereas 33% of EMS helicopter crashes involved a fatality. The primary factors in the higher fatality rates in the EMS crashes seem to be lack of a pilot with a first-class medical certificate and lack of a second pilot. Of note, per 100,000 hours flown, EMS flights have a much lower crash rate, at about 3% for EMS flights versus 6% for non-EMS flights. Further, the rate of fatal crashes does not differ between EMS and non-EMS flights. The concern lies in the disproportionate tendency of the EMS crash to be fatal.

Causes of Air Medical Crashes

The NTSB has found that aircraft crashes are rarely caused by a single event. Instead, they are the culmination of a series of factors that ultimately contribute to the final event. As FAA Advisory Circular Number 60-22 states, “One bad decision often leads to another. As the string of bad decisions grows, it reduces the number of subsequent alternatives for continued safe flight.”

Because a crash may involve multiple factors, researchers attempt to cite all possible contributing or causal factors in each crash, which creates a complex picture in which certain factors appear with disproportionate frequency, although they may not in themselves have caused a crash. Any one of these factors may have prompted the next contributing factor to occur, which prompted the next, and so on, in what the NTSB terms “the accident chain.”

When trying to appreciate the contributing factors most relevant to HEMS, a common approach is to compare EMS helicopter crashes to non-EMS helicopter crashes. The NTSB reports from 2008 to 2017 suggest that several factors are more likely to contribute to EMS crashes:

- Pilot incapacitation (10.54 times more likely in EMS crashes)
- Pilot inexperience (7.69 times more likely in EMS crashes)

- Visibility/darkness (5.18 times more likely in EMS crashes)
- Organizational compliance issues (4.91 times more likely in EMS crashes)
- Nonscheduled operations (4.55 times more likely in EMS crashes)
- Multiengine aircraft (3.76 times more likely in EMS crashes)
- Pilot decision-making or judgment issues (3.38 times more likely in EMS crashes)

Thus, pilot incapacitation, broadly defined as issues related to impairment, incapacitation, fitness, alertness, or fatigue, was more than 10 times as likely to factor into an EMS helicopter crash as it was a non-EMS crash.

When comparing EMS flights to non-EMS flights, it must be noted that EMS flights are much more likely to occur at night, with poor visibility being a significant risk factor. Other factors that complicate this comparison include the types of aircraft used, the types of equipment transported, and the inherent risks of on-scene responses.

When looking specifically at fatal EMS helicopter crashes from 2008 to 2017, the most common contributing factors, in order, were as follows:

- Pilot decision making
- Visibility or darkness
- Mechanical problems with the aircraft
- Pilot attention/orientation
- Organizational compliance
- Object/terrain encounter
- Pilot experience
- Pilot flight preparation

Two factors, pilot decision making and visibility, were associated with a much higher rate of fatality when compared to non-EMS helicopter crashes.

When assessing the role of weather in EMS helicopter crashes, the key issue is rarely the pilot's disregard for weather at takeoff, but rather encounters with unpredicted (inadvertent) **instrument meteorological conditions (IMC)**, such as cloudiness or low visibility, during flight. Weather is cited as a contributing factor in approximately 25% of crashes, but two-thirds of those crashes are fatal.

HEMS is an inherently dangerous form of aviation. Although risk can be mitigated in this setting, it can never be completely eliminated. Recognizing the factors that contribute to crashes is a key step in the ongoing effort to reduce risk. Specific safety initiatives are discussed later in this chapter.

Human Errors

Human factors contributing to error can be classified into three types: errors that involve skill deficiency, perception errors, and decision-making errors. Pilots and other members of the flight crew are expected to have the basic skills necessary to fly an aircraft safely. When there are deficiencies in these basic skills, a number of hazards can occur. Examples of these types of errors include losing control of the aircraft on the runway, flying at an improper speed, and not following standard operating procedures in the event of an emergency.

Errors in perception (discussed earlier in this chapter) involve spatial disorientation, a somatogravic illusion, or a mistake in judgment regarding distance, altitude, or airspeed. Spatial disorientation may occur during a flight that becomes out of control in midair. Errors in perception may also occur during nighttime landings and during landings that involve reduced visibility.

Errors in decision making may lead to an undesirable outcome as well. Decision-making errors include failing to choose the appropriate emergency procedure and failing to take corrective action when the aircraft is flying below the minimum altitude.

Areas Requiring Improvement

Retrospective studies of air medical crashes conducted by the NTSB, the FAA, and the Air Medical Physician Association (AMPA) have identified several areas within HEMS operations that need improvement:

- Weather forecasting
- Flight operations during instrument meteorological conditions
- Personnel training
- Design standards
- Crashworthiness
- Operations management

Other areas of HEMS operations identified as risk factors for air medical personnel include the following:

- Unprepared landing sites
- Complacency
- Additional stress of responding and caring for critical patients

Safety reports also indicate that communication problems with ATC and collision with ground objects are issues that warrant improvement.

Adding to the risk is the time-critical nature of the job. Because of the rapid preparation involved, crews do not have the luxury of conducting a leisurely preflight inspection of the aircraft, nor do they have plenty of time to check and recheck current and forecast weather reports. Instead, crews must move quickly to provide timely, life-saving care. Use of crew resource management has improved the decision-making process after receipt of a request. Most program policies have all flight crew members perform a quick walk-around the aircraft prior to initial startup. The rule of thumb is that three sets of eyes are better than one.

Making the Industry Safer

Within the industry, several solutions have been proposed to reduce the number of air medical crashes. Crew resource management training (discussed in the next section) for all flight team members is now the industry standard. All new flight team members are required to attend initial training, and most programs offer annual refresher training.

Another important safety measure is information sharing between competing agencies. In the air medical industry, the term **helicopter shopping** describes the practice of making sequential calls to numerous air medical providers in an attempt to find a service that will accept a mission request that has been declined by other services based on safety factors such as poor weather, limited landing zone availability, exceptional distances, or other factors. To prevent helicopter shopping, air medical providers should share their decisions to decline certain missions based on safety issues with surrounding air medical services, even if they are in direct competition with those services. Field providers, hospital personnel, and dispatch/referral centers may also shop for helicopters, and this dangerous referral pattern should be addressed and eliminated.

Air medical programs need full support from their organization’s administration and the aircraft vendor when they choose to decline a mission. Some believe that stiff competition in the air medical industry prompts some services to take missions even when safety is in question. In the face of intense scrutiny of the air medical industry from the federal government, other oversight agencies, and the community, air medical services have implemented numerous guidelines to prevent flight crews from being pressured into taking questionable flights.

To facilitate cooperation among the various parties involved in the transport decision, joint agency training is encouraged between air medical providers and the various agencies with which they interact.

Air medical providers should routinely train with other area HEMS programs, EMS agencies, fire departments, and hospital providers. This training should include aircraft familiarization, landing zone requirements, flight activation criteria, and flight request training.

Advanced technology that can increase the safety of flight operations is now available. Many HEMS programs use night vision goggles **FIGURE 4-22** on the aircraft. Unfortunately, implementation of this measure throughout the industry has been slow because of the cost of the equipment, required modifications to the aircraft cabin, and the need for extensive flight crew training.

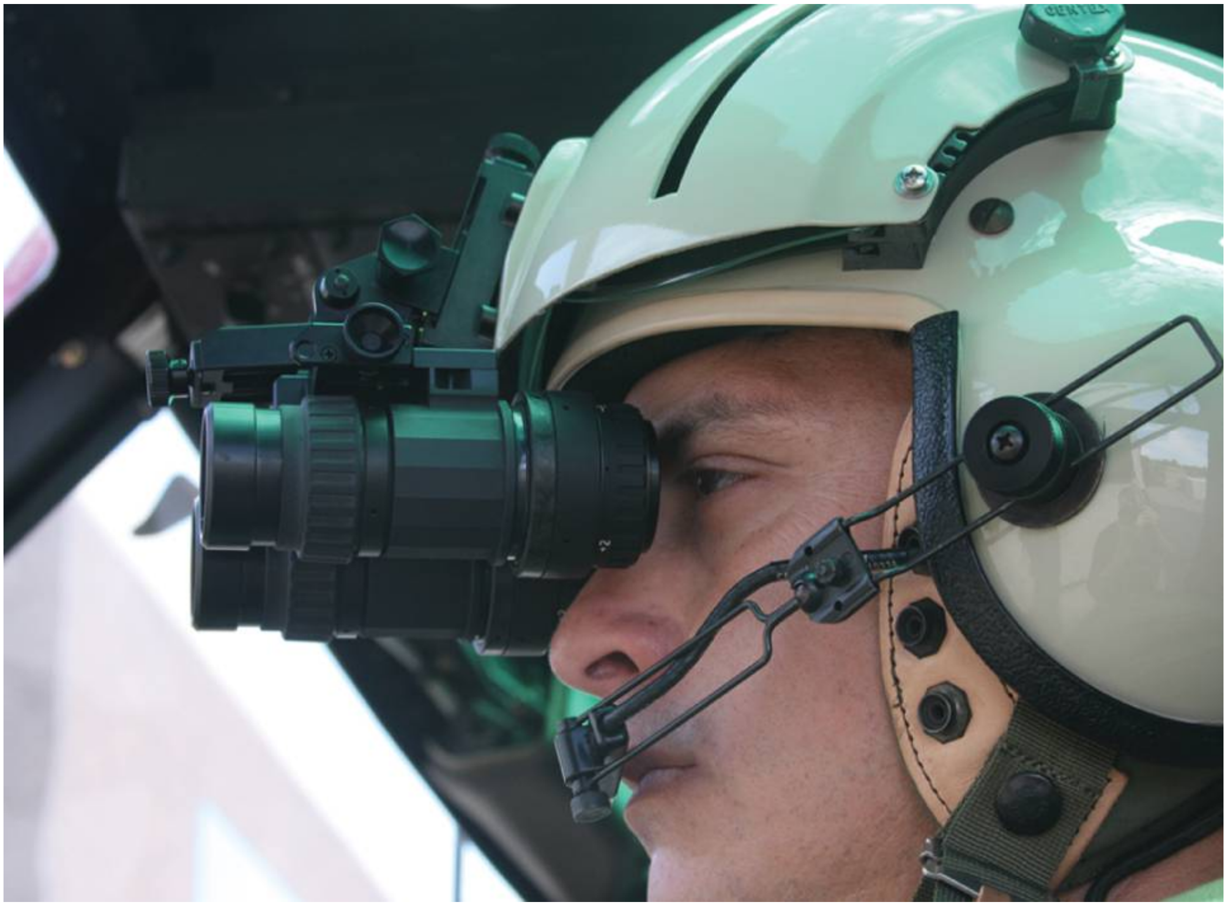

FIGURE 4-22 Night vision goggles.

Flight-tracking software is now used throughout the industry to assist with real-time tracking of the aircraft at all times. The practice of flight following can help locate an aircraft that crashes or loses radio contact. Some air medical programs have also begun implementing ground-proximity warning systems and obstacle detection and alerting systems on their aircraft, also known as a terrain awareness and warning systems (TAWS).

Most rotor-wing aircraft do not have real-time weather data available in the aircraft. Instead, the pilot must rely on weather data obtained before launch as well as weather information given by the flight-following center. To provide for better in-progress forecasts, some aircraft now have weather display and alerting systems installed that can give pilots real-time weather data and warnings. Additionally, operational control centers (OCC) and flight dispatch and communications centers can monitor the weather and notify a pilot of changes in weather conditions.

Crew Resource Management

With the implementation of cockpit voice recorders and flight recorders in the 1960s and 1970s, investigators discovered that many crashes were not the result of mechanical or technical malfunctions of the aircraft or its systems, nor were they caused by poor piloting skills or lack of knowledge or experience from the crew. Instead, more than 80% of crashes involved human error—primarily related to the crew’s inability to respond appropriately to the situations in which they found themselves.

Crew resource management evolved as a result of both that statistic and the KLM Royal Dutch Airlines/Pan American crash on Tenerife, Canary Islands, in 1977, in which two 747s collided on the runway. The deadliest crash in aviation history, this disaster was primarily attributable to unclear communication between the KLM pilot and the control tower regarding takeoff. The pilot understood that the aircraft was cleared for takeoff, but the control tower was only confirming position for takeoff, not actually clearing the flight for takeoff. The control tower made a clarifying statement, but the KLM pilot could not hear it because of interference. The Pan American aircraft was taxiing on the main runway when the KLM aircraft started to take off. The KLM flight engineer heard a transmission from the Pan American crew and asked the pilots if Pan American was clear of the runway; the KLM pilot assumed Pan American was clear and continued with takeoff. All KLM passengers and crew members died (248 total people) as well as most (335) of the 396 people on the Pan American flight.

In response to this crash and a series of alarming statistics, the National Aeronautics and Space Administration (NASA) held a workshop in 1979 focusing on ways to improve air safety. Before this workshop, the captain or pilot-in-command of the aircraft was considered to be the only person who was able to make decisions regarding the operations of the aircraft. The other crew members, including the first officer, had minimal input into the final decision that was made. The new procedure advocated as a means to overcome this reliance on only one person's judgment was called **crew resource management**, defined as "using all available resources—information, equipment, and people—to achieve safe and efficient flight operations." In air medical programs, this approach is often referred to as **air medical resource management (AMRM)**.

Crew resource management challenged the assumption that the pilot should make decisions alone. Flight crew members were encouraged to speak up when they did not agree with the pilot; pilots were encouraged to listen and take into account flight crew input. In short, the aviation industry learned to accept that human-to-human interactions are an integral part of any team performance.

Crew resource management is not concerned with the technical aspects of flying an aircraft. Instead, it focuses on the cognitive and interpersonal skills needed to successfully complete the flight:

- Cognitive skills take into account the mental processes needed to maintain situational awareness, make decisions, and solve problems.
- Interpersonal skills focus on individual and group behavior, communication, and teamwork.

Today, the International Civil Aviation Organization (ICAO) requires crew resource management for airlines in 185 countries. A study by the University of Texas Human Factors Research Project found that commercial airline flights experience an average of four threats per flight. Most of these threats or errors are caught through crew resource management and have no detrimental consequences.

Crew resource management allows for subordinate crew members to participate in the decision-making process, but it does not imply that all decisions are made by committee without considering rank. That is, the amount of participation by subordinate crew members depends on the situation. For the most part, your role as a medical crew member in crew resource management focuses on passive monitoring. You will not typically provide flight instructions to the pilot, nor will you be involved in technical decisions made in regard to operation of the aircraft. Instead, you are obligated to intervene if the level of skill displayed by the pilot falls below a safe standard (eg, if you notice that the aircraft is on an imminent collision course with a radio tower, or to advise the pilot of nearby air traffic).

One area of crew resource management in which all members of the crew should have equal empowerment is the decision of whether to accept a mission. In the past, it was often solely the pilot’s decision to accept, decline, or abort a mission. More recently, this practice has been changed by the majority of air medical providers and replaced by the “all to go, one to say no” rule. Under this rule, every member of the crew, regardless of time or rank, has the power to decline a flight. Although the pilot does have the ultimate authority over all operations of the aircraft, if any crew member does not feel comfortable with a mission, the mission should be aborted.

Federal Aviation Administration Guidelines

All aircraft fall under one or both of the following guidelines set forth by the FAA:

- Title 14 of the Code of Federal Regulations (14 CFR) Part 91 governs the operation of all aircraft within the United States, including the waters within 3 nautical miles (6 km) of the US coast. All aircraft must abide by this guideline. General aviation (private) aircraft operate under these less restrictive rules.

- **Title 14 of the Code of Federal Regulations (14 CFR) Part 135** governs the operations of all commuter or on-demand commercial operations. The guidelines for 14 CFR Part 135 operations are much stricter than those for 14 CFR Part 91 aircraft and apply to almost all air medical operators.

One of the significant differences between 14 CFR Part 91 and 14 CFR Part 135 is the minimum weather conditions in which the aircraft is allowed to operate. Under previous regulations, a pilot could potentially accept a mission under 14 CFR Part 91 weather requirements, fly to the scene, and then be under 14 CFR Part 135 weather requirements for the transport to the hospital. This discrepancy posed a major safety hazard, in that the aircraft would be allowed to launch under weather standards that were not conducive for patient transport with the hope that the weather would improve by the time the patient was loaded on the aircraft.

Only Part 135 is relevant to you as a CCTP: All commercial operators must abide by Part 135 regulations. Only a few government operators (such as law enforcement) can operate solely under Part 91.

Due to the high rate of accidents in air transport missions, air ambulance operations were placed on the NTSB's "Most Wanted Safety Improvements List" for 2014. In response to this and ongoing concerns, the FAA released updated rules aimed at increasing the safety of HEMS operations **TABLE 4-7**. Although not all of these rules were scheduled to take effect immediately, their implementation is intended to address the areas of greatest concern in air transport operations **TABLE 4-8**.

TABLE 4-7 **FAA Helicopter Emergency Medical Services Regulations**

Conduct all flights under Part 135 regulations when medical crew are on board

Install helicopter terrain awareness and warning systems (HTAWS) on all aircraft

Mandate that all pilots-in-command have instrument rating

Install a flight data monitoring system in all aircraft within 4 years (implemented as of 2018)

Utilize an FAA-approved preflight risk analysis tool

Increase VFR minimums for Part 135 operations

Permit IFR operations at airports without weather reporting systems

Establish guidelines for transitioning from IFR to VFR

Require life preservers to be worn by all crew members when conducting flights over water

Increase pilot training requirements for inadvertent instrument meteorological conditions

Require all aircraft to have a radio altimeter

Description

Weather-Related Issues

Weather has an obvious effect on the ability to accept and complete missions. Some mission requests result in a **weather decline**; that is, an air medical provider is requested, but the pilot and the flight team determine that the weather conditions do not meet established company or FAA guidelines for flight operations. In addition to visibility and ceilings, other considerations related to weather and flight include icing, thunderstorms, and high winds.

Crew Safety Precautions

CAMTS strongly emphasizes the need for adequate crew rest and ongoing safety precautions, both of which affect CCTPs and patients. The following are standards that CAMTS suggests for all CCTPs:

- Shifts longer than 24 hours are discouraged.
- Personnel should have at least 8 hours of rest before starting any shift longer than 12 hours.
- Personnel should not be on duty more than 16 hours within any 24-hour span.
- Crew members who must work longer than 16 hours must have the right to take an unscheduled break.

Other requirements have been adopted by CAMTS for pilots. Some CAMTS standards indicate that pilots must have the following qualifications:

- A minimum of 2,000 total flight time hours, with 1,500 of those hours in a helicopter

- 1,000 hours qualified as pilot-in-command time
- 200 hours of night flying
- A minimum of 500 hours of turbine time, with 1,000 hours encouraged
- 5 hours of geographic orientation with another pilot before accepting a mission alone

Summary

The air medical environment comprises a complex mix of aircraft operations and treatment of critically ill and injured patients. Medical crew personnel must have a strong knowledge base in both aircraft operations and critical care treatment. As a CCTP, you must have a thorough knowledge of flight physiology, not only for your patients, but also for yourself and your fellow flight team members. Even if you are ground based, you need to recognize the physiologic implications of flight because a large number of your patients will be prepared for flight or received from a flight. Because the majority of patients whom you will encounter have comorbid conditions or will have multiple traumatic injuries, the effects of altitude will be far more pronounced in these already vulnerable individuals.

The most important aspect of flight medicine is safety. The air medical environment is filled with risks, and providers must take every step possible to limit their exposure to danger. Many different agencies are actively working to reduce the risk of aircraft crashes, and flight team personnel are encouraged to become involved and aggressively work to make the industry safer. The air medical transport industry continues to grow, and flight team personnel must be ready to meet the myriad challenges they will inevitably face as air medical transport professionals.

CASE STUDY

You and your partner are working for a small, rural air medical transport service located in southeastern West Virginia that operates an American Eurocopter H-135. The terrain to which you are accustomed is extremely mountainous, with elevations of more than 5,000 feet above sea level. Owing to the geographic layout of your service area, many of the flight legs are completed in mountainous terrain with limited signs of human population.

It is 1700 hours, and you are about halfway through your 24-hour shift when you are dispatched to a small community hospital 45 nautical miles (83 km) from your base. The requesting facility is asking your team to transport a patient via rotor-wing aircraft to a university hospital that is 2 hours away by ground and 25 minutes away by helicopter.

Your pilot-in-command checks the local weather, and the decision is made to accept the flight. Once your pilot-in-command calls your operations center to confirm that the crew can accept the flight, you head to the aircraft and prepare for departure.

As soon as your aircraft reaches cruise altitude and speed, the communications center informs you that the patient is a 64-year-old man with respiratory failure caused by bilateral pneumonia and exacerbation of chronic obstructive pulmonary disease (COPD). The patient was admitted to the hospital 2 days ago with acute shortness of breath and required immediate ventilatory support, including endotracheal intubation. The patient's condition has been stable during the hospital stay, but the family is requesting transport to the university hospital for a second opinion. The patient is receiving a propofol infusion for sedation, normal saline, and ceftriaxone. The patient is being mechanically ventilated with the following ventilator settings: tidal volume, 750 mL; synchronized intermittent mandatory ventilation rate, 12 breaths/min; and FIO_2, 70%.

When you reach the patient in the outlying hospital's intensive care unit, you are met by the staff nurse, who provides you with a more detailed patient report. During this report, the nurse tells you that the local pulmonologist has been weaning the patient's ventilator settings with the goal of extubation. You and the staff nurse review the results of the patient's laboratory studies, including blood gases. The most recent set of vital signs are as follows: blood pressure, 124/64 mm Hg; pulse rate, 84 beats/min; respiratory rate, 16 breaths/min (patient is breathing 4 breaths/min on his own); and pulse oximetry, 94%. The nurse tells you that a copy of the patient's chest radiograph and medical chart are in a folder for you to review and asks that you take them to the accepting hospital.

Once the patient assessment has been completed and the medications are transferred to your transport pumps, you secure the patient to your stretcher and prepare him for transport. You and your partner are concerned about his respiratory status owing to the bilateral pneumonia and are worried that he may not tolerate your transport ventilator as well as he did the hospital ventilator. You and your partner decide to perform a trial with the patient on your ventilator for at least 10 minutes before departing for your aircraft. The trial goes smoothly, and you proceed toward the aircraft.

During the initial phase of your flight to the university hospital, the patient remains adequately sedated and his vital signs remain unchanged. About 12 minutes into the flight, you notice that the patient's oxygen saturation readings are beginning to drop into the low 90% levels. After checking the patient and troubleshooting the ventilator and oxygen connections, you determine that ventilator settings are appropriate. You adjust the FIO_2 to 100%; within minutes of making this change, the pulse oximetry readings return to normal, at 99%. The remainder of the flight is unremarkable, and you give a full patient report to the nurse in the intensive care unit upon your arrival at the university hospital.

1. What is the most likely cause of the patient's hypoxia that arose during the flight?
2. Which type of changes would you expect to see, as a result of the barometric pressure changes, with the IV solutions that you are infusing through the transport pump?
3. What are some common medical conditions that are typically worsened by altitude changes?

Analysis

It is important to first understand the critical state of a patient who has been diagnosed with bilateral pneumonia and has an underlying lung disease. Patients with these conditions often experience desaturation rather quickly with any change in position, altitude, or ventilator settings. In this particular case, flying at 6,000 feet above sea level over very mountainous terrain was required to get to the university hospital. In such situations, it is very important to understand Dalton’s law, which states that the FIO_2 should be adjusted upward proportionate to the change in barometric pressure in the helicopter cabin. Because the barometric pressure in the hospital and the barometric pressure in the air are rarely available to CCTPs in advance, it is essential to recognize that increasing the FIO_2 en route may be necessary as altitude increases.

The second question asks which type of changes would be expected as a result of barometric changes when IV solutions are infused through the transport pump. The answer is none! As long as the infusions are being maintained on a pump, the barometric changes will not affect the flow rates. However, if the patient is receiving an infusion via gravity, the infusion rate will increase as the barometric pressure decreases, which occurs with increasing altitudes.

Pneumonia is one of the most common medical conditions that might require additional oxygen therapy to prevent worsening hypoxia. Other medical conditions that are adversely affected by altitude changes include COPD, asthma, coronary artery disease, pneumothorax, shock, and blood loss. Close attention should be given to patients with these conditions, and medical consultation should be obtained before departing the referring facility to discuss adaptive therapies that might be needed throughout the transport.

PREP KIT

Ready for Review

- As a CCTP, you must have a thorough understanding of flight physiology and its implications for both your patients and you. The medical environment during flight is complex and extremely dynamic, and the changes in barometric pressures and the forces experienced in flight can have a significant effect on disease pathophysiology.
- Critically ill or injured patients and those who would have a negative outcome with prolonged transport by ground units may benefit most from air medical transport.
- The earth's atmosphere contains several distinct layers. The first layer, called the troposphere, is located beneath the tropopause; together, these two layers constitute the lower atmosphere. Above the tropopause are the stratosphere, stratopause, mesosphere, and thermosphere, respectively. Critical care transports do not usually fly above the tropopause.
- The earth's atmosphere is divided into three distinct zones that directly correlate with a human's response to hypoxia. The physiologic zone extends from sea level to 10,000 feet; it contains the oxygen and has the barometric pressure needed for a healthy person to live. In the physiologically deficient zone (from 10,000 to 50,000 feet), the barometric pressure begins to decrease and protective equipment, supplemental oxygen, and pressurized aircraft are necessary. In the space equivalent zone (from 50,000 feet to 120 miles), pressure suits and sealed cabins are required.
- Barometric pressure, also called atmospheric pressure, is a direct result of the weight of air. It is also influenced by air density, air temperature, height above the earth's surface, and weather.
- You need a thorough knowledge of several gas laws—Boyle's law, Charles's law, Dalton's law, Fick's law, Gay-Lussac's law,

Graham’s law, and Henry’s law—that have integral roles in aviation medicine and flight physiology.

- Boyle’s law states that as altitude increases, atmospheric pressure decreases, and the gases inside the body expand. Boyle’s law also applies to the expansion of any trapped gas within the body (eg, in the chest, skull, middle ear, sinus, stomach, and intestines) and to situations characterized by increasing tension and pressure. Medical equipment and supplies can also be sensitive to changes in barometric pressure, including IV fluids, nasogastric and orogastric tubes, and colostomy bags.
- Charles’s law states that the higher the altitude, the lower the pressure and the colder the temperature, which puts patients and crew members at risk for hypothermia.
- Dalton’s law states that the total pressure of a gas mixture is the sum of the pressures of the individual gases in the mixture. At higher altitudes, oxygen molecules are less densely distributed; thus, at higher altitudes, the presence of an insufficient number of oxygen molecules can lead to hypoxia.
- Fick’s law states that the rate of diffusion is affected by atmospheric pressures, the surface area, and the thickness of the membrane. This gas law governs the diffusion of oxygen across the alveolar membrane, and it means that patients with chronic obstructive pulmonary disease and pneumonia will have decreased gas exchange.
- Henry’s law states that as the pressure of gas over a liquid decreases, the amount of gas dissolved in the liquid will also decrease. Thus, as the barometric pressure decreases, nitrogen, which normally saturates the tissues in the body, will form gas bubbles that travel to the lungs.
- Gay-Lussac’s law states that as pressure decreases, temperature decreases; thus it is important to keep patients warm.
- Graham’s law states that if an existing permeable or semipermeable membrane separates regions of unequal

pressure, the gas at higher pressure will diffuse through the membrane into the region of lower pressure.

- CCTPs need to be familiar with both rotor-wing (helicopter) and fixed-wing (airplane) operations.
- The four primary forces that act on all types of aircraft in flight are lift, thrust, weight (gravity), and drag, with lift counteracting gravity and thrust counteracting drag. In flight, thrust equals drag and lift equals weight. To take off, a greater amount of thrust and lift are needed, whereas a greater amount of drag and weight are required to land.
- Advantages of rotor-wing transport include vertical takeoff and landing (ability to access areas where other vehicles cannot) and ability to maneuver.
- Disadvantages of rotor-wing transport include weather limitations, interior space limitations, weight limitations, and cost.
- Advantages of fixed-wing transport include that it is generally safer than rotor-wing transport. In addition, fixed-wing aircraft are more often able to fly under instrument flight rules, to fly at high speeds, to travel great distances, and to carry multiple patients, and they have no weight limitations.
- Disadvantages of fixed-wing transport include the high cost of operating the aircraft, performing maintenance work, and maintaining a hangar for housing the aircraft.
- Pressurizing an aircraft, which is accomplished by increasing the barometric pressure inside the aircraft above the ambient pressure outside, is the most effective method of protecting people from the physiologic effects of reduced barometric pressure during flight.
- Aircraft decompression at altitude is categorized as either slow (eg, a small leak develops) or rapid (a dramatic event that occurs with a loud explosion). Decompression exposes the occupants of the aircraft to the dangers of hypoxia, decompression sickness, gastrointestinal expansion, and hypothermia.

- Flight crew members will experience many stressors during their career; however, some stressors may cause catastrophic outcomes.
- A decrease in the P_{O_2} can quickly cause hypoxia in flight crew members and passengers.
- The greatest change in barometric pressure occurs from sea level to 5,000 feet. Thus, problems associated with pressure may occur even in nonpressurized aircraft that are not flying at high altitudes at which supplemental oxygen or cabin pressurization is required.
- Flight crew members are subjected to a variety of extreme temperature changes as a result of changes in air temperature and altitude, as well as the greenhouse effect (radiant solar heat). These changes affect the metabolic rate and the oxygen demands on the body, while simultaneously making the body less tolerant of the effects of hypoxia.
- Vibration is noted in all helicopters, in most turboprop aircraft, and, minimally, in jet-engine aircraft. As the body becomes fatigued from prolonged exposure to vibration, the person becomes more susceptible to pain, decreased vision, and fatigue. Preventive measures to decrease vibration include not leaning against the airframe and providing extra padding for the patient.
- Humidity is the degree of moisture in the air and is relative to temperature. Humidity decreases during a long flight, and the dry air in the aircraft can cause cracked mucous membranes, chapped lips, and sore throats and lead to dehydration. To counteract these risks, crew members should increase their fluid intake, and all patients should be properly hydrated.
- Noise in the cabin of an aircraft can make it difficult for patients and care providers to communicate and for providers to assess patients’ heart and lung sounds. Monitoring errors and malfunctions can be attributed to the noise and vibrations associated with air medical transport; however, pulse oximetry

and hemodynamic monitoring can lessen these negative effects and help identify complications.

- Most physiologic problems encountered in the flight environment can cause significant fatigue and, when coupled with a lack of restful sleep, quickly become cumulative. Jet lag in the fixed-wing environment becomes another fatigue factor. While caring for critically ill or injured patients, you should request crew rest, up to 4 hours, when you feel fatigued.
- Gravitational forces can have a significant effect on the human body, including the feeling of being pushed down in the seat or feeling weightless, depending on whether the aircraft is accelerating or decelerating. As the gravitational force increases, other complications may arise, including difficulty breathing, hypoxia, loss of vision, loss of consciousness, petechiae, rashes, bruising, seizures, amnesia, confusion, and cardiac arrhythmias.
- Spatial disorientation is the state of having an incorrect understanding of the body’s position in relation to the earth and can cause significant nausea and vomiting. The three components to maintaining spatial orientation on the ground are effective perception, integration, and interpretation of visual, vestibular (from the organs of equilibrium in the inner ear), and proprioceptive (from the skin, muscles, tendons, and joints) sensory information.
- Third spacing is the loss of fluids from the intravascular space into the tissues, causing hypovolemia and potentially hypoxia. In the flight setting, it may result from high-speed turns in conjunction with acceleration or deceleration of the aircraft.
- Flicker vertigo is an imbalance in brain cell activity caused by exposure to low-frequency flickering or flashing or a relatively bright light that occurs when sunlight flickers through the rotor blades or propeller, at night by the anticollision lights reflecting off the clouds, or by rotating beacons or strobe lights. This condition may result in nausea, vomiting, seizures, or unconsciousness.

- Exposure to the noxious odors of fuel vapors occurs mostly when the flight crew is loading or unloading a patient; it can cause headaches and nausea if prolonged.
- Flight stressors include weather, anxiety, and night flying.
- Factors affecting tolerance of the stressors of flight can be remembered by the mnemonic IM SAFE, which stands for Illness, Medication, Stress, Alcohol, Fatigue, and Emotion. Other contributing factors, such as tobacco use and hypoglycemia, may also affect stress tolerance.
- Although incapacitation to altitude does not begin to manifest until 10,000 feet of physical altitude, the body may perceive itself as being at a much higher altitude, possibly thousands of feet higher, because of human factors.
- A major hazard in aviation is hypoxia (oxygen deprivation). Hypoxia mimics fatigue and hypoglycemia, making it difficult to recognize. In addition, one of the earliest effects of hypoxia is impaired judgment, which likewise limits an aviator’s ability to recognize this condition.
- Effective performance time is the length of time a person can function with an inadequate level of oxygen. Time of useful consciousness is the period between an individual’s sudden deprivation of oxygen at a given altitude and the onset of physical or mental impairment to the point at which deliberate function is lost.
- Hypoxic hypoxia, which can be due to increased altitude, results from a lack of oxygen or an inability of oxygen to diffuse into the bloodstream. Its symptoms begin to manifest at heights greater than 5,000 feet.
- Histotoxic hypoxia arises when the cells are unable to adequately use oxygen, even though plenty of oxygen is available, because the tissues are not able to accept it or because the oxygen cannot detach itself from the hemoglobin.
- Stagnant hypoxia is the failure to transport oxygenated blood. In flight medicine, venous pooling during acceleration maneuvers can

lead to a reduction of blood flow. Stagnant hypoxia can also result in blood pooling in the lower extremities of patients and crew members when they sit in aircraft for extended periods.

- Hypemic hypoxia, also known as anemic hypoxia, occurs when the blood’s ability to carry oxygen to the tissues is reduced due to a lack of hemoglobin or red blood cells.
- The symptoms of hypoxia are divided into four stages—the indifferent, compensatory, disturbance, and critical stages—that are directly related to the altitude, approximate barometric pressure, and oxygen saturation of the blood.
- The indifferent stage is experienced between sea level and 10,000 feet but can occur at altitudes as low as 5,000 feet. At this stage, night vision begins to deteriorate; electrocardiographic changes, including tachycardia, are common; a slight increase in alveolar ventilation may be noted; and the oxygen saturation varies from 98% to 87%.
- In the compensatory stage, which occurs between 10,000 and 15,000 feet, the body is able to provide short-term physiologic compensation against the effects of hypoxia, such that the respiratory rate and depth may increase and the cardiac output increases. At this stage, hemoglobin saturation varies from 87% to 80%.
- In the disturbance stage, which occurs between 15,000 and 20,000 feet, the physiologic compensatory mechanisms are no longer able to provide adequate oxygenation to the tissues. In turn, respiration, the senses, mental processes, personality manifestations, and psychomotor functions may all be affected. At this stage, hemoglobin saturation varies from 79% to 70%.
- The critical stage, occurring above 20,000 feet, is the last stage of hypoxia. Within 3 to 5 minutes of hypo-oxygenation, judgment and coordination deteriorate, and mental confusion is quickly followed by incapacitation, unconsciousness, and death, if the hypoxia is not corrected. At this stage, hemoglobin saturation is less than 65%.

- Recovery from hypoxia is rapid, and full mental abilities can be recovered within 15 seconds after receiving high-flow oxygen. Prevention and avoidance of hypoxia are key to safety, but if hypoxia is detected, immediate use of supplemental oxygen and descent to below 10,000 feet are necessary.
- Illnesses such as dysbarism (a condition that results from the difference between the barometric pressure and the pressure of gases within the body) are directly related to the effects of altitude as described by various gas laws. As gases expand at altitude, they can cause pain in closed cavities. Barotrauma can result from gases expanding and contracting in the body. This expansion causes pain, usually in the digestive tract, sinuses, teeth, middle ear, or lungs.
- Barotitis media results from the failure of the middle ear space to equalize pressures when going from low to high atmospheric pressure. As the pressure increases, the tympanic membrane is depressed inward and becomes inflamed; petechial hemorrhage also develops. Blood and tissue fluids are then drawn into the middle ear cavity, and the eardrum may rupture if the pressure does not equalize.
- Although decompression sickness is not the most frequent dysbarism, it is the most commonly known.
- The Commission on Accreditation of Medical Transport Services (CAMTS) is a program dedicated to ensuring high-quality patient care and safety within ground, rotor-wing, and fixed-wing medical transport services. CAMTS has established many communication standards to help improve the overall safety of most critical care transport systems.
- The term “sterile cockpit” is used by the pilot-in-command to describe the mode of operation during takeoffs, landings, and any other critical phase of flight. During this time, communication should be restricted to only that necessary for the safety of the flight so as not to distract the pilot-in-command.

- Visual flight rules (VFR) are used when there is generally very good visibility and minimal cloud cover.
- Instrument flight rules (IFR) apply when adverse weather conditions exist, visibility is poor, or the cloud cover is low.
- An authorized air-traffic control (ATC) facility may provide flight following to aircraft flying VFR; in this process, the controller notifies the aircraft about traffic in the area.
- If a pilot flying VFR in a helicopter decides not to flight follow with ATC, real-time radio contact with a communications center must occur every 15 minutes.
- During fixed-wing operations, when a flight plan has not been filed, the pilot-in-command must make contact with ATC or a communications center every 30 minutes.
- Helicopter emergency medical services are consistently shown to be safer than non-EMS helicopter flights. However, the EMS community must address a concerning reality: When an EMS helicopter crashes, the crash is more likely to be fatal.
- Aircraft crashes are never caused by a single event, but rather by a series of factors. Human error is the number one cause, and weather is the main contributing factor.
- Crew resource management was developed to address communication issues that resulted in fatal crashes.
- All members of the crew should have equal empowerment regarding whether to accept a mission. If any crew member does not feel comfortable with a mission, the mission should be aborted.
- Two Federal Aviation Administration guidelines apply to air medical operations: Title 14 CFR Part 91 and Title 14 CFR Part 135. The guidelines for 14 CFR Part 135 operations are much stricter than those for 14 CFR Part 91 aircraft and apply to almost all air medical operators.
- A weather decline occurs when an air medical provider refuses a mission because the weather does not meet established company

or Federal Aviation Administration guidelines for flight operations.

- CAMTS publishes safety standards to which CCTPs and pilots should adhere. It strongly emphasizes the need for adequate crew rest and ongoing safety precautions, both of which affect CCTPs and patients.

Vital Vocabulary

Air Medical Physician Association (AMPA) An organization of physicians and air medical professionals that promotes safe patient transport.

air medical resource management (AMRM) The term used in air medical programs to denote the concept of crew resource management—an initiative designed to ensure all parties involved in an operation have decision-making input.

atmosphere Gases that extend from the earth’s surface to space; composed primarily of nitrogen, oxygen, argon, and trace gases.

barodontalgia A condition caused by ambient pressure changes that may result from gas bubbles trapped below the gums during restorative dental treatments, from periodontal cysts or abscesses; previously referred to as flyer’s toothache.

barometric pressure The weight per unit area of all the molecules of the gases above the point at which the measurement was taken.

barosinusitis An inflammation of one or more of the paranasal sinuses resulting from a pressure gradient between the sinus cavity and atmosphere.

barotitis media Inflammation and possible petechial hemorrhage in the middle ear and possible rupture of the eardrum that results from the failure of the middle ear space to ventilate when going from low to high atmospheric pressure; also known as ear block.

Boyle’s law A gas law stating that the volume of a gas is inversely proportional to the pressure to which it is subjected. Gases trapped in body cavities will expand with increases in altitude and will contract with decreases in altitude.

Charles’s law A gas law stating that when pressure is constant, the volume of a gas is very nearly proportional to its absolute temperature. Thus, the volume is directly proportional to the temperature when it is expressed on an absolute scale where all other factors remain constant.

Commission on Accreditation of Medical Transport Services (CAMTS) An organization dedicated to improving the quality of patient care and safety of the transport environment for both rotor-wing and fixed-wing providers. CAMTS also provides voluntary accreditation of critical care transport agencies.

compensatory stage A stage of hypoxia in which the physiologic adjustments that occur in the respiratory and circulatory systems are adequate to prevent the effects of hypoxia. Factors such as environmental stress and prolonged exercise can potentiate certain effects of hypoxia.

crew resource management A system that originated as the result of a National Aeronautics and Space Administration workshop in 1979 as a means to improve air safety. It incorporates equipment, procedures, and crew concerns to make the best decision during flight operations, focusing on interpersonal communication, leadership, and decision making.

critical stage The stage of acute hypoxia in which there is almost complete mental and physical incapacitation, resulting in rapid loss of consciousness, seizures, respiratory arrest, and death.

Dalton's law A gas law stating that the total pressure of a gas mixture is the sum of the individual or partial pressures of the gases in the mixture; also referred to as the law of partial pressure.

decompression sickness A condition resulting from exposure to low barometric pressure, causing inert gases normally dissolved in body fluids and tissue to come out of physical solution and form bubbles.

disturbance stage A stage of hypoxia in which physiologic responses are inadequate to compensate for the oxygen deficiency, and hypoxia is evident.

drag The resistance of an aircraft to forward motion, directly opposed to thrust.

dysbarism A condition resulting from the effects (excluding hypoxia) of a pressure differential between the ambient barometric pressure and the pressure of gases within the body.

effective performance time The amount of time an individual is able to perform useful duties in an environment of inadequate oxygen; also known as expected performance time.

Federal Aviation Administration (FAA) A US governmental agency within the Department of Transportation that regulates and oversees civil aviation within the United States; it established and enforces the Title 14 CFR that govern aircraft operation within the United States.

Fick's law A gas law stating that the net diffusion rate of a gas across a fluid membrane is proportional to the difference in partial pressure, proportional to the area of the membrane, and inversely proportional to the thickness of the membrane.

flicker vertigo An imbalance in brain cell activity caused by exposure to low-frequency flickering or flashing light. Light flickering from 4 to 20 times per second can precipitate reactions including nausea, migraines, unconsciousness, and seizures.

flight following A service in which an authorized air-traffic control facility maintains constant contact with aircraft to notify the crew about traffic in the area.

flight surgeon A physician who specializes in flight medicine and has been trained extensively in various aspects of aviation and the effects of flight on the human body; also specializes in working with pilots and flight crew members.

Gay-Lussac's law A gas law stating that the pressure of a gas when volume is maintained at a constant level is directly proportional to the absolute temperature for a constant amount of gas. Simply stated, as pressure increases, temperature increases.

Graham's law A gas law stating that the rate at which gases diffuse is related inversely to the square root of their densities.

gravitational forces Force changes that occur with acceleration and deceleration.

helicopter emergency medical service (HEMS) Use of a rotor-wing aircraft to deliver air medical service, for which the goals are to rapidly transport CCTPs to a patient, stabilize the patient's condition, and rapidly transport that patient to a tertiary care center.

helicopter shopping The practice of making sequential calls to numerous air medical providers in an attempt to find a service that will accept a mission request that has been declined by other services based on safety factors such as poor weather, limited landing zone availability, exceptional distances, or other factors.

Henry's law A gas law stating that the amount of gas dissolved in solution is directly proportional to the pressure of the gas over the solution.

histotoxic hypoxia Hypoxia caused by the inability of the tissues to use oxygen, usually as a result of poisoning by toxins such as carbon monoxide and cyanide.

humidity The degree of moisture in the air, expressed as a percentage.

hypemic hypoxia Hypoxia caused by a decrease in the blood's oxygen-carrying capacity due to a reduced amount of hemoglobin in the blood or a reduced number of red blood cells; also known as anemic hypoxia.

hypoxia A state of oxygen deficiency in the body, which is sufficient to cause an impairment of function. Hypoxia is caused by a reduction in the partial pressure of oxygen, inadequate oxygen transport, or an inability of the tissues to use oxygen.

hypoxic hypoxia Hypoxia caused by a decrease in the amount of oxygen in the blood due to a reduction in oxygen pressure in the lungs, a reduced gas exchange area, exposure to high altitude, or lung disease.

indifferent stage The stage of altitude hypoxia in which the body is able to compensate for the hypoxia induced by low barometric pressures.

instrument flight rules (IFR) A mode of flight used when adverse weather conditions exist, visibility is poor, or cloud cover is low. The pilot may not be able to see outside the aircraft, must rely on instruments, and must be in constant contact with an air-traffic controller who assists in maintaining proper separation from other air traffic.

instrument meteorological conditions (IMC) Weather conditions (eg, cloudiness or low visibility) in which a pilot must fly under instrument flight rules, depending on instruments to guide the aircraft.

International Civil Aviation Organization (ICAO) An agency of the United Nations that defines standards for international air navigation and, as part of its role in developing safe practices, requires crew resource management.

lift The upward force created by the wings moving through the air, which sustains the aircraft in flight.

National Transportation Safety Board (NTSB) An independent federal agency that promotes transportation safety, including aviation, railroad, highway, maritime, pipeline, and hazardous materials safety; it investigates transportation crashes to identify the cause and make safety recommendations.

partial pressure of oxygen (arterial) (PaO_2) The amount of the total pressure in the blood contributed by oxygen; a value measured when analyzing the arterial blood gas level.

physiologically deficient zone The zone that extends from 10,000 to 50,000 feet. Noticeable physiologic deficits occur above 10,000 feet. A decrease in barometric pressure results in oxygen deficiency, causing hypoxic hypoxia; the manifestation of trapped and evolved gases then occurs. The use of pressurized aircraft and/or supplemental oxygen is necessary in this zone.

physiologic zone The atmospheric zone that extends from sea level to 10,000 feet; the area of the atmosphere to which humans are well adapted. The barometric pressure is sufficient in this zone to facilitate adequate oxygenation. The changes in pressure encountered with rapid ascents or descents within this zone can produce ear or sinus trapped-gas problems.

pneumocephalus A condition in which air or gas accumulates within the cranial cavity.

pneumomediastinum The collection of air within the mediastinum (the space within the chest that contains the heart, major blood vessels, vagus nerve, trachea, and esophagus; located between the two lungs).

pneumoperitoneum The collection of air within the peritoneum (the membrane in the abdomen encasing the liver, spleen, diaphragm, stomach, and transverse colon).

proprioceptive Referring to information that comes from receptors located in the skin, muscles, tendons, and joints; this information helps a person know the position of their body.

rapid decompression A condition that occurs when a large leak or hole develops in a pressurized aircraft; it can result in hypoxia and injury to people inside the aircraft and catastrophic failure of the aircraft.

somatogravic illusion An error in perception that occurs with acceleration, as the otolith organs are displaced rearward, similar to when a person is looking up. This perception of a nose-up altitude may cause the pilot to push the nose of the aircraft down inappropriately at night or in unlit terrain.

space equivalent zone The atmospheric zone that begins at 50,000 feet. In this zone, 100% oxygen is not sufficient to prevent hypoxia without the use of a pressurized aircraft or suit. Unprotected personnel may experience boiling of body fluids at a level above 66,500 feet.

spatial disorientation An error in perception that may result from a person’s inability to determine their position, altitude, and motion in relation to the surface of the earth or to a significant fixed object during flight.

stagnant hypoxia Hypoxia caused by a malfunction of the circulatory system resulting in a decrease in blood flow.

sterile cockpit The time when unnecessary communication that could distract the pilot is banned in the cockpit—usually during takeoffs, landings, and any other critical phase of flight at the discretion of the pilot-in-command.

third spacing A loss of fluids from the intravascular space into the tissues caused by an increase in intravascular pressures and/or increased permeability of the cell membranes. Physical stressors of flight such as temperature, vibration, and changes in gravitational force can cause or aggravate this condition.

thrust The force exerted by the aircraft engine, which pushes air backward with the objective of causing a reaction of the aircraft in the forward direction.

time of useful consciousness The time between a person’s sudden deprivation of oxygen at a given altitude to the point at which deliberate function is lost. With the loss of effective performance during flight, a person is no longer capable of taking proper corrective or protective actions.

Title 14 of the Code of Federal Regulations (14 CFR) Part 91 A guideline established by the Federal Aviation Administration that governs the operation of all aircraft within the United States, including the waters within 3 nautical miles (6 km) of the US coast.

Title 14 of the Code of Federal Regulations (14 CFR) Part 135 A guideline established by the Federal Aviation Administration that governs the operations of all commuter or on-demand commercial operations.

tropopause The space between the troposphere and the stratosphere. It rises to 60,000 feet at the equator owing to the expansion of heated air masses and sinks to about 30,000 feet at the poles owing to contracting cold air masses.

troposphere A portion of the earth's atmosphere that extends from the surface of the earth to 5 to 10 miles (26,000 to 52,000 feet) high depending on the relation to the equator and the poles. This layer is characterized by the presence of water vapors, a constant decrease in temperature with increasing altitude, and large-scale vertical currents.

Type I spatial disorientation A loss of positional awareness in which the pilot is unaware of becoming disoriented.

Type II spatial disorientation A loss of positional awareness in which the pilot is initially unaware of spatial disorientation, but senses that something is wrong.

Type III spatial disorientation A sudden incapacitating form of loss of positional awareness.

vestibular Related to the organs of equilibrium located in the inner ear.

visual flight rules (VFR) A mode of flight used when weather conditions are good, meaning there is generally very good visibility and minimal cloud cover; the pilot is responsible for maintaining separation from other aircraft.

weather decline A situation in which an air medical provider is requested, but the pilot and the flight team determine that the weather does not meet established Federal Aviation Administration guidelines and therefore decline to make the flight.

weight The downward force due to the weight (gravity) of the aircraft and its load; directly opposed to lift.

CHAPTER 5

Patient Assessment

Kevin Collopy, MHL, NRP
Vahé Ender, NRP, FP-C, C-NPT

OBJECTIVES

After completing this chapter, you will be able to:

1. Discuss the unique aspects of patient assessment as they relate to scene calls and interfacility transports, and modifications to assessments based on the individual transport setting (p 122).
2. Discuss the importance of critical thinking to clinical decision making and differential diagnosis (p 122).
3. Explain the necessity for the critical care transport professional to utilize physical and technological assessment findings to develop a clear clinical picture (p 122).
4. Identify similarities and differences in assessment as they relate to scene calls and interfacility transport (pp 122–125).
5. Explain the importance of reviewing all available information from the sending facility, including any available patient care records (pp 125–127).
6. Explain the assessment process used to establish the initial care plan, make appropriate treatment decisions, and assess the effects of treatments (pp 125–127).
7. Describe the SAMPLE approach used to determine the patient's history (pp 127–128).
8. Describe the ABCDE approach used to guide the primary assessment to evaluate organ systems and anatomy fundamentally necessary for life (p 129).
9. Describe the various elements of the primary assessment, including the following:
    - Airway assessment (pp 129–131)
    - Respiratory assessment (pp 131–132)
    - Circulatory assessment (pp 132–134)
    - Gastrointestinal assessment (pp 134–135)
    - Genitourinary assessment (p 135)
    - Assessment of bleeding control (p 134)
    - Neurologic assessment (pp 135–137)
10. Explain the importance of and safety considerations relating to patient exposure during the primary assessment (pp 139–141).

11. Describe the process of conducting a secondary assessment (p 141).
12. Discuss the inherent instability of the transport environment, and the potential need to adjust infusion settings, ventilator settings, and pain relief and/or sedation as the patient's condition demands (p 141).
13. Describe unique stabilization, packaging, and transport considerations for technology-dependent patients (pp 139–141).
14. Explain the importance of continuous assessment during transport, especially for technology-dependent patients (pp 144–147).
15. Discuss the elements of the patient handoff report necessary to assure continuity of care at the transport destination (p 147).

Introduction

A comprehensive patient assessment is one of the most important skills critical care transport professionals (CCTPs) perform. The assessment builds the foundation for the CCTP's treatment plan and helps guide which interventions may be performed before and during transport. Assessment of critical care patients differs from the traditional emergency medical services (EMS) field assessment in two respects: Critical care patients have often received significant treatment and stabilization prior to the CCTP's arrival, and sophisticated diagnostic information is often available. While this information provides invaluable insights into the patient's condition, prior assessments may not reflect the patient's current status; hence it is vital to confirm the information relayed to you and to conduct your own comprehensive assessment. Patients change over time, and your assessment may reveal new information related to the patient's condition.

While the assessment findings may be no different in a hospital intensive care unit (ICU) than in a wrecked car, patient acuity in the critical care transport (CCT) environment will generally be far higher. Critical care patients are also likely to be attached to invasive equipment. All equipment, from an intravenous (IV) line to an intraventricular drain, must be evaluated as a component of the patient assessment. CCTPs may also have the opportunity to integrate advanced technology, such as ultrasonography, into the assessment process, when these modalities were not available or employed prior to arrival. This equipment provides additional diagnostic information and helps develop a more comprehensive clinical picture. CCTPs must then employ critical-thinking skills to incorporate the information gained from these advanced assessments into problem lists and care plans.

Scene Versus Interfacility Transports

Scene Responses

While CCTPs do not primarily respond to prehospital scenes, operating in this environment does remain within their scope of practice. Critical care flight teams often complete scene flights, and many EMS systems use CCTPs in a dual role, assigning the CCTP to either 9-1-1 responses or high-acuity interfacility transports. CCTPs responding to an emergency scene ideally should be authorized to use their critical care equipment and medications, as appropriate. While the approach to such scenes is not significantly different than that employed in any other prehospital scene, the CCTP must realize that the patient may have received significant advanced life support (ALS) care by ground EMS crews prior to the CCTP's arrival. Moreover, the CCTP may not have the opportunity to survey the scene and the mechanism of injury directly, or have the opportunity to interview family members. Effective communication is paramount to a seamless and rapid transfer of care. Information can be lost during the transfer of care if clinicians are not diligent about asking questions and actively listening to answers.

On scene, the CCTP should query the first responders as to the exact nature of the patient's illness and/or mechanism of injury, assessment findings, interventions performed, and the patient's response to those interventions. Trust this information but verify it as much as you can through your own patient assessment. Prehospital scenes, by their very nature, are less controlled than a hospital emergency department (ED) or intensive care unit (ICU), and the interventions performed are done under austere conditions with a minimum of personnel. Expect devices to move or be dislodged during packaging and transfer to the ambulance or landing zone. For example, endotracheal (ET) tubes may become dislodged or pushed down into the right main stem; IV lines may get kinked or dislodged.

Assess items before and after movement and have the necessary equipment ready to reapply dislodged devices.

Interfacility Transport Responses

Interfacility transports usually account for the majority of a CCTP's workload. The amount of information that is gathered and passed on to CCT teams at dispatch varies greatly among medical transportation systems. In some situations, the CCT team will know only basic details about the patient, such as name, sex, age, medical category, referring and receiving locations, and equipment needed. In other situations, a team member may participate in physician-to-physician conference calls during the referral process and have immediate access to electronic medical records; in this scenario, the team will have extensive information about the patient's condition and needs.

Whenever possible, the CCT team should use the response time to develop a plan that includes all members. Some systems use this time to phone the bedside nurse to obtain an updated patient report and provide an estimated time of arrival (ETA). Most interfacility transport responses occur without the use of red lights and siren. Limit emergency responses to situations when the patient has been diagnosed with a time-sensitive emergency that cannot be treated at the referring facility.

Four distinct variables influence interfacility transport planning:

- The reason for transport
- The type of originating facility and location within the origination facility
- The duration of transport
- The receiving facility type and destination bed

Understanding these variables helps the transport team frame the expectations for transport and the ongoing management plan.

Reason for Transport

Physicians ordering a patient transport are not making a benign decision. Patients who require interfacility transport for medical care tend to have longer length of stays and increased risk of morbidity and mortality compared to patients who are not transported.

The reason for transport will likely inform the anticipated patient care needs when planning interfacility transports. Patients who require services not available at the referring facility are at the greatest risk of needing urgent interventions and deteriorating. Patients transferred for the purpose of maintaining continuity of care may have specialized needs unrelated to the reason for admission or may be receiving ongoing care at the accepting facility. Examples include specialized oncology, cardiology, and neurology services. Bed capacity is a major health care issue, and calls to transport patients due to a lack of available beds within a hospital or a region are becomingly increasingly common. Bed capacity on a regional level also results in increased transportation distances.

Originating Facility and Patient Location

Patients are frequently transferred from critical-access hospitals, free-standing EDs, and smaller community hospitals in both urban and suburban settings. The type of facility from which the transfer originates influences the interventions patients may receive prior to transport. Critical-access and free-standing EDs typically have a limited number of ventilators and limited support staff, and are unlikely to have emergent surgical support services or access to sophisticated imaging. Community hospitals may have ICUs where patients receive invasive interventions, ongoing critical care management, and other forms of comprehensive care prior to transport. Tertiary care centers may transport patients to other tertiary or quaternary care centers, such as academic medical centers. These transports typically involve patients with complicated conditions who are transported for specialized care, such as burn treatment, extracorporeal membrane oxygenation, limb reattachment, or organ transplant.

Within facilities, patients may be transferred from the ED, a floor bed, an ICU, or a procedural area or operating room. The type of care the patient has been receiving will depend largely on the type of unit making the referral. The CCT team should consider this information in anticipating the patient's needs. The team should also consider the referring unit's location within the facility; a referring unit located deep within the facility may considerably extend or complicate the transport process.

Transport Length and Mode

While there is no standardized definition of short versus long transport, the length of transport influences how teams should approach patient care planning. Certainly a 15-minute transport from a free-standing ED to a tertiary care center is a short transport, whereas a trans-Atlantic flight is a long transport. As a general guideline, transports of less than an hour may be considered short. Transports lasting 1 to 3 hours may be considered medium or long transports, and those lasting more than 3 hours are certainly long.

Types of Medical Facilities

- **Critical-access hospitals**. The Centers for Medicare and Medicaid Services provides the *critical access* designation to hospitals that have 25 or fewer beds, are located more than 35 miles from another hospital, have an average length of stay of less than 96 hours, and provide 24/7 emergency medicine services. Critical-access hospitals are a lifeline and provide some level of medical access in rural communities, but offer very limited services. Most acutely ill or injured patients require transport to higher levels of care once stabilized.
- **Community hospitals**. Community medical centers offer emergency medicine and inpatient facilities. They may have standard consultant and specialist services. Community hospitals typically are not affiliated with graduate medical education (residency programs) and focus on providing general medical care. Some may offer limited specialty services such as low-risk labor and delivery management, pediatric care, critical care, cardiology, or neurology. Across the United States, most nonfederal acute care hospitals qualify as community hospitals.
- **Primary care centers** and **secondary care centers**. Primary care centers offer outpatient, routine family medicine services, including obstetrics and gynecology, geriatric care, and pediatric primary care. These centers are responsible for coordinating patient care with outpatient specialists as appropriate. Secondary care centers may offer primary care within the same facility but also offer outpatient specialties such as cardiology, neurology, nephrology, mental health, endocrinology, or

oncology. Interfacility transport teams in some systems may transport patients from primary or secondary care centers to hospitals when patients are directly admitted from their care center to a hospital bed.

- **Tertiary care centers**. Tertiary care centers offer highly specialized inpatient medical care, including advanced and complex medical interventions performed by specialty physicians. Examples of tertiary care include interventional cardiology and cardiothoracic surgery, neurosurgery, acute care surgery, pediatric surgery, inpatient dialysis, and orthopedic surgery. Tertiary care centers are often recognized as regional referral centers and are frequently associated with medical residency and fellowship programs or medical schools.
- **Quaternary care centers**. Centers offering highly specialized or novel interventional therapy are often referred to as quaternary care centers. These highly specialized tertiary care referral centers may be dedicated to advancing the clinical research of one or more areas of medicine and serving as academic medical centers. Quaternary care centers generally accept the most acutely ill patients whom physicians at tertiary care centers may infrequently treat or whose care is identified as too risky. Think of quaternary care centers as the specialty center for specialists. Examples include hospitals that place left ventricular assist devices or perform organ transplantation, cancer centers that offer bone marrow transplantation, and centers that offer experimental therapies.

Time is used when planning transport length because it is a consistent and reliable factor across transport modes. Mileage, in comparison, can have very different implications depending on the transport mode. For example, a 100-mile (161-km) transport may take 2.5 hours by ground transport but only 45 minutes by helicopter; mileage, therefore, is not nearly as relevant in predicting the patient’s needs as is time. As transport length increases, more planning is needed to determine strategies to care for a patient’s medical and physical needs. Planning to turn and reposition a patient may be unnecessary on a 30-minute trip, but becomes imperative during a 3-hour transport.

Destination Facility

The destination facility may be considered a higher, equivalent, or lower level of care from the referring facility. In general, patients who require services that are unavailable at a referring facility or who are transported due to bed capacity issues need to be transported to an equivalent or higher level of care facility. Most interfacility transports will be to a facility that offers a higher level of care, such as a tertiary or quaternary care center. A community hospital with an ICU may be a higher level of care when compared to a critical-access hospital but a lower level of care when compared to an academic medical center.

In some systems, CCT teams may be asked to transport patients to long-term acute care facilities if the patient is ventilator dependent, requires long-term physical therapy or rehabilitation, or has a chronic medical condition requiring long-term acute care. It is important that CCT teams continue the care plans implemented by the referring facility, which may involve careful forethought given the differences between transport-based equipment and hospital-based equipment, and the physiologic conditions of the transport itself.

Finally, patients can be transported to a variety of locations at referring facilities, including the ED, a flood bed, an ICU, or an interventional unit such as radiology or the operating room. It is important to confirm that the receiving staff are aware of the medications and equipment used to care for the patient and can accept and continue the same level of care. Although your interventions should never be based on the care that the destination unit will provide, it may become necessary to call an accepting facility and change destination units based on the care transport teams have provided.

Arrival and Planning

Upon arrival at the referring facility, introduce yourself to the patient's care team. Ask for a moment to review the chart and all available diagnostic information prior to taking a handoff report. This introduction serves the same purpose as it does on a prehospital scene: It lets caregivers know that you have arrived and are ready to render care.

Reviewing the chart prior to obtaining a handoff report and physically assessing the patient give you a general understanding of the patient's condition, allow you to focus your assessment accordingly, and avoid the likelihood of the hospital care team repeating information that is already readily available. The purpose of the handoff report from the treating nurse or physician is the same as it is when a 9-1-1 paramedic gives a handoff report to the ED staff: to fill in the blanks between the written patient care report and the prearrival notification. Do not be surprised if the nurse or physician giving the handoff report is not the person who has delivered most of the patient care. Transfers are often delayed while waiting for a bed at the destination facility to open up, and new care teams may be on duty by the time the transfer occurs.

When gathering information, immediately determine if the patient has a traumatic injury or is experiencing a medical illness, and adjust your questions appropriately. Identify the following key items when preparing to transport injured patients:

- Time of injury
- Mechanism of injury and speeds
- Whether the incident was accidental or deliberate
- Whether safety equipment was used
- Diagnosed injuries
- Applicable diagnostic tests that have been performed and their results, if available

- Diagnostic tests indicated but not yet performed

When transporting patients with a medical complaint, obtain the following details:

- Onset of symptoms (time)
- Time of arrival at the referring facility
- Symptom progression over time (improving versus deteriorating)
- Diagnostic tests performed and their results
- Differential diagnosis
- Presence or absence of complications
- Interventions and the patient’s response to those interventions

For all patient transports, a wealth of information can be gleaned from the hospital patient care record. Indeed, the CCTP may be given a large amount of information, and must quickly separate necessary information from irrelevant information. Anticipated transport time is a critical variable in differentiating between the two. More information may be necessary to provide appropriate assessment and interventions for a longer transport.

The following items in the hospital patient care record are of particular note:

- Demographics
- Transfer order, including the sending and accepting physicians, the destination hospital and care unit, and contact information for each
- As-needed and standing orders for transport
- History and physical (H&P) examination findings **FIGURE 5-1**
- Physician notes
- Nursing notes and flow chart
- Medication administration record

- Lab values and results of diagnostic studies, including imaging copies (digital media)
- Physiologic scoring method results
- Advance directives
- Family and caregiver names and contact information

Description

Careful review of the hospital patient care record, particularly the H&P report, physician notes, nursing notes, and medication administration record, may yield valuable clues as to the patient's condition and guide the CCTP's bedside assessment. The prehospital patient care record, if available, can also be a valuable source of information. The CCTP should note any details in these reports that suggest the patient has a time-sensitive injury or illness that requires immediate intervention. Time is of the essence when packaging patients with time-sensitive emergencies for transport, and scene time needs to be kept to a minimum.

Diversity and Cultural Considerations

Providing the right care to each patient means more than just following the clinically indicated evidence-based interventions. The right care is patient-centered care, which places patients at the center of the care team and embeds them in care planning. A simple and effective way to include patients in care planning is to ask them about their personal and cultural preferences. Determine patients' gender and address them as they would like to be addressed, which includes using the correct pronouns. Inquire about cultural preferences that may impact their care during transport and while hospitalized. For example, some cultures do not allow blood transfusions. Reviewing a patient's cultural preferences may also help identify social determinants of health, which are predictors of worsened health outcomes. Keep in mind that some cultures are distrustful of health care or follow practices that do not align with Western medicine practices. It is imperative to discuss your treatment plans with patients and align those plans with their cultural needs to the best of your ability.

SAMPLE History

SAMPLE is a familiar and useful acronym for remembering the pertinent details of a patient's history: Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, and Events leading up to the illness or injury. While CCTPs may use this framework to guide their history gathering, they should not think of it as a simple checklist; instead, they should strive to obtain in-depth details for each component.

Signs and symptoms continue to serve a vital role in the ongoing assessment. Determine how symptoms have changed over time, and use the detailed physical exam (discussed later in this chapter) to assess whether physical signs of injury/illness are improving or worsening.

Understanding the patient's allergies is critical. Try to determine whether the patient has medication, environmental, and food-based allergies. Food-based allergies are important because some medications are prepared using food derivatives.

The patient’s medications include any over-the-counter and prescribed medications, recreational drugs, and herbal supplements and vitamins. You should also determine whether the patient has been complying with prescribed medications. Review any ordered medications that need to be continued or administered during transport. Consult medical direction if you believe an ordered medication may not be indicated. Do not delay administration of ordered medications on the assumption that the accepting facility will promptly administer them after arrival. Accepting facility staff will likely need to wait for a new physician evaluation and order before administering medications, which can result in significant delays.

While 9-1-1 providers focus on a *pertinent* past history, the CCTP should consider the patient’s *entire* past medical history. Although some aspects of the history may seem unrelated to a current complaint, diseases are often interrelated, which may increase the risk of complications or influence drug administration decisions. For example, suppose a patient receiving transport for a fractured distal femur requires analgesia. This patient has never broken a bone before but has a history of atrial fibrillation and chronic kidney disease. The medications prescribed for these conditions place the patient at risk for increased hemorrhage, impaired compensation, and slow drug elimination.

Last oral intake actually means *last ins and last outs*. Yes, it is important to document whether a patient has a full or empty stomach, but this questioning falls short. In addition to documenting the last foods and liquids consumed (including time and quantity), CCTPs must document output. Output includes urine output, vomiting, blood loss, bowel movements, and each drain attached to the patient. In the context of the patient assessment, anticipate documenting how much of each output occurs per hour. Urine is the most frequently measured output and should be documented during every patient contact. Normal adult urine output is 0.5 to 1 mL/kg/h. Other drains should be labeled to assist in documenting output.

For the CCTP, *events* describe the context, including the mechanism of injury or nature of illness, leading up to the patient’s hospital presentation, but also interventions and observations that have occurred since then. Although much of this information will be documented in a hospital record, there are two reasons to summarize this information in your records. First, doing so forces each CCTP to obtain a complete understanding of the patient's current condition, which will improve critical thinking when determining treatment plans for the patient. Second, the interfacility transport record must stand as its own complete document for reimbursement and legal purposes.

Transport Paperwork

Paperwork is an essential component of safe, appropriate, and proper interfacility transports. In addition to the transport-specific patient care report, the CCTP must complete other important forms for each interfacility transport.

A *physician certification statement (PCS) form* is required by insurers for reimbursement. The PCS form, more aptly referred to as a medical necessity certification statement, documents the reason for transfer, the risks of transfer, the monitoring and treatment needed during transport, and the patient's physical condition at the time of transfer. As a CCT team member, you must ensure not only that the PCS form is completed but also that it accurately represents the patient at the time of transport and provides the necessary orders for care during transport. Inaccurate PCS forms delay reimbursement for transports and may expose the CCTP to liability for omissions or additions of care during transport.

All interfacility transports require a *patient consent form*. Often the consent is included in an ambulance assignment of benefits (AOB) form. This form states that the patient or their legal representative agrees to ambulance transport and authorizes the release of applicable health records to the ambulance service and the patient's insurer for the purposes of appropriate reimbursement. While it is a best practice to have the patient legibly sign the AOB, the patient's legal representative may also sign the form. When no legal representative is available and the patient cannot sign, this form must be signed by the receiving facility's medical staff to validate that no other appropriate party was available to sign for the patient and the patient arrived at the receiving facility.

Referring Facility Interventions

The patient's history includes the referring facility's management. Specifically, the CCTP should determine any diagnostic tests and imaging performed and their results, the differential diagnosis, and any interventions performed and the patient's response to them.

Tests may include blood samples and laboratory results, radiologic exams, and physical exams. Lab values should be assessed to recognize trends over time and responses to interventions (eg, transfusion, hyperkalemia treatment).

The **differential diagnosis** is the process of selecting the most likely underlying cause of the patient's condition by comparing multiple potential causes of the presenting signs and symptoms. For example, a patient may present with signs and symptoms suggestive of two different disorders, ST-segment elevation myocardial infarction and Takotsubo cardiomyopathy. Thus, these conditions would be included in the differential diagnosis. The actual diagnosis would not be determined until angiography is completed in the cardiac catheterization lab. As a CCTP, you may have access to that diagnosis if the patient is being transferred from a facility where the necessary diagnostic workup can be performed; however, you may be transferring the patient from a facility where such studies have not been completed. In that case, your care may be guided by a **working diagnosis**, which is based on the best information available in the differential diagnosis.

Finally, determine what interventions the referring facility has performed to manage both the patient's underlying problem and the patient's symptoms. These interventions may be separate from one another. For example, in septic shock, a vasopressor may be administered to treat the symptom of hypotension while antibiotics are given treat the underlying infection. CCTPs must understand the differences between interventions that treat symptoms and those that treat underlying problems and recognize when they need to be modified. Whenever possible, the CCTP's interventions should align with the receiving facility's definitive interventions. If the receiving facility has requested interventions that the sending facility has not yet performed, the CCT team should include these interventions in the transport treatment plan, provided they are indicated and within the CCTP's scope of care.

Primary Assessment

The **primary assessment** provides a brief glimpse into the patient's condition. During this assessment, providers place absolute priority on quickly identifying any acute life threats, doing so at the cost of thoroughness. This brief exam should seldom take more than 60 seconds, as acutely life-threatening problems require timely intervention. This survey involves a stepwise, rapid evaluation of organ systems and anatomy fundamentally necessary for life. Primary assessment is also used whenever sudden or unexpected patient deterioration occurs during transport.

Generally speaking, the provider completes the primary assessment while positioned at the patient's head, though many gross abnormalities, such as hemorrhage or pallor, can be noted at a glance from a distance.

While many abbreviations have been used to guide clinicians in carrying out a structured primary assessment, two have taken hold: MARCH and ABCDE. The MARCH acronym, introduced by the Committee on Tactical Combat Casualty Care (CoTCCC), lists assessment priorities in the following order:

- **M**assive hemorrhage
- **A**irway
- **R**espiration
- **C**irculation
- **H**ypothermia

The CoTCCC rightfully prioritizes massive hemorrhage, which is the primary cause of death in trauma. That said, seldom will a CCT team be the first-arriving responders at most incidents; exsanguinating injuries will have likely been addressed long before their arrival. Moreover, the work of a transport team spans all medical domains, and as such the MARCH acronym is likely too specific to trauma care to be the model framework proposed in this text.

The **ABCDE** abbreviation is preferred in this text. It prioritizes the assessment sequence as follows:

- **A**irway
- **B**reathing
- **C**irculation
- **D**isability
- **E**xposure

This abbreviation is already familiar to most providers and applies to the broad patient population seen by transport teams.

XABCDE and CABDE

The ABCDE mnemonic is sometimes adjusted during the primary survey in two scenarios. First, when life-threatening bleeding is present, the sequence may be described as XABCDE, where X represents eXsanguination (life-threatening bleeding). Second, when the patient appears lifeless and is in suspected cardiac arrest, the sequence is described as CABDE to prioritize circulation.

Airway Assessment

Understanding the human airway, including how it is supposed to function and what to do when normal functioning is impaired, is fundamental to patient care. A brief discussion of the airway, in the context of the decision making that occurs during the assessment of a patient in critical condition, is provided here; it is discussed in detail in Chapter 6, *Respiratory Emergencies and Airway Management*, and Chapter 7, *Ventilation*.

Much like other organ systems, the airway is a dynamic anatomic structure subject to change during the course of disease. An airway deemed adequate early in the patient's care may change over time, requiring intervention. Conversely, a threatened airway may become “safe” (meaning the airway is patent and ventilation appears to be effective) following the correction of a broader clinical illness; for example, a lethargic patient with sepsis may regain mentation, and thus airway control, after effective resuscitation.

Determining the Need for Airway Intervention

The first priority of the primary assessment is to determine whether the airway is safe in its current state or whether intervention is needed. This determination is best made collaboratively as a team, with clinical and logistical considerations being weighed to determine if, when, and where airway management should occur.

Anatomic evaluation of the airway is aimed at identifying pathology and diseases of the airway as well as factors associated with difficulty intubating the patient, if that step is required. The exam needs to be tailored to the patient’s ability to follow commands. For example, while a Mallampati classification can yield useful information regarding intubation difficulty, the exam cannot be performed in a supine or obtunded patient. (The Mallampati classification is described in Chapter 6, *Respiratory Emergencies and Airway Management*.)

In transport medicine, several significant, inherent logistical factors can affect clinical decision making. Generally speaking, the most conservative airway plan will be the best and safest option. Intubation, including high-risk anesthesia, is best performed in the least chaotic environment. Providers should err on the side of caution by intubating the patient in the hospital or at the emergency scene prior to transfer. That said, in certain cases, it may be feasible to perform an elective in-transport intubation to mitigate delays to definitive care. In-transport intubation requires careful patient selection and screening, with only patients determined to be reasonably anatomically “easy” being selected. Most importantly, intubation en route requires prior practice and equipment configurations to ensure this intervention does not pose unreasonable risk. Some vehicle types may preclude or complicate intubation. The confined cabin of smaller single-engine aircraft may be a suboptimal environment for in-flight intubation, whereas a twin-turbine aircraft may offer more ample space. Finally, distance and transport time should be weighed when deciding whether to perform airway management. A patient with an already tenuous airway, who has a lengthy transport time, is at risk for requiring emergent intervention in transit.

Assessing the Intubated Patient

For patients with an artificial airway in place, such as a supraglottic or ET tube, the airway and respiratory exam should focus on immediate risks to the patient. The CCTP should consider the life-threatening **sequelae** of an inappropriately placed ET tube. Tube placement and positioning must be confirmed as part of the initial survey. The CCTP should visually inspect the ET tube, including its size and depth. Once ET tube size has been identified, appropriate depth can quickly be approximated by multiplying the tube size times three:

$$\text{ET tube size} \times 3 = \text{Tube depth}$$

Providers must perform auscultation to evaluate for signs of right main stem intubation. A patient with decreased lung sounds on the left side is presumed to have a right main stem placement until proven otherwise.

While physical examination is an important part of confirming ET tube placement, the gold standard in confirming placement is waveform capnography, which measure end-tidal carbon dioxide (ETCO_2) levels. A patient with an artificial airway must be placed on continuous ETCO_2 monitoring. When considering the often hectic, loud environment in which CCT teams often work, ETCO_2 monitoring is a standard of care essential to the safe transfer of an intubated patient.

Because CCT inherently involves relocating and repositioning the patient and medical apparatus, maintaining the security of the artificial airway is paramount. CCTPs must inspect the securing device to ensure it is adequately holding the ET tube in place and, just as importantly, to confirm the securing strap is correctly routed. The securing strap must be routed around the base of the skull, not the occiput. A strap that is secured high over the occiput could slide downward, rendering the device ineffective and threatening ET tube security.

Much like the natural airways of the human body, artificial airways are prone to becoming filled with secretions. Because sedation suppresses the cough reflexes, ET tubes can be blocked by mucus plugs or obstructions by other contaminants such as blood. Evidence of mucus plugging can present with high peak inspiratory pressures and decreased breath sounds. It is not unreasonable to perform a preventive suction maneuver during the initial assessment of the intubated patient. An added advantage of suctioning during the initial assessment is that it helps providers determine the adequacy of analgesia and sedative infusions. The stimulation that occurs during packaging and transport is similar to that resulting from suctioning an invasive airway. Thus, CCT teams should review the patient’s suction needs during the transport planning stage. If a patient will need frequent suctioning, an in-line suction device should be placed and suction must be available during all phases of patient care.

Respiratory Assessment

Primary assessment of the respiratory system should focus on detecting any injury or illness that is directly affecting the respiratory system. This assessment takes into consideration evidence of illness by proxy, where the respiratory rate, effort, or breathing patterns may suggest underlying nonpulmonary pathology.

Frequently, the first harbinger of illness is a change in the respiratory rate, as this rate fundamentally serves as a compensatory mechanism. A patient with subtle tachypnea may have occult illness, and a patient with air hunger should be presumed to be critically unwell until proven otherwise. A cardinal finding, air hunger suggests dyspnea profound enough to trigger the primal instincts of survival: fear and anxiety. Additionally, a large tidal volume should be assumed to be an adaptive response to acidosis. This finding is particularly important if intubation and subsequent mechanical ventilation are required.

During assessment, it is paramount that providers carefully note the respiratory rate and effort. Establishing the patient's initial rate enables early detection of changes during the course of care. As with other vital signs, trending is more useful than a single value, so providers should repeat this evaluation.

Recognizing Indications of Specific Injuries

Certain respiratory patterns can suggest specific pathology, including diseases involving other organs (eg, metabolic or neurologic disorders). Chapter 6, *Respiratory Emergencies and Airway Management*, describes pathologic breathing patterns. Providers should consider any evidence of dyspnea. Supraclavicular or intercostal retractions suggest an increase in *inspiratory* resistance. In comparison, abdominal "see-saw" breathing, in which the abdominal muscles forcefully contract during exhalation, is suggestive of *expiratory* resistance to flow. This finding may be seen in obstructive lung diseases, though it can also appear during severe dyspnea.

Palpation of the chest wall can provide valuable clues regarding injury burden that may be missed by other means. By placing their open palms over the patient's chest wall, the provider may detect clues that suggest injury, such as rib fractures, flail chest, or pneumothorax. Asymmetry in chest excursion, though subtle, can be seen in patients with significant pneumothorax. Note that this finding is seldom sensitive enough to rule out a collapsed lung and should be considered as part of a constellation of other findings suggestive of pneumothorax. Tactile crepitus over a specific area can indicate fracture of the chest wall; similarly, paradoxical movement of the chest wall can point to flail chest, a condition in which fractures over two points of a rib produce a free-floating segment that moves in the opposite direction as the rest of the chest.

Assessing the Patient on Mechanical Ventilation

This section briefly discusses how to integrate the assessment of mechanical ventilation into the broader patient assessment; a more thorough review of caring for patients on mechanical ventilation can be found in Chapter 7, *Ventilation*. As part of obtaining an initial "snapshot" of an intubated patient, mechanical ventilation parameters should be assessed, with a closer, more targeted assessment to follow.

First, during patient packaging, the CCTP should confirm the adequacy and safety of mechanical ventilation. *Safe* mechanical ventilation implies the patient is receiving ventilatory support that is both adequate and not injurious to the lungs. The first confirmatory steps should be aimed at assessing adequate tidal volume delivery. Providers may encounter a patient who, due to either inadequate sedation or mucus plugging, is not receiving adequate tidal volumes and thus is developing a respiratory acidosis. Alternatively, a patient on noninvasive mechanical ventilation could have declining mental status, resulting in inadequate ventilation. Generally speaking, exhaled tidal volumes should be 5 to 8 mL/kg of ideal body weight. If the tidal volume is significantly above or below this approximation, further investigations should be made.

To determine whether ventilation is injurious to the lungs, peak inspiratory pressure levels should be evaluated. Though high peak inspiratory pressures are not direct evidence of barotrauma, they can be caused by high plateau pressures, which may result in lung injury. Plateau pressure should be maintained at less than 30 cm H_2O in patients with poor lung compliance. Before connecting the ventilator to the patient, a high-pressure alarm should be preset, either by measuring a baseline peak inspiratory pressure from the hospital ventilator or by starting at 30 to 35 cm H_2O and titrating accordingly. A peak inspiratory pressure greater than 35 cm H_2O should prompt further evaluation of ventilatory parameters. As part of the early formulation of the transport plan, the CCT team should review the fraction of inspired oxygen (F_{IO_2}) level. This information will help providers determine anticipated oxygen consumption for transport and can also elicit useful information about the patient's condition. A patient with an oxygen saturation (Sp_{O_2}), as measured by pulse oximeter, less than 92% with an F_{IO_2} of 1.0 is exhibiting significant pulmonary dysfunction.

Teams should screen for patients at risk for hyperoxia, as this condition has clinical significance: A growing body of literature suggests significant patient harm is associated with hyperoxia. Given this risk, patients with $\mathrm{SpO_2}$ levels of 100% with an $\mathrm{FIO_2}$ of 1.0 should have their $\mathrm{FIO_2}$ level down-titrated to an $\mathrm{SpO_2}$ level of 93% to 97%.

Circulatory Assessment

Assessment of the circulatory system requires the collation of information from multiple diagnostic sources, including the physical exam, monitoring equipment, and other diagnostic tools. For the transport team, circulatory assessment may be complicated during ICU transfers by the presence of advanced monitoring tools. That said, the rapid assessment of patient acuity can be initially surmised by simple bedside examination.

Skin

Skin color, temperature, and condition can provide a valuable initial glimpse into illness severity. **Pallor** in isolation, without associated diaphoresis (sweating), may indicate anemia, with its earliest manifestations being found in the mucosa of the eyelids. In conjunction with other skin findings, pallor is a sign of impaired cutaneous capillary perfusion. As part of the sympathetic response to an insult, whether from injury or illness, sweating of the brow or clammy skin is a cardinal sign of inadequate perfusion and increased sympathetic response. Cool skin temperature indicates vasoconstriction and directing of blood away from the superficial dermal layers toward the more essential organs necessary for survival.

Assessing Skin Pallor

The word *pale*, as used in this text, may apply to any patient whose skin presentation suggests reduced blood flow or oxygenation. In patients with light skin, pallor typically presents as unusual lightness compared with the person's baseline skin color. In patients with dark skin, pallor may appear as ashen or gray skin on general assessment. In general, the mucous membranes inside the inner lower eyelid and the oral mucosa will have a pink coloration in all healthy patients, regardless of baseline skin color; thus, a white or pale appearance of these areas in any patient suggests reduced blood flow or oxygenation.

Because providers do not necessarily know the patient's baseline skin color, they should consider the observations of friends or family members on scene. Simply asking, "Does her skin look like its usual color to you?" may produce useful insights into the patient's condition.

While it can be hard to quantify many physical findings, **capillary refill time (CRT)** of the nail bed can serve as a window into the state of peripheral perfusion. Many exam findings, such as the severity of pallor or pulse strength, are subject to the shortcomings of poor interobserver reliability. CRT can be a valuable exam finding that is reproducible by another clinician with reasonable accuracy. In the 2019 ANDROMEDA-SHOCK trial, CRT was found to be as reliable as serum lactate for guiding teams during the resuscitation of patients with sepsis. Considering its ease of use, reliability, and availability, CRT is likely underutilized during patient assessment.

Cold Shock Versus Warm Shock

Assessment of skin temperature may play an additional role in differentiating forms of shock. It has been theorized that "cold shock" suggests disorders resulting in a low cardiac output state. Patients with cold shock present with tachycardia, pallor, decreased peripheral pulses, and cold extremities—the last due to insufficient cardiac output to adequately perfuse the skin. This finding can be seen in cardiogenic shock and hypovolemic shock, both of which are associated with a low output state.

In contrast, "warm shock" suggests adequate cardiac output but vasodilation that is hindering systemic perfusion. The vasodilatory state causes a relatively warm skin condition and preserved or bounding pulse pressure. This finding is seen in patients with shock secondary to syndromes that cause a vasodilatory state, such as sepsis or anaphylaxis.

Vital Signs

Descriptions of how to obtain and interpret vital signs in specific CCT contexts are presented throughout this text. For the purposes of this chapter, it is worth noting some key insights relating to the use of vital signs during the primary patient assessment.

During the primary assessment, the evaluation of vital signs is limited to looking for evidence of acute instability. However, providers should keep in mind that their initial documentation establishes the reference point against which later vital signs recordings will be compared. Ongoing measurement of vital signs is a fundamental element in documenting trends and responses to interventions (eg, response to vasopressors, ventilatory changes).

In the CCT domain, vital signs serve as both a diagnostic tool and a threshold for intervention. It is essential for the CCTP to be familiar with the use of **mean arterial pressure (MAP)**. While much of prehospital care focuses on systolic blood pressure (SBP) values, the MAP is a more physiologic representation of systemic blood flow.

Finally, CCTPs should remain mindful that vital signs, although an integral part of a patient assessment, are not without their limitations. For example, some types of medications can alter physiologic response (eg, beta blockers may suppress adaptive tachycardia). Failure to consider this possibility could result in misinterpretation of the patient’s condition.

Shock Index

The **shock index**, defined as heart rate divided by SBP, was first described in a Swiss paper in 1967 and was subsequently validated across multiple observational studies. These studies evaluated the use of the shock index to predict mortality and the need for transfusion. It is from these studies that a shock index threshold of 0.9 or greater was identified as being of clinical value in determining critical illness.

A limitation of these observational studies is the relatively young age of the patients included, largely a result of trauma historically being a disease disproportionately affecting the young. Basing the shock index threshold on this young trauma patient cohort leads to particular challenges when dealing with other patients at the extremes of age, including the pediatric and geriatric patient populations.

To account for the variable significance of hemodynamic derangements in the older patient, the age shock index was developed. This tool multiplies the conventional shock index by the person’s age:

$$\text{Age} \times (\text{Heart rate} \div \text{SBP}) = \text{Age shock index}$$

It is reasonable to assume that a shock index of 1.2 would be of greater significance in a 70-year-old than in a 22-year-old. Thus, the age-adjusted shock index increases the accuracy with which we can predict mortality in an injured patient who is older than 55 years. A cutoff value of 50 is used to avoid arbitrarily high values.

Considering the significant variations in hemodynamics across age groups in children, the conventional shock index can be an unreliable tool for grading illness or injury severity in this population. The shock index pediatric-adjusted (SIPA) was derived to address this problem. It clusters heart rate and blood pressure (BP) values by age to establish thresholds for a shock index of statistical and clinical significance:

- 4 to 6 years: 1.2
- 6 to 12 years: 1
- >12 years: 0.9

Assessment of the Patient With Hemorrhage

As part of early assessment of the injured patient, providers must seek sources of hemorrhage. Life-threatening external hemorrhage should have already been controlled prior to the arrival of a CCT team. That said, an initial survey for external hemorrhage should be performed to ensure continued efficacy of the bleeding control interventions performed prior to arrival. Additionally, with the presence of a large distracting major hemorrhage, initial providers may miss other sources of bleeding. The occult oozing bleed, whether from a tourniquet or from a fracture site, can result in a significant amount of blood loss if left unaddressed.

Examination for external hemorrhage must be done early and in a systematic fashion. Extremity sweeps should be performed, including a review of the axillae, groin, and neck. From there, an inspection of the chest, abdomen, and back must be made. If a truncal injury is found, it is paramount to inspect both sides of the patient to avoid missing an associated exit wound. Extremity wounds should be packed, dressed, and splinted. If a tourniquet has been placed prior to the CCT team’s arrival, its efficacy should be confirmed: The hemorrhage must be controlled and there must be no palpable distal pulse to the limb. Care should be taken to secure the tourniquet to avoid its accidental dislodgement or release during patient moves.

Signs of internal hemorrhage can be difficult to detect. Grey Turner sign (ecchymosis of the flanks) is a late finding, seldom seen during the initial transport phase, and should not be relied upon for early detection of internal bleeding. Instead, detection relies on thoughtful consideration of the mechanism of injury and detection of external signs of blunt trauma. Examination of the skin for abrasions and underlying contusions is helpful to guide assessment. From there, palpation may reveal point tenderness over solid organs. Seat belt sign is a significant finding, particularly in the patient with tenderness on exam, as the risk of organ injury can be high.

Evaluation of the pelvis is an important part of the exam of the major trauma patient. CCTPs should examine the pelvis for injury in patients who have experienced a significant mechanism of injury, including a vehicle rollover or ejection, significant fall, or vehicle–pedestrian collision. Through gentle palpation, providers should evaluate symmetry of the anterior-superior iliac spine. CCTPs should also review imaging studies conducted at the sending facility prior to their arrival.

Gastrointestinal Assessment

Inspection

A general overview of the oral mucosa and abdominal areas gives CCTPs general information about the gastrointestinal (GI) system. For example, the lips and mucous membranes should be moist and without lesions. Dry mucous membranes may indicate dehydration, and pale mucous membranes may indicate hypovolemia. A large abdomen may indicate ascites, especially if abdominal wall veins are noted. Hernias or masses may be visible. Bruising over the abdominal wall may indicate trauma or bleeding into the abdominal cavity.

Critical care patients often have GI bleeding as a secondary stress response to their illness. Stools should be assessed for color, consistency, and a foul odor. Upper GI bleeding is characterized by dark melena stools, and lower GI bleeding by stools mixed with bright red blood (although bright red blood may also suggest brisk bleeding from higher up). Either of these findings should be reported promptly.

Auscultation

In the GI assessment, auscultation of the abdomen should precede palpation or percussion of the abdomen. The rationale is that the CCTP may get a false-positive assessment for bowel sounds if manual manipulation of the intestines occurs first. Bowel sounds should be present in all four quadrants of the abdomen. These sounds may be hypoactive or hyperactive in various disease states. Nevertheless, there is great variation in bowel sounds with clinical conditions such as an ileus.

Auscultation of bowel sounds, if necessary, should be done in a quiet ICU or ED room. Bowel sounds auscultated during transport have a tendency to sound exactly like the engine of the transport vehicle.

Palpation

A CCTP typically uses palpation to document tenderness or rebound tenderness. Tenderness occurs with simple palpation; rebound tenderness occurs when the pain is reported as the pressure of palpation is removed. Rebound tenderness suggests peritoneal inflammation.

If a pelvic fracture is suspected, the pelvis should not be assessed for stability by every caregiver. Any hematoma that has formed to maintain hemostasis in such a case may be disrupted by the repeated palpation exams, inducing internal hemorrhage.

The **Murphy sign** is noted when the patient has severe right upper quadrant pain on deep palpation, which is often exacerbated by deep inspiration and associated with cholecystitis. Deep palpation is performed by applying firm pressure to the abdominal wall. The liver may also be palpated by placing the left hand behind the patient under the liver and applying firm pressure upward. The fingers of the right hand are placed on the right upper quadrant of the patient’s abdomen, and the patient is asked to take a deep breath. The edge of the liver can be felt as it comes down to meet the examiner’s fingers **FIGURE 5-2**. Next, the applied pressure is lightened and nodules or tenderness are noted as the liver slips under the fingers. Nodules of the liver may be related to a malignancy.

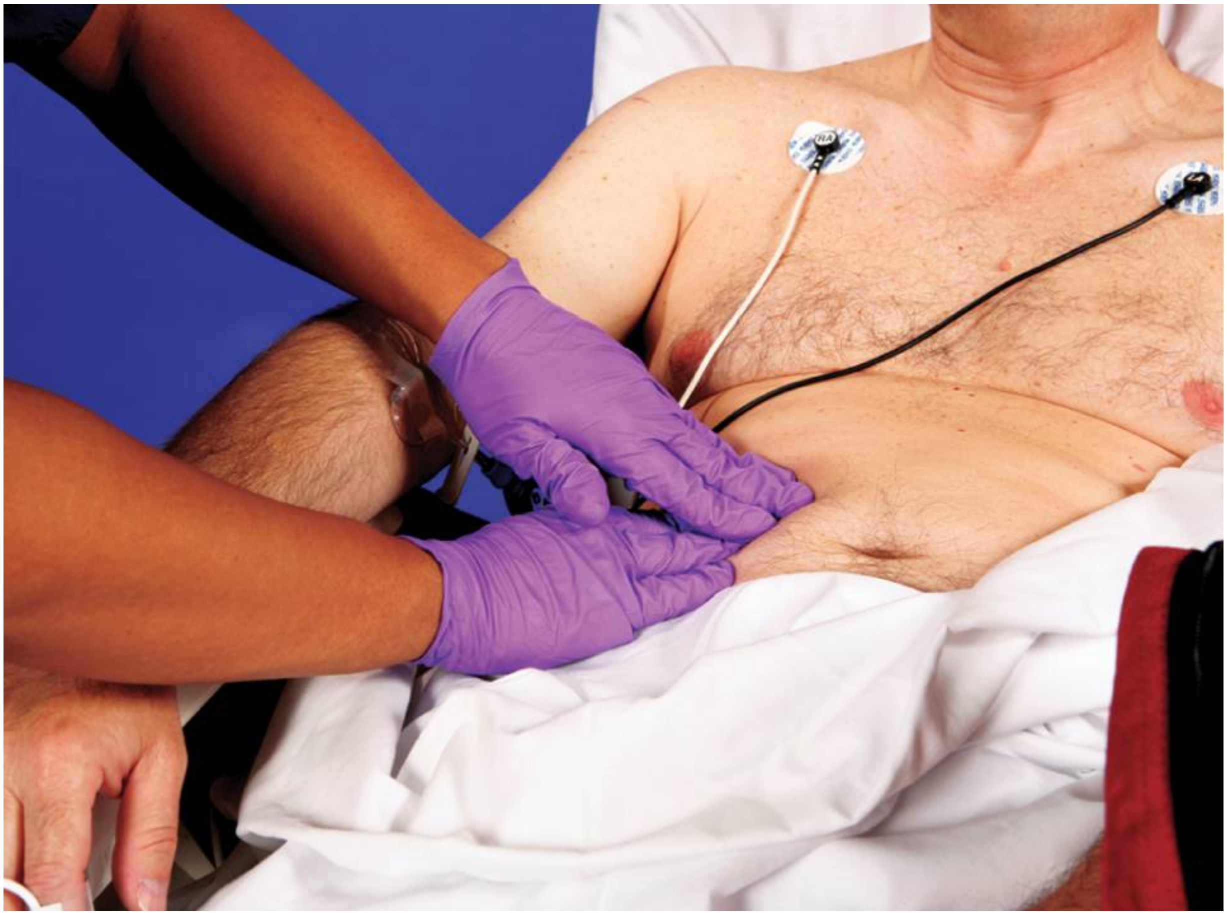

FIGURE 5-2 Palpation of the liver.

© Jones & Bartlett Learning.

The spleen is generally not palpable. The right kidney may be palpated, but this examination is not of much clinical value. The kidney should never be palpated if the patient has a history of polycystic kidney disease.

Genitourinary Assessment

Assessment of the genitalia includes the mammary, testicular, and prostate glands. These assessments are limited to patients with specific needs, such as those with spinal cord injuries or trauma.

In end-stage renal disease, patients may require peritoneal dialysis (PD) or hemodialysis. In PD, a catheter is placed in the peritoneum, and the peritoneum serves as the filter to remove waste from the peritoneal cavity using a dialyzing solution. Patients who rely on this type of dialysis are especially prone to peritonitis. Therefore, an aseptic technique is important when assessing or performing PD. Patients undergoing hemodialysis will often have an arteriovenous (AV) shunt in the forearm or thigh, or a tunneled dialysis catheter in the chest.

The AV shunt should be assessed for a thrill, which indicates that the shunt is patent and functioning normally. AV shunts should be used only for hemodialysis. In patients who have a central line and a tunneled line access for dialysis, these lines should not be accessed except in dire emergency and only while maintaining the strictest sterile technique possible. Additionally, these lines are typically heparin locked at the completion of treatments. Lines that contain heparin should not be flushed prior to aspiration of a significant amount of waste (a minimum of 10 mL per port).

Disability Assessment

The neurologic exam should be performed not only during initial survey, but also subsequently during transport to establish and monitor for trends. Neurologic emergencies can be dynamic, particularly in the acute phase, during which the CCT team may be involved in the patient's care. The exam can be tiered, with an initial exam focusing on identifying major neurologic pathology and a subsequent, more thorough exam focusing on detecting more subtle findings.

Neurologic Scoring

As part of the initial survey, the patient's level of consciousness should be determined. The most rudimentary means of assessment is to determine patient responsiveness to voice or pain using the **AVPU scale** **TABLE 5-1**. In the absence of sedatives, failure of the obtunded patient to respond to a painful stimulus is concerning for major intracranial pathology.

TABLE 5-1 AVPU Scale

Awake: eyes open spontaneously

Verbal: arouses to stimulation by voice

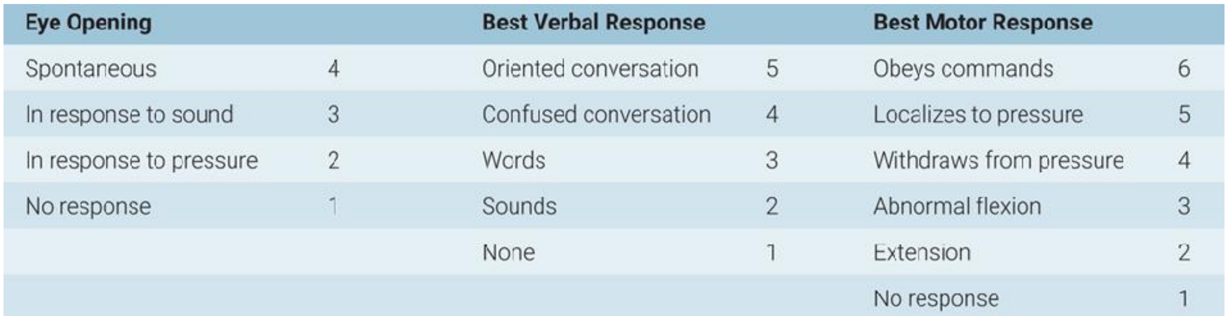
Painful: purposeful movement to a painful stimulus such as a pectoral pinch

Unresponsive: not responsive to any stimuli

© Jones & Bartlett Learning.

While the Glasgow Coma Scale (GCS) was initially developed and validated for the purpose of neurologic prognostication following traumatic brain injury, it has become the de facto means of measuring and conveying mental status across health care settings. Though it remains subject to poor interobserver reliability, this scoring tool is best applied in a structured fashion with the use of a reference guide, such as that shown in **TABLE 5-2**.

TABLE 5-2 Glasgow Coma Scale



Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to sound	3	Confused conversation	4	Localizes to pressure	5
In response to pressure	2	Words	3	Withdraws from pressure	4
No response	1	Sounds	2	Abnormal flexion	3
		None	1	Extension	2
				No response	1

[a] Some systems use a “Not testable (NT)” score for any element that cannot be tested. Eye opening cannot be tested in a patient whose eyes are closed due to a local factor, such as swelling; verbal response cannot be tested in a patient who has a preexisting factor interfering with communication, such as mutism; and motor response cannot be tested in a patient who has preexisting paralysis or other limiting factor.

Score: 13–15 may indicate mild dysfunction, although 15 is the score a person without neurologic impairment would receive.

Score: 9–12 may indicate moderate dysfunction.

Score: 8 or less is indicative of severe dysfunction.

© Jones & Bartlett Learning.

Description

One of the most common errors made with the GCS is assuming that the tool's value lies in the total derived score. In reality, the tool more accurately conveys the patient's condition when each component's score is reported individually.

Another scale, useful for assessment of both agitation and sedation, is the **Richmond Agitation–Sedation Scale (RASS)**. The RASS score is often used as a target for sedation. With an agitated patient, this score quantifies the severity of the agitation **TABLE 5-3**. To determine the RASS score, observe, but do not speak to or otherwise engage, the patient. Scores of +1 to +4 can be observed without interacting with the patient. If necessary, speak to the patient to determine the patient's response and thereby assign a score of 0 or –1. A score of –2 means the patient responds to verbal stimulation with eye contact lasting less than 10 seconds; a score of –3 indicates that a voice stimulus triggers a motor response other than eye opening; –4 means only physical stimulation elicits a response; and –5 signifies no response to any stimuli.

TABLE 5-3 Richmond Agitation–Sedation Scale

Score	Classification	Description
Observation		
+4	Combative	Violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent nonpurposeful movements, fights ventilator
+1	Restless	Anxious but movements not aggressive, vigorous
0	Alert and calm	Spontaneously pays attention to caregiver

Score	Classification	Description
Verbal Stimulation		
–1	Drowsy	Not fully alert, but has sustained awakening (eye opening or eye contact) to voice (>10 seconds)
–2	Light sedation	Briefly awakening to voice with eye contact to voice (<10 seconds)
–3	Moderate sedation	Movement or eye opening to voice (but no eye contact)
Physical Stimulation		
–4	Deep sedation	No response to voice, but movement or eye opening to physical stimulation
–5	Unarousable	No response to voice or physical stimulation

Focused Neurologic Assessment

Assessment of the patient with a suspected neurologic disorder includes efforts to identify signs of disease by proxy. During this assessment, examination of visual fields, sensation, or balance may provide outward evidence of dysfunction deep within the brain. As such, targeted neurologic assessments require careful attention to a broad list of findings.

For the CCT team, primary assessment of neurologic status should be envisioned as occurring at three phases of care: (1) prior to the event, (2) on initial presentation, and (3) on team arrival for transfer. This approach establishes a comprehensive baseline that will allow providers to note any trends and changes during transport.

It has been said that “the eyes serve as windows into the brain,” as they provide valuable and early indications of neurologic disease. Beyond conventional pupillary assessment, there is great value in assessing visual fields and observing for nystagmus. The assessment of visual fields aims to identify lesions affecting the patient’s ability to perceive objects within their field of view. Patients with medial or posterior cerebral artery occlusions can lose the ability to identify objects placed within the left or right side of their visual field. This exam can be performed by asking the patient to follow a fingertip that sweeps across their visual field, while encouraging them to keep their head midline. Inability to track objects across midline is suggestive of visual field hemianopia.

Gaze-induced nystagmus is also of diagnostic value, particularly when trying to identify posterior cerebral lesions. This finding can be detected by observing the patient's eyes during extraocular movements; nystagmus induced by gaze will become apparent when the eyes are moved laterally or upward and downward.

Pupil Assessment

Another neurologic indicator of great concern is the pupil assessment. Pupils are assessed bilaterally for size (1 to 6 mm), reactivity to light (direct and consensual), and shape. **TABLE 5-4** lists common pupil findings related to size and reactivity and their possible causes.

TABLE 5-4 Pupil Response

Pupil Finding	Possible Etiology
Unilaterally dilated, fixed, and nonreactive	Increased intracranial pressure May be normal in some patients Brainstem herniation Impending death
Bilaterally dilated, fixed, and nonreactive	Hypoxia Severe brain damage at the level of the midbrain
Bilaterally pinpoint and nonreactive	Narcotic use Severe brain damage at the level of the pons Ischemia

© Jones & Bartlett Learning.

Pupil reactivity to light is described as brisk, sluggish, or nonreactive. Occasionally, a CCTP will note a pattern of response in which rapid constriction of the pupil in response to light is followed by dilation. This so-called **hippus phenomenon** may be a variant of normal, but it is also seen with compression of cranial nerve III. **Anisocoria**, or unequal pupil size bilaterally, is a normal variant and is seen in approximately 17% of the population.

Unexplained changes in pupil assessment findings should be reported immediately. Consideration must be given to medications the patient is receiving (such as narcotics or cholinergics), anxiety, and other extraneous influences on pupils.

Speech should be assessed for impaired ability to speak such as dysarthria and dysphasia. Following ischemic stroke, the loss of control of the muscles of the face, tongue, or larynx can lead to a muffled speech despite appropriate word choice.

Cranial Nerve Assessment

A cranial nerve assessment is valuable in a patient with a neurologic insult. Subtle changes may indicate impending herniation. Cranial nerve assessment is covered in detail in Chapter 12, *Neurologic Emergencies*.

Assessment of cranial nerve III (the oculomotor nerve) is especially helpful in caring for the patient with a neurologic insult. Changes in the extraocular movements and papillary response controlled by this nerve are often the first signs of an increase in intracranial pressure (ICP).

Exposure Assessment

After addressing the ABCD phases of the initial assessment, the CCTP should expose the patient to conduct a rapid head-to-toe, anterior and posterior, assessment of the entire patient. Exposure affords the CCTP the opportunity to make key observations, such as scars that may provide clues to remote history, pressure injuries, and items that have inadvertently slipped under the patient during resuscitation and must be removed to avoid pressure injuries during transfer.

Although exposing the patient inherently increases their risk of hypothermia, doing so is actually an important step in ensuring normothermia. Wet clothes should always be removed, because they significantly contribute to cooling and create an opportunity for skin breakdown during prolonged contact. Removal of clothing is also beneficial when pelvic binders are indicated because these devices are best placed on bare skin. Placement on bare skin mitigates skin breakdown and, more importantly, avoids the need for subsequent loosening and removal of the splint before imaging is performed at the receiving hospital. Loosening the splint would result in a loss of hemostasis of underlying pelvic hemorrhage, undermining resuscitation efforts.

Open wounds should be evaluated for severity and continued bleeding. Open fractures should be splinted and bandaged. Contaminated wounds ideally should be irrigated to help mitigate the risk of infection. As a CCTP, your primary role may be ensuring that wound management performed prior to your arrival continues during transport to provide adequate hemorrhage control. In patients with major penetrating trauma, you may need to repack wounds.

CCTPs should also assess splinting efficacy, and replace any splints that do not adequately stabilize fractured limbs. Ensure that distal circulation is not compromised by the splint. Further, check for adequate padding under the patient, as inadequate padding can result in pressure injuries.

In the CCT setting, edema and pressure injuries are particularly relevant concerns given the increased likelihood that the patient has been bedbound for an extended time. When edema is present, its location and severity should be noted. Pedal edema is usually graded on a scale from trace to 3+ or 4+ pitting, depending on the scale used **FIGURE 5-3**. To evaluate pedal edema, press on the skin behind the medial malleolus, over the shin, and over the dorsum of each foot with the thumb and index finger for at least 5 seconds. Indentation can be noted by running the pads of the fingers over the area pressed. A slight indentation that disappears in a short time is termed trace edema. Grade 3+ or 4+ (depending on the scale) is deep pitting that does not disappear readily. The location of the edema and the usual position of the patient should be noted to differentiate between dependent and nondependent edema. In ambulatory and seated patients, edema develops in their lower extremities, whereas patients confined to bed may have more edema in the sacral area.

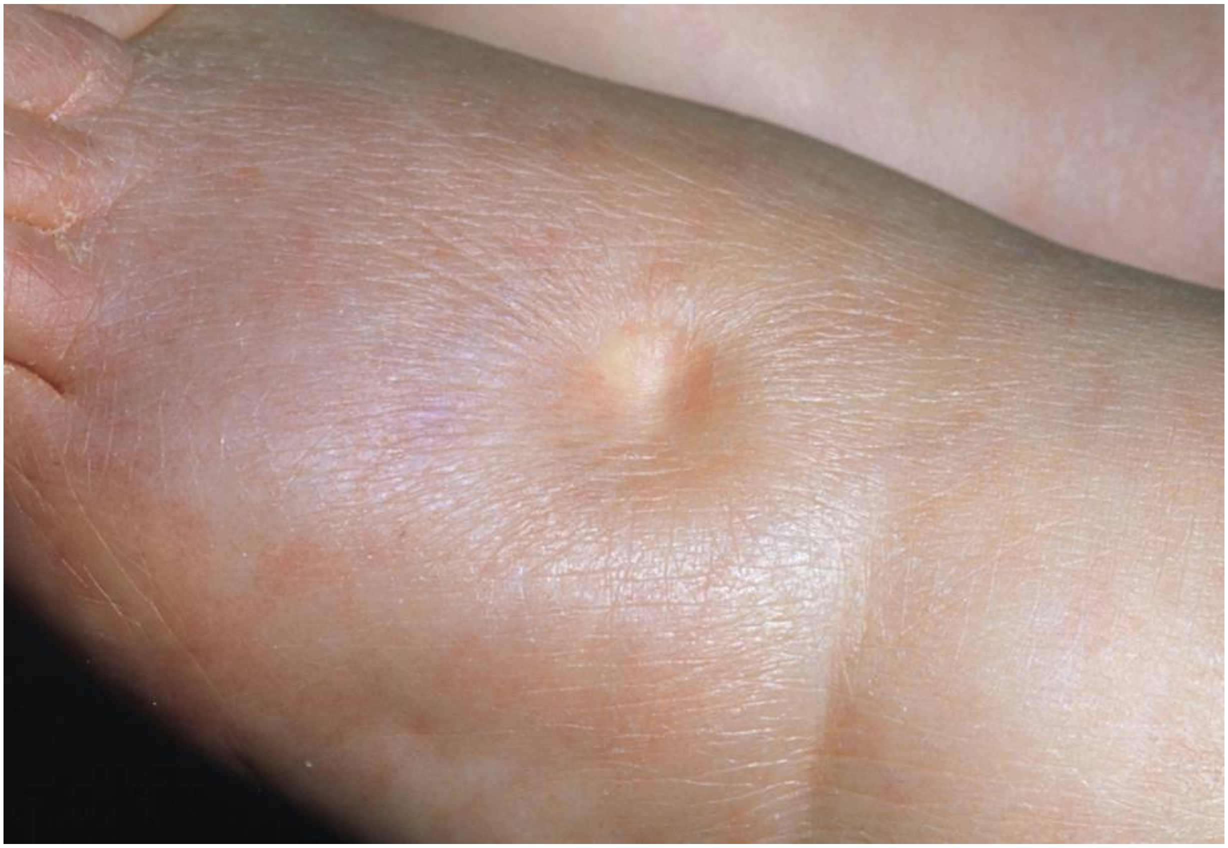

FIGURE 5-3 Pitting edema.

© Dr. P. Marazzi/Science Source.

As mentioned earlier, the exposed patient is at increased risk of hypothermia. Following exposure of the patient, a plan must be made to maintain normothermia. Considering that critical illness and injury as well as sedation suppress adaptive mechanisms to the cold, patients under the care of a CCT team are at risk for hypothermia. Patients should be covered with dry, warm blankets whenever possible. The use of moisture–vapor barriers such as blankets can also assist in maintaining patient warmth. Kits specifically designed to mitigate hypothermia provide excellent thermal insulation; these kits are extensively used by the military but are also available in the commercial market. On the lower end of the cost spectrum, bubble wrap has been used by some mountain rescue teams to help stave off hypothermia.

Skill Drill 5-1 shows the steps for packaging patients for interfacility transports, which are also described here:

SKILL DRILL 5-1 Packaging Procedure for an Interfacility Transport

Step 1

Transfer the patient to the transport ventilator, duplicating as many settings as possible. It may take a few minutes for the patient to become acclimated to the transport ventilator.

Step 2

Once monitoring equipment is in place, transfer any infusions to the transport infusion pumps. Consolidate infusions wherever possible. Use a nursing drug reference to confirm medication compatibility.

1. Transfer the patient to the transport ventilator, duplicating as many settings as possible. It may take a few minutes for the patient to become acclimated to the transport ventilator **STEP 1**.
2. Once monitoring equipment is in place, transfer any infusions to the transport unit infusion pumps. Consolidate infusions wherever possible. Use a nursing drug reference to confirm medication compatibility **STEP 2**.
3. Be certain to:

   - Read the labels of the medication bags **STEP 3**.
   - Trace the infusion tubing completely between each bag and its connection to the patient **STEP 4**.
   - Label the distal end of the tubing with the infusion name **STEP 5**.
4. Secure all equipment to the transport unit stretcher or carrier, bundle the patient as appropriate for the weather conditions, and reassess the patient to ensure that no change in their condition has occurred **STEP 6**.
5. Before leaving the patient care area, be certain that all necessary equipment adapters and connectors are with the patient, ensure that family members have directions to the receiving facility, and provide the sending staff with contact information should they want to follow up on the transport of the patient. Show your appreciation for the care and assistance provided by the staff in packaging and transferring the patient to your care.

Secondary Assessment

Begin the secondary assessment after completing the primary assessment and identifying and stabilizing immediate life threats and hemodynamic instability. The **secondary assessment** involves several components, including a detailed head-to-toe examination, a systems-based approach to specific diseases, and a complete evaluation of vital signs. Specific systems-based and disease-based assessments are detailed throughout this text. Every patient should receive a detailed physical exam, and a best practice is to perform the same head-to-toe exam on every patient. This discipline helps CCTPs master their understanding of "normal," which increases the likelihood of identifying subtle abnormal findings earlier.

Another key reason for the secondary assessment is to detect changes in the patient's condition. For example, following abdominal trauma, bruising may not develop for several hours; similarly, a flail chest may not become visually apparent until the thoracic muscles have become fatigued. Patients encountered later in their injury or disease process, the time when CCTPs are often involved in the patient's care, are likely to have different findings than those seen initially.

Finally, as a part of the secondary assessment, CCTPs must evaluate invasive equipment in use on each patient as well as any fluids infusing.

Vital Signs

Initial vital signs will nearly always be available from referring facilities and obtained during the primary assessment. Basic vital signs warranted for every patient include pulse rate, BP (including MAP), respiratory rate, pulse oximetry, mental state, and patient temperature. Single measurements of vital signs are rarely significant or helpful. Instead, the greatest value of vital signs comes from their ongoing monitoring and trending over time. Patients whose vital signs are unchanging are typically stable. Changing vital signs indicate the patient's condition is changing: The more rapidly the vital signs change, the more rapidly the patient's condition is changing.

Placing patients on a cardiac monitor for continuous monitoring is often appropriate. When patients do not require ongoing cardiac monitoring, the frequency with which vital signs are reassessed is somewhat debatable. The CCTP should determine an appropriate interval for this reassessment based on clinical findings, anticipated outcomes, and local practice protocols. Typically, reassessments are conducted every 5 to 15 minutes. Additional vital signs to consider include capnography, central venous pressures, ICP, airway pressures in intubated patients, and pulses in injured or cannulated extremities.

Spo_2 Versus Sao_2

The terms SpO_2 and SaO_2 are often erroneously interchanged.

- SpO_2, which stands for oxygen saturation as measured by pulse oximeter, measures the number of hemoglobin molecules passing the device's infrared light. Conventional pulse oximeters cannot distinguish when oxygen molecules, as opposed to other molecules, are saturating hemoglobin. Pulse oximeter readings are expressed as a percentage.
- SaO_2 stands for oxygen saturation as measured in the plasma by an arterial blood gas machine. Some point-of-care devices calculate SaO_2, in which case the value is expressed as $cSaO_2$.

Capnography

Capnography is a tool used to evaluate and monitor the respiratory carbon dioxide levels in critically ill patients **FIGURE 5-4**. This reading may be obtained by measuring $ETCO_2$ via mainstream or side-stream sampling of exhaled gases, or by measuring the partial pressure of carbon dioxide (PCO_2) via blood gas sampling.

Description

While there is little practical difference in mainstream and side-stream sampling, there is a difference between ETCO_2 and PCO_2 readings. ETCO_2 values will always be lower than PCO_2 values, as carbon dioxide diffuses from high-pressure to lower-pressure environments. Thus, for this gas to diffuse from the bloodstream to the lungs, the carbon dioxide concentration must always be higher in the bloodstream. The gradient between PCO_2 and ETCO_2 values in healthy patients is typically only 2 to 5 mm Hg. Because the normal P_{CO_2} level is 35 to 45 mm Hg, and given the small gradient between P_{CO_2} and $ETCO_2$ values, the same range is generally recorded for $ETCO_2$ even though it is expected to be slightly lower. However, in critically ill patients, particularly those with lung disease or a ventilation/perfusion mismatch, the gradient may be much larger. A focused review of critically ill patients being treated in ICUs found poor correlation between the two values and recommended against using $ETCO_2$ values as a surrogate for P_{CO_2} values. Thus, in critically ill patients, $ETCO_2$ is a reasonable tool to monitor for changes in their condition, but only P_{CO_2} should be used to monitor the ventilation strategy's effectiveness.

Evidence supports the use of $ETCO_2$ as an indicator of metabolic acidosis in critically ill patients with septic shock or diabetic ketoacidosis. $ETCO_2$ also represents cardiac output when ventilation and oxygenation are maintained at a steady state, which explains its use in monitoring the effectiveness of CPR.

Vital Signs as an Indicator of Underlying Diseases

When linked together, several groupings of vital signs can provide evidence for specific underlying disease states.

In *pulsus paradoxus*, the patient's BP declines by greater than 10 mm Hg during inspiration. In some patients, this condition may also be associated with the loss of peripheral pulses. Pulsus paradoxus needs to be considered within the overall context of the patient's clinical presentation and may indicate cardiac tamponade, advanced obstructive lung disease (chronic obstructive pulmonary disease and asthma), or croup; it occurs because of excessive pressures compressing the right side of the heart.

The *Beck triad* is the combination of three findings: hypotension or narrowed pulse pressure, muffled heart tones, and jugular venous distention. Beck triad is associated with pericardial tamponade, although studies have suggested it is actually present in fewer than 20% of these cases.

The *Cushing triad* is highly suggestive of increasing ICP and presents first with hypertension and tachycardia. Without intervention, it progresses to the classic findings of hypertension with a widened pulse pressure (declining diastolic BP), bradycardia, and abnormal respirations. While respirations are sometimes described as *decreased*, providers should look for abnormal breathing patterns such as Biot or Cheyne-Stokes respirations. Both of these patterns feature overall slow respirations, but the respirations are also highly irregular. Chapter 6, *Respiratory Emergencies and Airway Management*, further discusses breathing patterns.

Aortic dissections may be associated with different BP readings between the patient's right and left arms. The left arm often has a higher SBP, and a difference of greater than 20 mm Hg is suggestive of aortic dissection.

As patients progress through *hemorrhagic shock*, vital signs follow a predictable pattern. The body attempts to keep SBP at a normal level. As long as the body is compensating, SBP is relatively unchanged, while both pulse and respirations continuously increase. The more rapidly pulse and respirations are rising, the more quickly shock is progressing. Simultaneously, urine output decreases along with skin perfusion. Decompensated shock begins when both BP and mental state begin to decline.

Assessment of Severity

Many clinical scores are available to help clinicians objectively assess the severity of disease and injury. The CCTP must be proficient in selecting the correct assessment tool for the patient, administering it, and interpreting its results. It is often during the ongoing assessment phase, after the patient's most urgent needs have been addressed, that these tools come into play.

Assessment tools are often tailored to specific organ systems. For example, the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) and quick SOFA (qSOFA) scores are used to rapidly identify life-threatening organ dysfunction caused by a dysregulated host response to infection, culminating in septic shock; these scores are discussed in detail in Chapter 10, *Resuscitation, Shock, and Blood Products*. Likewise, the shock index, which was discussed in the primary assessment portion of this chapter but is also applicable during the secondary assessment, is a predictor of post-intubation hypotension (score > 0.8) and cardiac arrest (score > 0.9).

Scales relating to pain and sedation tend to have wider application across patient encounters. Sedation scores should be obtained in all patients receiving ongoing sedation, including push-dose benzodiazepines. The most widely used ICU sedation score is the RASS score, introduced earlier in the chapter (Table 5-3). This scale has a range of +4 to –5. Patients with scores of +1 to +4 may require additional sedation, and those with a score of 0 are considered calm and alert. Providers sedating nonintubated patients should generally target a score of –1 or –2, whereas scores of –3 to –5 should be associated with only intubated patients during CCT.

Pain is a vital sign and should be monitored over time using validated pain scales. The perception and severity of pain are unique to each patient. Use a numeric pain scale of 0 to 10, where 0 is no pain and 10 is the worst pain the patient has ever experienced, when patients are at least 9 years of age and are able to communicate effectively with the transport team. The Wong-Baker FACES Pain Rating scale is appropriate for patients older than 3 years, including adults, who may have difficulty using a numeric scale **FIGURE 5-5**. Both the FLACC (Face, Legs, Activity, Cry, Consolability) scale **TABLE 5-5** and the CRIES (Crying, Requires oxygen, Increased vital signs, Expression [facial], and Sleeplessness) scale **TABLE 5-6** are validated scales for pediatric patients.

Description

Reassess pain throughout transport, after analgesia, and following painful procedures. Premedicating patients with analgesia prior to painful procedures may be appropriate.

IV Access and Fluid Therapy

While completing your secondary assessment, ensure that the patient has appropriate IV access. Discuss your plan of care with the other team members, and review anticipated medication administrations. If the planned drugs are not compatible with each other, establish additional lines so that all indicated therapies may be given. When IV access cannot be obtained, consider obtaining intraosseous access or placing a central line.

After ensuring appropriate IV access, review the IV fluids being administered to the patient. IV fluids for volume resuscitation must be isoelectric and free of additives. Ensure that hourly fluid input is at least equal to hourly urine output plus other volume loss (eg, vomiting, blood loss). Recall that normal urine output is 0.5 to 1 mL/kg/h. Also consider insensible fluid loss, such as the fluid lost during exhalation—particularly when transporting pediatric patients. See Chapter 24, *Pediatric Emergencies*, for further details on the unique challenges of managing fluid volume in this population.

Different fluids can have different effects on patients; therefore, fluid selection must be carefully considered. Normal saline is actually hyperchloremic and has a pH of roughly 5.5. Lactated Ringer solution is more neutral, with a pH of 6.5; however, it is slightly hypotonic, with an osmolarity of 272 mOsm/L and sodium level of only 130 mEq/L. Two more balanced fluids are gaining popularity for volume resuscitation: Plasma-Lyte and Normosol. Both are more pH neutral and have more balanced electrolytes.

Ongoing Assessment

Imaging

As transport medical care has evolved, diagnostic tools previously available only within the confines of a hospital have been modified for use in the out-of-hospital setting. Imaging modalities such as ultrasonography, radiography, and computed tomography are increasingly available to CCT teams during patient transport. Imaging techniques are discussed broadly in Chapter 9, *Laboratory Analysis and Diagnostic Studies*, but also more specifically throughout this text in the context of specific injuries and illnesses.

In the context of the CCT team's assessment, providers will identify which imaging has been completed and why, determine which actions have been taken based on the imaging findings, and decide which additional imaging is still needed. The information gained from these studies can be indispensable in anticipating the patient's needs and monitoring the patient's ongoing condition and response to interventions. For example, ultrasonography provides a bedside assessment of cardiac status, allowing providers to grade the function and condition of the left and right ventricles; in effect, this tool provides rapid snapshots into cardiac output and thus a glimpse inside the patient's chest at the point of care.

Electrocardiography

Electrocardiography is a valuable tool to CCT teams, just as it is to their prehospital EMS counterparts. Beyond providing continuous monitoring of a patient undergoing transport, 12-lead electrocardiography is an essential diagnostic tool with innumerable uses, spanning the broad spectrum of patients seen by transport teams.

Twelve-lead electrocardiography can serve a purpose in settings other than the conventional cardiac transport. It can reveal useful information for patients with many disorders, including acute right ventricular failure, pulmonary embolism, metabolic disorders, and toxicologic issues. While Chapter 14, *Electrophysiology, Pacemakers, and Defibrillators*, provides a detailed review of the 12-lead electrocardiogram (ECG), CCTPs must be familiar with ECG findings associated not just with diagnostic criteria, but also treatment criteria. For example, a patient who has overdosed on tricyclic antidepressant (TCA) medication will present with ECG abnormalities associated with the resulting sodium channel blockade. ECG findings are routinely used as a treatment trigger, where widening QRS duration indicates sodium bicarbonate administration.

Electrocardiography is also valuable because it can be performed in a serial fashion. In the example of a TCA overdose, obtaining repeat 12-lead ECGs is necessary to monitor for worsening toxicity. Such monitoring is also important for patients with cardiac disorders, whereas a patient being transferred for non-ST-segment elevation myocardial infarction may develop ECG evidence of ST-segment elevation during transfer, prompting the need for emergent reperfusion therapy. Serial ECGs should be obtained whenever the patient's initial 12-lead ECG contained abnormal findings and following any change in the patient's condition.

Evaluating Tubes and Lines

Ongoing clinical care for many patients requiring interfacility transport involves insertion of invasive devices. CCTPs must recognize the indications for invasive equipment, assess each device's patency and effectiveness, and monitor for complications.

Gastric Tubes

Nasogastric and orogastric tubes may be placed to facilitate gastric decontamination, medication administration, or ongoing drainage of the upper GI system when treating bowel obstructions. In less common situations, a gastric tube may be placed to confirm a GI hemorrhage or to look for evidence of an esophageal rupture. Gastric tubes can help reduce the risk of aspiration but will not prevent it as a stand-alone intervention.

Nasogastric tubes are typically used unless a patient is unresponsive and intubated. When inspecting these tubes, ensure they are properly secured (ie, taped in place). Note the tube size and depth at the beginning and end of transports. The staff at the referring facility should have confirmed gastric tube placement via radiography before placing the tube on intermittent suction. When feasible, review the radiograph: Trace the gastric tube down the esophagus and observe the tip's position, which should be clearly visible below the diaphragm and at least 10 cm into the stomach. Although it is common to inject air into the stomach during gastric tube placement (listening for a "whoosh" sound), doing so is not an acceptable way of confirming placement. Observing gastric aspirate in the tube indicates that aspirate is being suctioned from the body, but it does not confirm where in the digestive tract the tube has been placed.

Once their placement is confirmed, gastric tubes are placed on low intermittent suction. It is reasonable to disconnect gastric tube suction while moving a patient to and from an ambulance; however, do not leave the tube capped throughout transport. Gastric tubes must continue to drain regularly to effectively remove the fluid developing within the upper GI tract.

Foley Catheters

A Foley catheter is indicated when patients have ongoing incontinence or require accurate fluid output monitoring. Normal urine output is 0.5 to 1 mL/kg/h, but occasionally higher urine output is desired, such as in the treatment of **rhabdomyolysis** or fluid overload. Foley catheters pose particularly high risk for infection, and the Centers for Medicare and Medicaid Services will not reimburse hospitals for infections associated with Foley catheter insertion. Thus, most health care systems will evaluate the need for continued Foley catheter use every 24 hours.

Begin assessing a Foley catheter by inspecting its entrance site. The site should be free of redness, drainage/discharge, and pain.

Urine should be present in the catheter's tubing, and a small amount of blood is also occasionally present following insertion. Ensure the catheter's tubing is secured to the patient's leg with slack between the securing device and the urethra. Note the volume of urine, its color and clarity, and the presence/absence of any particulate matter or blood. Document these findings, and then drain the bag before departing the referring facility; beginning with an empty catheter bag makes it easier to document total output while the patient is your care.

Feeding Tubes

While feeding tubes are rarely placed in the emergency setting, they are used during prolonged hospitalizations to provide enteral nourishment directly into the GI tract. CCTPs may encounter feeding tubes during transfers between ICUs, during transfers to long-term acute care facilities, or when transporting a chronically ill patient experiencing decompensation or an acute illness. The types and purposes of feeding tubes are discussed in Chapter 17, *Gastrointestinal and Genitourinary Emergencies*.

To assess feeding tubes, begin by listening to the patient's bowel sounds. Palpate the patient's abdomen, noting rigidity or pain and tenderness; these signs or vomiting may indicate a feeding tube complication and the need to discontinue feedings. Inspect the stoma where the feeding tube enters the patient. The skin around this hole should not be inflamed or irritated, and there should be no discharge. When the tube is initially inserted, gauze is placed between the feeding tube's flange and the skin; replace this gauze if it is discolored, wet, or dirty.

All patients with a prepyloric tube (ie, a tube that enters the GI tract above the pyloric sphincter) must have their head elevated at least 30° to prevent aspiration; placing the patient supine, even for a short time, creates a risk that gastric contents will migrate up the esophagus and into the hypopharynx. When placing these patients supine, such as for lifting and moving, temporarily pause the feeding. Continue ordered feedings as soon as the patient's head is returned to its elevated position. Enteric nutrition mixes often contain only simple sugars; therefore, discontinuing feeding poses a risk of hypoglycemia. Note that when patients cannot reliably sit up, postpyloric tubes are useful, as they are less likely to be associated with aspiration. Be sure to document the total volume of nourishment administered during transport.

External Ventricular Drains

For the purposes of the secondary assessment, the CCTP must assess the functionality of, and patient's response to, any external ventricular drain (EVD). The management and monitoring of EVDs is discussed in great detail in Chapter 12, *Neurologic Emergencies*. Assessment of the EVD should occur upon patient contact and after all major patient movements, including when moving the patient from one bed to another, after loading the patient into the transport unit, and after unloading the patient at the destination facility.

To assess an EVD, first review the orders for ICP monitoring and cerebrospinal fluid drainage. After reviewing the orders, evaluate the system, beginning at the patient. Never advance or withdraw an EVD! Ensure the drain is properly secured and the tubing is not kinked. Trace the tubing to the ICP drain and confirm all connections are tight. Align the ICP drain with the foramen of Monro, which is roughly in line with the tragus of the ear.

Re-zero the drain once it is connected to the transport monitor and after all major patient movements. Air medical transport teams must re-zero the drain upon reaching cruising elevation and after descent.

Assembling the Assessed Information

After reviewing the written information received from the referring facility, the findings from the CCTP’s own patient examination, current lab values, the patient’s response to therapeutic interventions, and the patency of any invasive equipment, the CCTP should develop a problem list. A problem list is effectively a differential diagnosis that defines associated symptoms or concerns that may require management during transport. For example, the differential diagnosis for a patient with acute coronary syndrome may include non-ST-segment elevation myocardial infarction that is associated with hypertension and pain, both of which will require management. Identifying the anticipated problems allows the CCTP to prioritize interventions and prepare for potential complications during transport.

Life threats, including potentially impending life threats, should be managed before initiating transport. When these conditions cannot be stabilized by the referring facility or transport team, an emergency transport is likely indicated. Identified conditions with anticipated problems that are unlikely to develop for hours or days can be managed during transport. For example, if an open fracture is the identified condition, one problem the transport team can anticipate is infection. The team can reduce the risk of infection by administering antibiotics.

While it is reasonable for CCT teams to initiate new interventions to stabilize patients prior to transport, a caveat applies: As the number of on-scene interventions increases, so does the scene time. The need to treat the patient on scene must be weighed against delayed delivery to definitive care. Limit on-scene interventions to those addressing severe pain, major life threats, or deterioration from baseline. Otherwise, consider deferring new interventions until transport has been initiated.

Communications With Receiving Facilities

While it might seem counterintuitive that staff at a hospital that has accepted a transfer might not know what they will need to care for the patient, often acceptance of transport simply involves approval from a house supervisor, acceptance by a physician, and confirmation of an available bed. Particularly after long transports, the staff receiving a patient may have had no direct communication with the staff at the sending facility, a particularly common scenario after a shift change. To ensure the staff at the receiving facility are prepared to treat the patient, contact the facility 20 to 30 minutes prior to your anticipated arrival and provide an update to the nurse or clinical team who will be caring for the patient. If you anticipate that the initial bed destination may be inappropriate and an upgrade to an ICU bed may be indicated, contact the facility even earlier, because many hospitals have limited ICU beds availability.

Transferring care to a referring facility is a high-risk opportunity for loss of important information. To avoid the loss of critical information during a transfer of care, employ critical communication strategies during the handoff. Further, take the time during and after the transfer to ensure your written patient care report provides an accurate reflection of the quality care your team provided. These skills are discussed further in Chapter 2, *Medical-Legal Issues*, and Chapter 3, *Patient Safety*.

Summary

The patient assessment is an essential skill for CCTPs. A complete patient assessment creates the foundation for a differential diagnosis and problem list and enables teams to develop meaningful treatment plans. Assessments performed by CCT teams extend beyond scene size-up, safety, and primary and secondary assessments. The CCT assessment includes a thorough review of the originating facility reports, a verbal report from the referring staff, a comprehensive primary and secondary assessment, a review of interventions and invasive medical equipment as well as their impact on the patient, and a review of pertinent lab values. Your assessment may be supported by a variety of advanced technology.

Never rush or short-change a patient assessment; this process is critical in ensuring success for both the transport team and the patient. Taking the time to obtain a complete picture of the patient's condition and progression helps improve outcomes. Remember, patients will change over time. Perform repeat assessments as necessary throughout the transport. Communicate early with receiving facilities to ensure they are prepared to treat the patient upon arrival, and use standardized communication strategies to help minimize the risk of information loss during the transfer of care.

CASE STUDY

You and your CCT team are providing an interfacility transport of a 48-year-old man who presented to the ED with severe chest pain. The patient was diagnosed with acute myocardial infarction, and an intra-aortic balloon pump (IABP) was inserted. The patient was admitted to the ICU while awaiting transport to the specialty heart hospital.

En route to the hospital, your crew receives an update on the patient's condition. The patient's vital signs are as follows: blood pressure, 120/75 mm Hg; pulse rate, 110 beats/min; respiratory rate, 30 breaths/min; and pulse oximetry reading, 93%. The patient is on 4 L of oxygen by nasal cannula. He continues to report chest pain, rating his pain as an 8 on a scale of 1 to 10. He also reports severe back pain.

On your crew's arrival, you find the patient in the ICU. You and your team receive a report from the ICU nurse. She states that the patient presented to the ED this morning around 0830 hours, reporting severe chest pain. He was given an aspirin, started on a nitroglycerin drip, and administered a total of 5 mg of morphine. Blood was drawn for lab analysis. The ICU nurse hands you the lab results. You review the results and report the findings to the rest of your crew. The lab results were as follows:

- Calcium: 9.5 mg/dL (normal range, 8.2 to 10.2 mg/dL)
- Chloride: 100 mEq/L (normal range, 96 to 106 mEq/L)
- Magnesium: 2.0 mEq/L (normal range, 1.3 to 2.1 mEq/L)
- Potassium: 4.0 mEq/L (normal range, 3.5 to 5.0 mEq/L)
- Sodium: 142 mEq/L (normal range, 136 to 142 mEq/L)
- Hemoglobin: 14.4 g/dL (normal range, 14.0 to 17.5 g/dL)
- Hematocrit: 45% (normal range, 41% to 50%)
- White blood cell count: 10,400/μL (normal range, 4,500 to 11,000/μL)
- Platelet count: 210 × 10^3/μL (normal range, 150 to 350 × 10^3/μL)
- Creatine kinase-MB: 3.5 ng/mL (normal range, 0 to 7 ng/mL)
- Creatine kinase: 100 U/L (normal range, 40 to 150 U/L)
- Cholesterol: total, 198 mg/dL (normal range, 200 to 239 mg/dL); high-density lipoprotein, 278 mg/dL (normal range, 40 mg/dL); low-density lipoprotein, 32 mg/dL (normal range, 160 mg/dL); triglycerides, 205 mg/dL (normal range, 160 mg/dL)

The arterial blood gas measurement results were as follows:

- pH: 7.30 (normal range, 7.35 to 7.45)
- $PaCO_2$: 55 mm Hg (normal range, 35 to 45 mm Hg)
- HCO_3^-: 25 mEq/L (normal range, 21 to 28 mEq/L)
- PO_2: 93 mm Hg (normal range, 80 to 100 mm Hg)

An ECG revealed sinus tachycardia with right axis deviation.

As you enter the patient's room, you find the patient lying supine, with 4 L of oxygen being delivered via nasal cannula. The patient is attached to the bedside cardiac monitor and the IABP. The cardiac monitor reveals a pulse rate of 130 beats/min, a blood pressure of 145/96 mm Hg, and a pulse oximetry reading of 93%. The patient is awake, is oriented, and follows all commands. His skin is paler than his baseline color. His respiratory rate is 30 breaths/min.

Your patient assessment reveals the following:

- **Cardiopulmonary assessment:** The patient's airway is patent, with a slight decrease in chest rise on the right side. Breath sounds are present bilaterally, but slightly diminished on the right side. No wheezes, crackles, or rhonchi are noted. Respiratory effort is labored. No subcutaneous emphysema is noted on palpation. The patient's skin is pale and diaphoretic. Capillary refill is 4 s. No murmur, rubs, friction, or gallops are noted on auscultation of the heart. Pulses are equal in pattern, intensity, and quality in all four extremities. The ECG reveals sinus tachycardia with a rate of 133 beats/min. No pitting edema is noted in the extremities.
- **Neurologic assessment:** The patient has a GCS score of 15. He is able to move all four extremities without difficulty. His pupils are equal, round, and reactive to light. All cranial nerves are intact.

- **GI assessment:** No ascites or bruising is noted on inspection of the abdominal area. The abdomen is soft, with no tenderness or distention on palpation. No masses or hernias are noted. No rebound tenderness is present. Auscultation of the abdomen reveals hyperactive bowel sounds. The patient denies having vomited blood or blood with a coffee-ground appearance and also denies having had dark, tarry stools.
- **Musculoskeletal assessment:** The patient is able to move all four extremities without difficulty. All reflexes are intact. No swelling to extremities is present. Pulses are present in all extremities.

1. Which complications could be occurring with this patient?
2. What do the lab values, arterial blood gas results, and ECG reveal?
3. What is your general impression of this patient?
4. Which additional information should you request from the hospital? Would you request any other test(s) prior to transport of this patient?

Analysis

This patient presented with severe chest pain that started 2 hours prior to his arrival at the ED. The patient stated that the pain occurred suddenly and nothing he did relieved it. He described the pain as sharp, and originally rated it as a 10 on a scale of 1 to 10. The ED physician made a diagnosis of acute myocardial infarction based on borderline lab values. An IABP was inserted and arrangements were made to transport the patient to a specialty heart hospital. The transport crew received the update that the patient was having severe back and chest pain.

The crew's first concerns while en route to the patient included dissection of the aorta, which is a potential complication after an IABP insertion. The classic presentation of an aortic dissection is chest and back pain. The crew discovered that a chest radiograph had not been obtained and asked for an updated chest radiograph. A chest radiograph should be performed before and after IABP insertion.

The lab results and ECG in this case did not confirm the physician's diagnosis of a myocardial infarction. More testing is needed to confirm an accurate diagnosis. The general impression of this patient is that he is in respiratory distress. Further investigation is warranted because of the possibility of heart failure, respiratory infection, or pneumothorax. Assessment reveals the possibility of a pneumothorax, which must be investigated further—for example, with the chest radiograph already requested.

In addition to the chest radiograph, the CCTP should consider requesting a rapid (point-of-care) determination of the patient's troponin level. Troponin is a cardiac enzyme specific to injuries of the cardiac muscle. Physicians diagnose myocardial infarction based on several factors, including an ECG, lab values, and patient presentation.

In terms of assessment and treatment, the patient has diminished breath sounds on the right side of the chest. He has labored respirations, and arterial blood gas determinations revealed respiratory acidosis, which are all classic signs of a pneumothorax and possible tension pneumothorax. In situations in which you believe more testing should be done to determine the diagnosis, the members of the CCT team should discuss their assessment findings and ask whether a radiograph or other relevant test can confirm their assessment. Professional and nonconfrontational communication patterns are expected. Respectful behavior on the part of the CCTP, regardless of the situation, helps to promote positive working relationships, whereas disrespect or negativity may result in a referring facility no longer calling that particular CCT service. If the physician disagrees with your team, a team member should contact the medical director and have this person contact the sending physician to help determine the best course of action.

In this case, on the crew's arrival to pick up the patient, the relieving attending physician stated that chest radiography revealed a pneumothorax. After chest tube insertion, the patient was transported to the specialty facility and was evaluated.

No cardiac problems were found.

PREP KIT

Ready for Review

- A comprehensive patient assessment is one of the most important skills critical care transport professionals (CCTPs) perform. It builds the foundation for the treatment plan.
- Assessment of critical care patients differs from the traditional emergency medical services field assessment in two respects: Critical care patients have often received significant treatment and stabilization prior to the CCTP's arrival, and sophisticated diagnostic information is often available.
- As part of prearrival planning, the CCTP team should consider the reason for transport, the type of facility from which the transfer originates, the length and mode of transport, and the type of destination facility. All of these considerations provide valuable clues in anticipating the patient's needs.
- Upon arrival, the CCTP should carefully review all available information from the sending facility, including any available patient care records, and should take the time to understand the patient as a person, including cultural preferences.
- CCTPs should be familiar with the assessment process used to establish the initial care plan and have an understanding of pathophysiology and differential diagnosis so that they can make appropriate treatment decisions and assess the effects of treatments.
- The systems-based assessment approach recognizes that critical care patients are usually receiving treatment for problems involving multiple systems and interrelated complications.
- The SAMPLE approach can be used to establish the pertinent details of a patient's history—Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, and

Events leading up to the illness or injury. Providers should strive to obtain in-depth details for each component.

- The patient’s history includes the referring facility’s management. Specifically, the CCTP should determine any diagnostic tests and imaging performed and their results, the differential diagnosis, and any interventions performed and the patient’s response to them.
- During the primary assessment, providers place absolute priority on quickly identifying any acute life threats. This brief exam should seldom take more than 60 seconds, as acutely life-threatening problems require timely intervention.
- The primary assessment follows a stepwise, rapid evaluation of organ systems and anatomy fundamentally necessary for life. The ABCDE mnemonic, which stands for Airway, Breathing, Circulation, Disability, and Exposure, is often used to guide this process.
- The primary assessment of the airway involves determining whether the patient’s airway is “safe,” meaning the airway is patent and ventilation appears to be effective. If not, the team may need to establish an effective airway, possibly by correcting existing interventions (eg, correction of an inappropriately placed endotracheal tube).
- Primary assessment of the respiratory system involves detecting any injury or illness that is directly affecting the respiratory system. Providers must understand the implications of irregularity in the respiratory rate for other body systems and processes.
- When assessing mechanical ventilation, the CCTP must ensure the patient is receiving ventilatory support that is both adequate and not injurious to the lungs.
- Assessment of the circulatory system requires the collation of information from multiple diagnostic sources, including the physical exam, monitoring equipment, and other diagnostic tools. Skin color, temperature, and condition can provide a valuable initial glimpse into illness severity.

- During the primary assessment, the evaluation of vital signs is limited to looking for evidence of acute instability. However, providers should keep in mind that their initial documentation establishes the reference point against which later recordings will be compared.
- Blood pressure can be a valuable clinical parameter, but it is important to remember that normal blood pressure may differ for individual patients. A more objective means of assessing perfusion status is mean arterial pressure.
- Before transport, trends in blood pressure over time should be noted, especially in response to cardiogenic medications and interventions.
- How frequently vital signs are assessed is dictated by the patient’s condition and may range from continuous to every 15 minutes.
- During assessment of the gastrointestinal system, examination of the oral mucosa and abdominal areas provides general information.
- In gastrointestinal assessment, auscultation of the abdomen precedes palpation and percussion.
- Palpation of the abdomen can determine tenderness and rebound tenderness.
- Genitourinary assessment includes assessments of the mammary, testicular, and prostate glands. Such exams are generally limited except in the case of trauma.
- During the primary assessment of a patient who has sustained traumatic injury, providers must seek sources of hemorrhage. Although life-threatening external hemorrhage will likely have been controlled before the transport team arrives, CCTPs must ensure continued efficacy of the bleeding control.
- Examination for external hemorrhage must be done early and in a systematic fashion. It includes an extremity sweep and inspection of the chest, abdomen, and back.

- Internal hemorrhage can be difficult to detect and requires thoughtful consideration of the mechanism of injury and detection of external signs of blunt trauma, such as skin abrasions and contusions. Palpation may reveal point tenderness over solid organs.
- Twelve-lead electrocardiography is an essential diagnostic tool. It can reveal useful information for patients with many disorders, including acute right ventricular failure, pulmonary embolism, metabolic disorders, and toxicologic issues.
- Before the critical care transport begins, a neurologic exam is necessary to establish the patient’s baseline status for comparison with the findings from later examinations.
- Neurologic evaluations should be repeated frequently, noting relevant findings, such as the patient’s level of consciousness, the Glasgow Coma Scale score, the Richmond Agitation–Sedation Scale score, cranial nerve assessment, and pupil assessment, including size, reactivity to light, and shape.
- As the final step in the ABCDE approach to the primary assessment, the CCTP should expose the patient to conduct a rapid head-to-toe, anterior and posterior, assessment of the entire patient. Exposure enables the CCTP to more fully determine the severity of injuries, confirm ongoing effectiveness of wound management performed prior to the team’s arrival, and assess the skin for edema and pressure injuries. Providers must guard against hypothermia in the exposed patient.
- The secondary assessment involves several components, including a detailed head-to-toe examination, a systems-based approach to specific diseases, and a complete evaluation of vital signs.
- The secondary assessment involves review of the basic vital signs (ie, pulse rate, blood pressure, respiratory rate, pulse oximetry, mental state, and temperature). Capnography is often used at this stage to evaluate and monitor the respiratory carbon dioxide levels in critically ill patients.

- A key reason for conducting the secondary assessment is to detect changes in the patient's condition. Typically, reassessments are performed every 5 to 15 minutes.
- During the secondary assessment, CCTPs may need to incorporate scales relating to pain and sedation. The CCTP must be proficient in selecting the correct assessment tool for the patient, administering it, and interpreting its results.
- CCTPs should prepare for the patient's medication needs before initiating transfer. They should examine any intravenous lines already started and ensure they will have the access needed for any medications they anticipate administering.
- Imaging modalities such as ultrasonography, radiography, and computed tomography are increasingly available to teams during patient transport. Providers will identify which imaging has been completed and why, determine which actions have been taken based on the imaging findings, and decide which additional imaging is still needed.
- The ongoing clinical care for many patients requiring interfacility transport involves insertion of invasive devices. CCTPs must recognize the indications for invasive equipment, assess each device's patency and effectiveness, and monitor for complications.
- Regardless of the patient's condition, CCTPs should always strive for compassionate and empathetic interactions with the patient and family, even in the face of critical illness.
- Assessment findings before transfer, en route, and after arrival at the destination facility (based on the acuity of the patient) should be documented.
- The medical record should include documentation of all assessment findings, as even subtle changes in an individual patient or an individual finding may be significant in critical-level patients.

Vital Vocabulary

ABCDE A mnemonic used to help providers remember the patient assessment sequence: Airway, Breathing, Circulation, Disability, and Exposure.

anisocoria A condition in which the pupils are not of equal size.

AVPU scale An evaluation tool used to determine patient responsiveness; stands for Alert, responds to Voice, responds to Pain, Unresponsive.

capillary refill time (CRT) The time it takes for baseline skin color to return to the nail bed after being pressed by the provider; serves as a window into the state of peripheral perfusion.

community hospitals Community medical centers that offer emergency medicine and inpatient facilities but with limited inpatient specialists other than hospitalists and general surgery physicians.

critical-access hospitals As defined by the Centers for Medicare and Medicaid Services, hospitals that have 25 or fewer beds, are located more than 35 miles from another hospital, have an average length of stay of less than 96 hours, and provide 24/7 emergency medicine services. Most acutely ill or injured patients treated at these hospitals require transport to higher levels of care once stabilized.

differential diagnosis The process of selecting the most likely underlying cause of the patient's condition by comparing multiple potential causes of the presenting signs and symptoms.

Glasgow Coma Scale (GCS) An evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response, which are then totaled; effective in helping predict patient outcomes.

hippus phenomenon A pattern of pupil response to light in which rapid constriction of the pupil is followed by dilation; it can be normal or signify compression of cranial nerve III.

mean arterial pressure (MAP) The average arterial pressure during a single cardiac cycle.

Murphy sign A painful reaction elicited by asking the patient to take and hold a deep breath as the provider palpates the right subcostal area; if pain occurs on inspiration, when the inflamed gallbladder comes in contact with the provider's hand, Murphy sign is positive. May signal the presence of gallbladder problems.

pallor Skin presentation suggestive of reduced blood flow or oxygenation. In patients with light skin, paleness typically presents as unusual lightness compared with the person's baseline skin color. In patients with dark skin, pallor may appear as ashen or gray skin on general assessment. In general, the mucous membranes inside the inner lower eyelid and the oral mucosa will have a pink coloration in all healthy patients, regardless of skin color; thus, a white or pale appearance of these areas in any patient suggests reduced blood flow or oxygenation.

primary assessment A brief assessment of the patient's condition in which providers quickly identify any acute life threats. This survey follows a stepwise, rapid evaluation of organ systems and anatomy fundamentally necessary for life, often described as the ABCDE (Airway, Breathing, Circulation, Disability, and Exposure) approach.

primary care centers Medical centers that offer outpatient, routine family medicine services, including obstetrics and gynecology, geriatric care, and pediatric primary care, and that coordinate patient care with outpatient specialists as appropriate.

quaternary care centers Highly specialized tertiary care referral centers that may be dedicated to advancing clinical research in one or more areas of medicine.

rhabdomyolysis A condition in which damaged skeletal muscle tissue breaks down rapidly.

Richmond Agitation–Sedation Scale (RASS) An evaluation tool used to assess both agitation and sedation.

SAMPLE An acronym for the pertinent details of a patient's history: Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, and Events leading up to the illness or injury.

secondary assessment A patient assessment that occurs after completing the primary assessment and identifying and stabilizing immediate life threats and hemodynamic instability. The secondary assessment involves several components, including a detailed head-to-toe examination, a systems-based approach to specific diseases, and a complete evaluation of vital signs.

secondary care centers Medical centers that may offer primary care within the same facility but also offer outpatient specialties such as cardiology, neurology, nephrology, mental health, endocrinology, or oncology.

sequelae Consequence of a previous disease or injury.

shock index An evaluation tool used to predict mortality and the need for transfusion in the trauma patient; defined as heart rate divided by systolic blood pressure.

tertiary care centers Medical centers that offer highly specialized inpatient medical care, including advanced and complex medical interventions performed by specialty physicians.

working diagnosis An assumed decision on the medical condition of a patient based on the preliminary investigation; assists in the provision of initial treatment and projection of further diagnostic testing requirements.

CHAPTER 6

Respiratory Emergencies and Airway Management

Lauren M. Maloney, MD, NRP, FP-C, NCEE
Rudolph Princi, BS, EMT-P

OBJECTIVES

After completing this chapter, you will be able to:

1. Summarize the anatomy and physiology of the respiratory system (pp 156–162).
2. Describe how ventilation and perfusion abnormalities affect blood gas values (pp 162–164).
3. Name the five requirements for normal ventilation and oxygenation (p 164).
4. Define tidal volume, vital capacity, and minute volume (pp 164–165).
5. Differentiate between obstructive and restrictive diseases (p 165).
6. Interpret normal and abnormal breath sounds (pp 166–168).
7. Describe particular clinical events that alter the functioning of the respiratory system in the critical care patient (pp 165–166).
8. Review the breath sound assessment technique used in critical care transport patients (pp 166–168).
9. Perform a basic respiratory assessment for adequacy of ventilation and oxygenation using inspection, auscultation, palpation, and noninvasive monitoring (pp 166–169).
10. Identify abnormal respiratory patterns (pp 169–171).
11. Assess a respiratory cycle (pp 164–171).
12. Identify the parameters measured in arterial blood gas monitoring and which parameter reflects the effectiveness of ventilation and oxygenation (p 172).
13. Discuss basic airway management strategies (pp 176–181).
14. Discuss advanced airway management strategies (pp 181–215).
15. Describe how pulse oximetry, capnometry, and capnography can be used to monitor respiratory function (pp 172–176).

Introduction

There is no more important—or controversial—skill associated with prehospital care than airway management. The ability to assess and manage the airway at the basic life support (BLS) level is the starting point in airway management. For advanced life support (ALS) providers, it is a standard to fall back on. This assessment will guide the critical care transport professional (CCTP) in developing a treatment plan that may be as simple as providing supplemental oxygen to a spontaneously breathing patient, or as complex as placing an artificial airway device or providing adequate ventilation with a bag-mask device or ventilator.

Ensuring the adequacy of ventilation and oxygenation in critically ill patients is one of the primary treatment goals of the CCTP. A thorough understanding of respiratory function and assessment is essential to meet this goal. The patient history and a focused physical exam, in conjunction with the analysis of hemodynamic parameters, laboratory values, and diagnostic imaging, all provide key information about the functioning of the patient’s respiratory system. When respiratory compromise occurs during transport, time is critical, and you as a CCTP must be prepared to perform a rapid, accurate respiratory assessment followed by implementation of the appropriate intervention.

Anatomy and Physiology of the Respiratory System

An understanding of airway anatomy and physiology is essential to successful airway management.

Upper Airway Structures

Important airway structures of the upper airway include the nose, mouth, pharynx, and larynx, which contains the epiglottis.

Nose

The nose is a cartilaginous, bony structure in the midline of the face that warms and humidifies inspired air. It is lined with coarse hairs in the vestibular area, which act as a filter to trap small, inspired particles. Olfaction (sense of smell) also originates here via the first cranial nerve (olfactory nerve). The nasal cavities connect to the four sinuses: frontal, ethmoidal, sphenoidal, and maxillary. These sinuses are hollow chambers lined with membranes that secrete mucus into the nasal cavities. The nasal cavity subsequently opens into the nasopharynx.

The nose, which is extremely vascular, can be a significant source of epistaxis. Such bleeding may complicate airway patency and management.

Mouth

Primarily designed for phonation and mastication, the mouth begins at the lips and ends with the oropharynx. The size of the oral cavity can affect airway management **FIGURE 6-1**. The mouth contains the tongue, which is attached to the mandible, as well as the teeth. When patients have edema of the lingual or sublingual spaces, both of these structures can make airway management more difficult. Additionally, prominent central incisors (buck teeth) or conditions affecting the mandible’s range of motion can make airway management more difficult, as they could interfere with insertion of the laryngoscope blade. Salivary glands continuously secrete saliva, which may make achieving topical anesthesia and visualizing airway structures difficult.

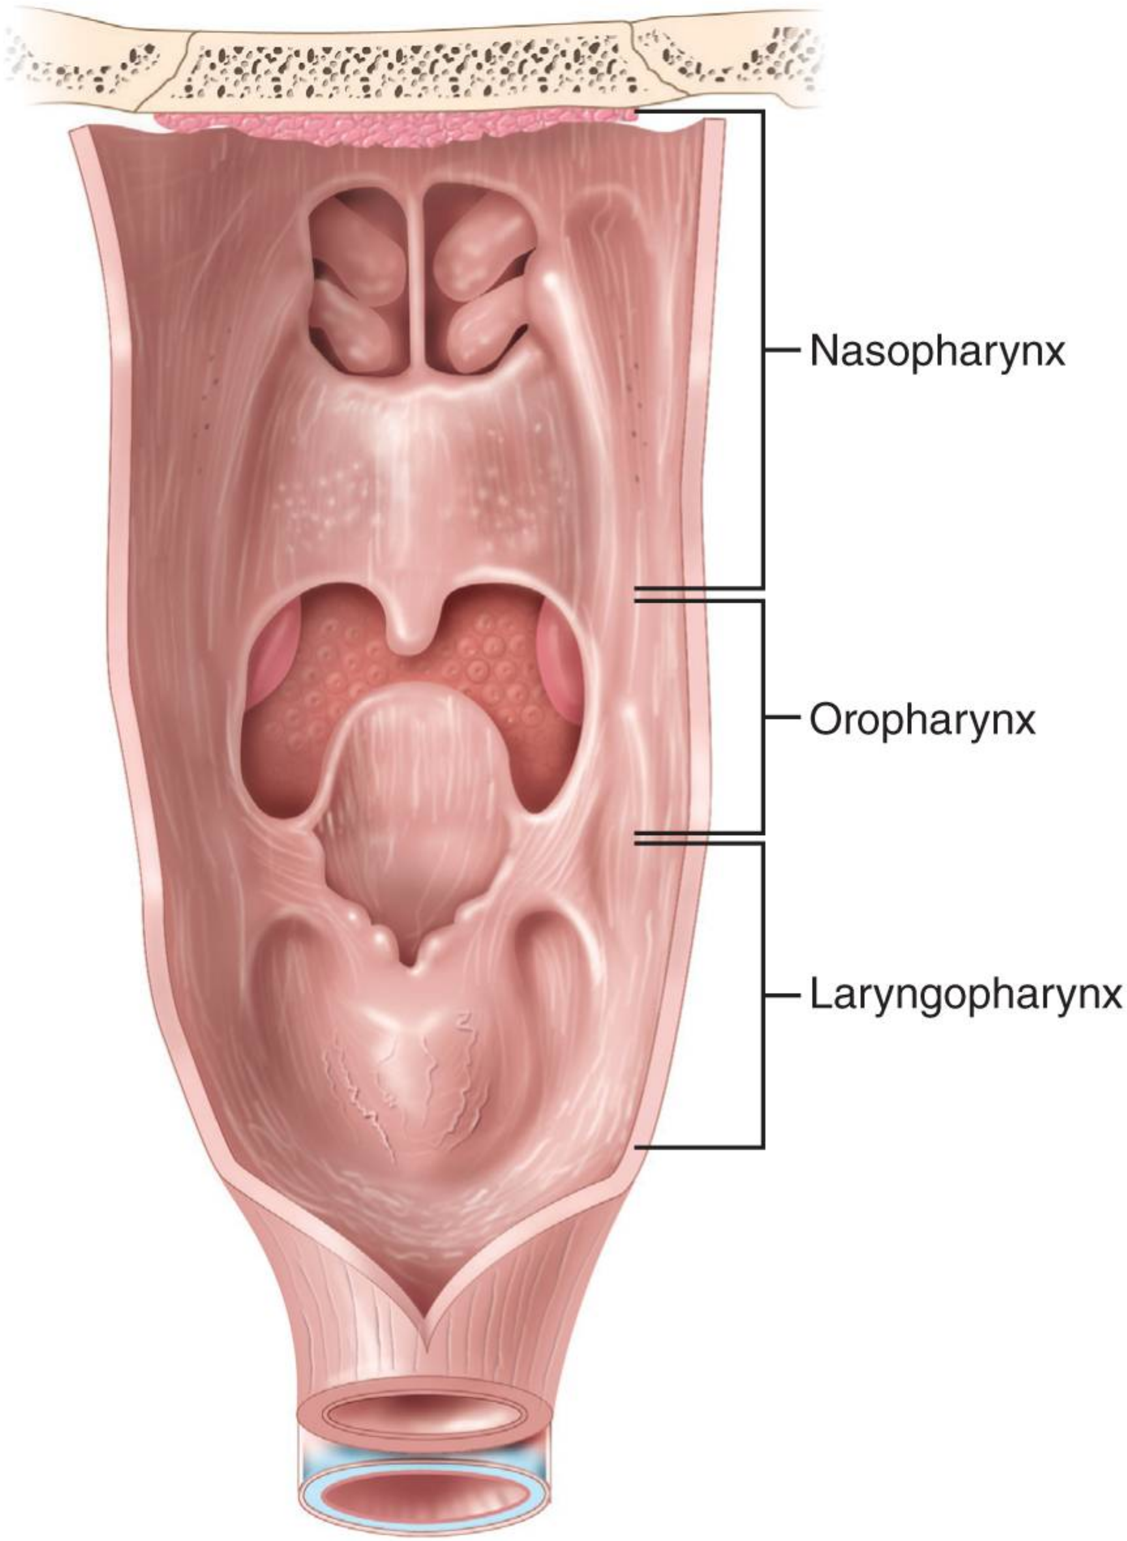
In the unconscious patient, the tongue is the most common cause of airway obstruction. A simple jaw-thrust maneuver may temporarily alleviate this airway obstruction and allow for effective bag-mask ventilation.

Pharynx

The pharynx is a U-shaped tube that begins at the base of the skull and extends to the lower border of the cricoid cartilage, a complete ring structure located at the level of C6, near the esophagus **FIGURE 6-2**. It is composed of three parts: the nasopharynx, the oropharynx, and the hypopharynx (or laryngopharynx):



Nasopharynx
Oropharynx
Laryngopharynx

FIGURE 6-2 The pharynx.

- The nasopharynx extends from the posterior choana (the posterior portion of the nasal cavity) of the nose to the soft palate. It contains the adenoid tissue and the eustachian tubes.
- The oropharynx extends from the soft palate to the vallecula. It is the portion that is visible when the mouth is opened.
- The hypopharynx is the portion of the pharynx found inferior to the epiglottis.

The normal resting muscle tone of the oropharynx maintains upper airway patency. The ninth cranial nerve, the glossopharyngeal nerve, provides sensory innervation to many of the structures in this area (posterior tongue, valleculae, and parts of the epiglottis). The inferior portion of the pharynx ends with the entrance to both the trachea and the esophagus.

Larynx

The structures contained within the larynx consist of the thyroid cartilage, aryepiglottic folds, epiglottis, vallecula, and arytenoid cartilages **FIGURE 6-3**. The larynx is the final structure encountered before entering the trachea. The 10th cranial nerve, the vagus nerve, provides strong sensory innervation to the larynx. Overstimulation of the larynx during airway management may cause parasympathetic nervous system stimulation, resulting in significantly decreased heart rate and blood pressure, especially in the pediatric population. The cricothyroid membrane is also located here, extending from the lower surface of the cricoid cartilage to the upper border of the thyroid cartilage. In the adult patient, the cricothyroid membrane is approximately 6 to 8 mm from superior to inferior border.

Lower Airway Structures

Important structures of the lower airway include the trachea, right and left main stem bronchi, bronchioles, alveolar ducts, and alveolar sacs.

Trachea

Beginning at the inferior border of the cricoid ring and ending at the carina, the trachea is approximately 9 to 15 mm in diameter and approximately 12 to 15 cm long. It is not cylindrical, but rather is composed of 16 to 20 C-shaped cartilaginous rings on the anterior portion, with the posterior portion consisting of fibrous tissue and muscular fibers. These rings help maintain luminal patency to allow unimpeded airflow. The trachea is larger in adult males than in adult females.

Lungs

The trachea divides into the right and left main stem bronchi, which lead to the right and left lobes of the lungs, respectively **FIGURE 6-4**. The right lung is divided into three lobes; the left lung has two lobes. The bronchi continue to divide into smaller bronchi, which then divide into progressively smaller branches called bronchioles. After a total of dozens of divisions into smaller and smaller branches, the bronchioles end at the alveolar ducts. These alveolar ducts lead to the alveoli, the area where gas exchange occurs. The adult lung contains approximately 300 million alveoli, each one in contact with a pulmonary capillary. This interface is referred to as the alveolar-capillary membrane.

An alveolus is composed of type I and type II squamous epithelial cells. Type I cells are involved in gas exchange, whereas type II cells manufacture surfactant. Surfactant, a phospholipid, reduces the surface tension within the alveolus, preventing its collapse and making it easier for the alveolus to expand during inhalation. Without surfactant, the work of breathing would be significantly more difficult. A lack of surfactant is commonly found in premature neonates and is a leading cause of respiratory issues in this patient population. Another type of cell, the alveolar macrophage, is also present in the alveolus; its function is to help defend the body by ingesting inhaled particles.

The blood supply in the lung arises from the right ventricle. The pulmonary trunk then splits into the right and left pulmonary arteries. The pulmonary arteries contain deoxygenated blood that is high in carbon dioxide (CO_2). These arteries subdivide into the pulmonary capillaries.

The pulmonary vasculature is a low-pressure system. The pressure in the normal pulmonary artery is approximately 25/10 mm Hg, as compared with a normal systemic pressure of approximately 120/80 mm Hg. For gas exchange to occur, blood flow must be in contact with the alveoli, a relationship described by the $\dot{V}/\dot{Q}$ ratio. The normal ratio is 0.8 for the entire lung. This means that for every 4 L of air ($\dot{V}$), a blood flow ($\dot{Q}$) of 5 L is needed. Gravitational effects cause perfusion to be better in areas that are positioned lower (dependent areas) and ventilation to be better in higher (nondependent) areas. Changes in the $\dot{V}/\dot{Q}$ ratio are one of the most common causes of **hypoxemia** (low oxygen level). Disruptions in the respiratory system can include changes in gravity, pulmonary artery pressure, alveolar pressure, airway obstruction, and lung compliance. Many diseases can cause these changes, including chronic obstructive pulmonary disease (COPD), pulmonary embolism, heart failure (HF), and pneumonia, to name a few.

Pediatric Considerations

Several variations in airway anatomy occur that are specific to the pediatric patient. Newborns and infants, for instance, have a proportionally larger head with a prominent occiput. This may cause flexion of the airway and create difficulty in visualizing laryngeal structures unless proper positioning is maintained. For example, placing a towel under the infant's shoulders to raise the rest of the body to align the airway axes usually improves airflow and direct laryngoscopy visualization. Infants are also obligate nose breathers, and congestion may result in respiratory distress.

The tongue occupies a much larger proportion of the oropharynx in pediatric patients compared with adults. This difference in tongue size may result in airway obstruction in the unresponsive pediatric patient and make visualization of the glottis more difficult when performing laryngoscopy. The glottic opening is more cephalad and anterior in the pediatric patient **FIGURE 6-5**. A child’s epiglottis is at a 45° angle to the anterior pharyngeal wall, whereas an adult’s epiglottis lies parallel to the base of the tongue. In addition, the epiglottis is proportionally larger, floppier, and U-shaped in a child compared with an adult. This may necessitate using a laryngoscope blade tip to directly lift the epiglottis to improve visualization during laryngoscopy of a child.

The larger adenoidal tissue found in pediatric patients, and particularly in infants, may result in significant hemorrhaging if subjected to trauma. Additionally, the cricothyroid membrane is small in young children. For this reason, only needle (not surgical) cricothyrotomy is generally recommended in children younger than 10 years.

Furthermore, children have significantly higher oxygen consumption rates when compared with adults. Oxygen consumption in the pediatric patient is approximately double that of an adult. This increased consumption, coupled with a decreased functional residual capacity, can result in significant hypoxemia despite adequate preoxygenation, a major concern when attempting to intubate a pediatric patient.

Special Populations

Children have significantly higher oxygen consumption rates as compared to adults.

Finally, with pediatric patients, the CCTP should exercise caution when using a bag-mask device. Excessive volumes and forceful ventilations may exacerbate gastric distention, causing vomiting; decrease lung compliance; and increase the risk of pneumothorax.

Physiology of the Respiratory System

Gas Exchange and Transport

Fick’s law of diffusion states that the rate of diffusion of a gas across a semipermeable membrane is proportional to the surface area available for diffusion and the concentration gradient of gases on either side of the membrane, and inversely proportional to the thickness of the membrane. Simply stated, gas will move from an area of higher concentration to an area of lower concentration in an attempt to achieve equilibrium. The difference between the partial pressures of gases on each side of the membrane is the driving force for diffusion. In the lungs, gas exchange is caused by the pressure gradient and driving forces across the alveolar-capillary membrane **FIGURE 6-6**.

FIGURE 6-6 With diffusion, molecules of oxygen (O_2) move out of the alveoli and into the blood because there are fewer O_2 molecules in the blood. Similarly, molecules of carbon dioxide (CO_2) diffuse out of the blood and into the alveoli because there are fewer CO_2 molecules in the alveoli.

© Jones & Bartlett Learning.

Description

Partial pressure can be determined by applying Dalton's law, which states that a gas mixture's total pressure is equal to the sum of the component gases' partial pressures. At sea level, the atmospheric pressure of all mixed gases is 760 mm Hg. Oxygen accounts for 21% of this gas mixture. Thus, the partial pressure of oxygen in the atmosphere at sea level is 159.6 mm Hg (760 × 21%). In the capillary, the partial pressure of oxygen (PO_2) is 40 mm Hg, whereas the partial pressure of carbon dioxide (PCO_2) is 45 mm Hg. In the alveolus, the PCO_2 is 40 mm Hg and the PO_2 is 100 mm Hg. This difference in the partial pressures of oxygen between the capillary and the alveolus forms a gradient. If the capillary PO_2 is 40 mm Hg and the alveolar PO_2 is 100 mm Hg, then the driving force of the oxygen molecule across the membrane is 60 mm Hg in the direction of the capillary. If the alveolar PCO_2 is 40 mm Hg and the capillary PCO_2 is 45 mm Hg, then the driving PCO_2 is 5 mm Hg in the direction of the alveolus. The result is that the blood returning to the left side of the heart via the pulmonary vein contains 100 mm Hg of oxygen and 40 mm Hg of CO_2; these are the normal **arterial blood gas (ABG)** values. Additionally, it is important to remember that carbon dioxide diffuses 20 times faster in the blood than does oxygen.

Factors that affect the diffusion of gases across the membrane may create a **ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch**. $\dot{V}/\dot{Q}$ mismatch can be caused by inadequate ventilation, perfusion, or both. Three types of $\dot{V}/\dot{Q}$ mismatch are possible: low, high, and silent.

- **Low $\dot{V}/\dot{Q}$ ratio.** Characterized by perfusion exceeding ventilation. The low ratio results in blood being shunted past the alveoli without adequate gas exchange taking place. A 20% shunting results in severe hypoxia. Causes may include pneumonia, atelectasis, tumors, and mucus plugs.
- **High $\dot{V}/\dot{Q}$ ratio.** Characterized by ventilation exceeding perfusion, resulting in dead space. In this case, the alveoli are inadequately perfused, preventing adequate gas exchange from occurring. Causes of high $\dot{V}/\dot{Q}$ ratio may include pulmonary embolus, pulmonary infarction, and cardiogenic shock.
- **Silent alveolar unit.** Characterized by decreased ventilation and perfusion, as is seen in patients with a pneumothorax and severe acute respiratory distress syndrome (ARDS).

Although it is common practice to assess oxygenation in terms of the partial pressure of (arterial) oxygen (PaO_2), it is important to remember that hemoglobin is the iron-containing protein found in erythrocytes that functions as the actual transporter of oxygen to tissues. The PaO_2 drives oxygen to be bound to hemoglobin, a relationship expressed in the oxyhemoglobin dissociation curve **FIGURE 6-7**.

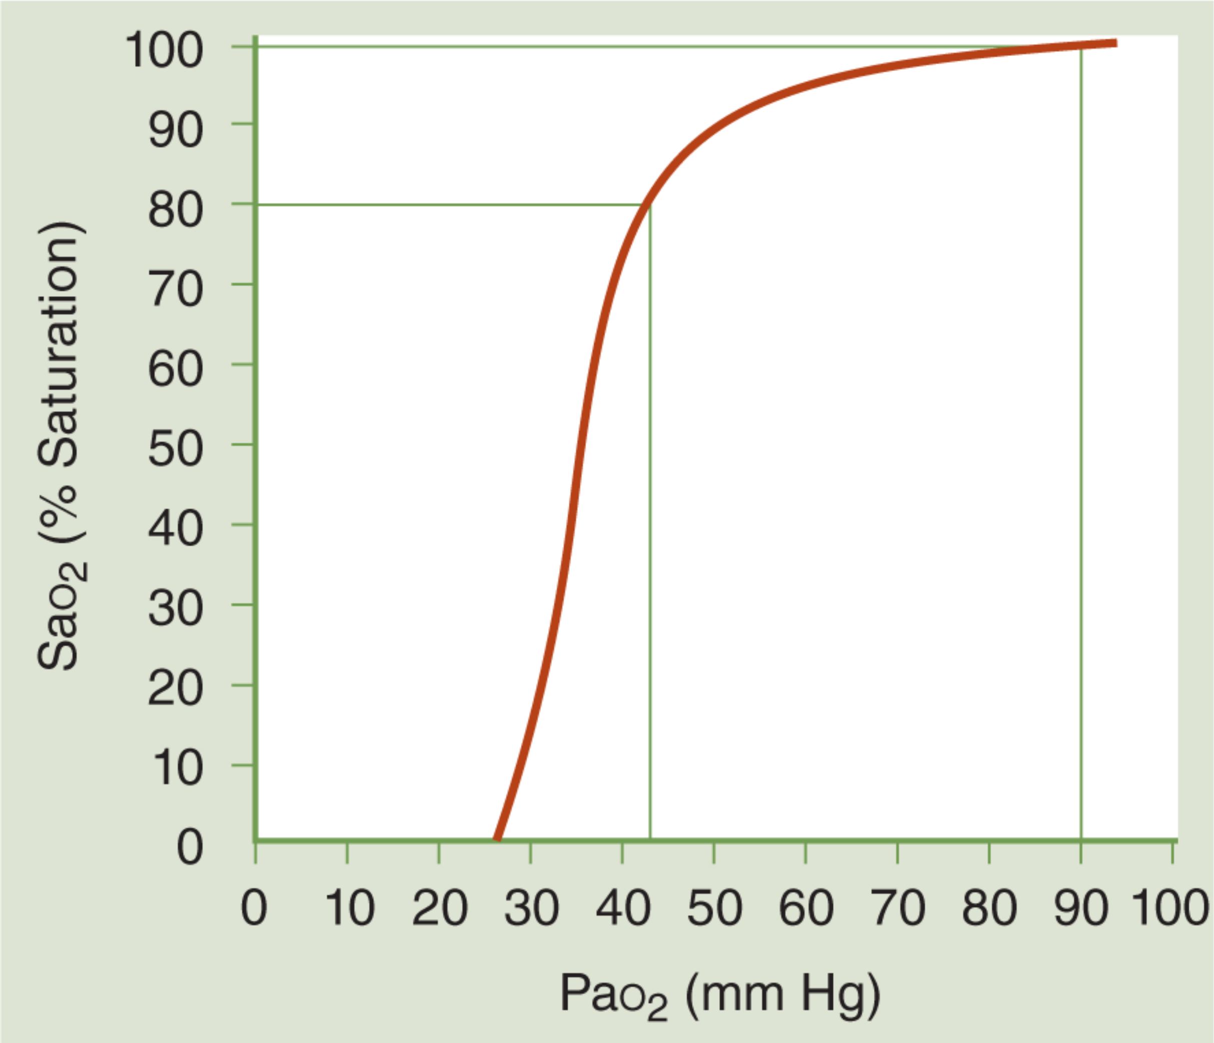

FIGURE 6-7 Oxyhemoglobin dissociation curve.

Abbreviations: PaO_2, arterial partial pressure of oxygen; SaO_2, arterial oxygen saturation

Description

The oxyhemoglobin dissociation curve is a graphical representation of hemoglobin's affinity for binding to oxygen molecules, as viewed from the perspective of oxyhemoglobin saturation (*y*-axis) compared to the partial pressure of oxygen (*x*-axis). At the base of the curve, oxygen is beginning to bind to hemoglobin. As the partial pressure of oxygen increases across the *x*-axis, oxygen saturation of the hemoglobin molecule (**Spo_2**) increases considerably, represented by the steep upslope on the graph. This increase in Spo_2 is directly related to hemoglobin's positive cooperativity with oxygen molecules.

Positive cooperativity, in this case, refers to the heme molecule within the hemoglobin increasing its affinity for binding to oxygen molecules with each successive oxygen bond formed. When the curve becomes flat (plateaus), SpO_2 is not increasing significantly for a given increase in partial pressure. At this point, the oxyhemoglobin is nearly saturated.

The oxyhemoglobin dissociation curve can shift left or right respective to the baseline curve depending on changes in the patient's pH, temperature, and 2,3-diphosphoglycerate (2,3-DPG) level. A right shift in the curve represents a reduction in hemoglobin's affinity for binding with oxygen molecules, which typically occurs in tissue cells where oxygen needs to be delivered. In a right shift, for a given partial pressure of oxygen there will be a correlated reduction in the amount of hemoglobin saturated with oxygen due to the loss of hemoglobin's affinity for binding to oxygen. This shift may be caused by an increase in PCO_2, an increase in the number of hydrogen ions (therefore a decrease in pH), an increase in temperature, or an increase in 2,3-DPG.

Shifts in the Oxyhemoglobin Dissociation Curve

Use the *r* from *right* and the *l* from *left* to help you interpret the oxyhemoglobin dissociation curve:
A shift to the *R*ight *R*eleases oxygen.
A shift to the *L*eft *L*oads oxygen.

In a left shift of the oxyhemoglobin dissociation curve, hemoglobin has an increased affinity for binding with oxygen; this typically occurs in the lungs, where oxygen needs to be loaded onto hemoglobin. In a left shift, for a given partial pressure of oxygen, there will be a correlated increase in hemoglobin saturated with oxygen due to hemoglobin's increased affinity for binding to oxygen. This shift may be caused by a decrease in the PCO_2, a decrease in the number of hydrogen ions (an increase in pH), a decrease in temperature, or a decrease in 2,3-DPG.

When hemoglobin's ability to bind with oxygen is impaired, a patient can experience tissue hypoxia even though the Pa_{O_2} and Sp_{O_2} may be normal. Many substances can bind to hemoglobin and cause it to be dysfunctional. For example, carbon monoxide's affinity for hemoglobin is 240 times greater than oxygen's. When carbon monoxide binds to hemoglobin, it results in the formation of carboxyhemoglobin, which in turn prevents oxygen from being transported and released to the tissues. In addition, nitrite poisoning can result in the formation of abnormal hemoglobin. When nitrite binds to hemoglobin, it results in methemoglobinemia. This phenomenon also alters the oxygen-carrying capacity of the hemoglobin molecule and can result in hypoxia.

Mechanics of Ventilation

The mechanics and dynamics of breathing involve four key concepts: elastance, compliance, resistance, and pressure gradients. Lung parenchyma, the functional part of the lung involved in gas exchange, in an independent state would tend to collapse. This tendency is known as **elastance**. The construction of the bony thorax and ribs, however, creates an opposing force that prevents the lung tissue from collapsing completely.

The ease with which the thorax and lungs expand is referred to as **compliance**. If compliance is reduced, it becomes more difficult for the lungs to expand; therefore, any process that affects the integrity of this relationship results in increased work to expand the lungs. We can define compliance as a change in volume per unit of pressure: $\Delta V/\Delta P$. For example, if the chest wall becomes rigid due to pain, injury, or disease, its expansion becomes more challenging and breathing becomes more difficult. Likewise, if the lung parenchyma becomes diseased and grows stiffer, the work of breathing increases.

Resistance refers to the amount of force needed to move a gas or fluid through a single capillary tube. As defined by Poiseuille's law, viscosity, length of the tube, driving pressure, and radius of the tube contribute to the work required to move a liquid or gas through a tube. Of these conditions, the radius of the tube is the most important factor affecting airflow. If the radius of the tube is decreased by half, the work required to move air through it increases 16 times. This concept is crucial when selecting an endotracheal (ET) tube size; to minimize the work required for gas delivery, the CCTP should generally use the largest appropriate size of tube possible when intubating patients. The relationship described by Poiseuille's law is also important in bronchospasm: A decreased tube radius results in more resistance to flow of gases. Thus, even small amounts of swelling in a child's relatively narrow airway can cause significant distress. The decreased flow of gas results in a greater sense of respiratory distress, which then increases respiratory effort, and ultimately further increases the work of breathing. Increased mucus production, basal membrane edema, and artificial airways will also reduce airway diameter, increase resistance, and potentially result in increased work of breathing.

Pressure gradients allow for the bulk movement of gas into and out of the lungs. During the **inspiration** phase of a patient-initiated spontaneous ventilation, contraction of the chest muscles increases the size of the thorax **FIGURE 6-8**. The increased size of the thorax results in an increase in the volume contained within the thorax. The increased volume, in turn, results in a negative pressure within the thorax relative to the atmospheric pressure, causing air to move into the lungs. At the end of inspiration, the muscles relax, allowing the thorax to return to its original size. This decrease in intrathoracic volume results in an increase in intrathoracic pressure, and **exhalation** occurs. Thus, spontaneous inspiration is an active process that requires work, whereas exhalation is usually a passive event.

Description

In contrast to patient-initiated ventilation, mechanically assisted ventilation is driven by positive pressure, which is generated by a ventilator or a bag-mask device. Positive-pressure ventilation increases both airway and alveolar pressures, which may then reduce venous return to the heart, thereby reducing cardiac output. For further discussion of positive-pressure ventilation, see Chapter 7, *Ventilation*.

The thoracic expansion that begins the inspiratory cycle is driven by muscle contraction. The primary muscles used during inspiration are the diaphragm and external intercostal muscles. In times of increased stress, accessory muscles such as the pectorals, sternocleidomastoid, and scalenes may be used for thoracic expansion, though this process also increases oxygen use. Continued use of these muscles can quickly lead to muscle fatigue, hypercapnia, hypoxemia, and respiratory failure. Some muscles can augment exhalation in times of increased work of breathing, although exhalation remains mostly a passive process. Specifically, if necessary, the intercostal and abdominal muscles can assist exhalation.

The stimulation and innervation of breathing is a complex process involving the pulmonary, cardiac, and neurologic systems. Normally, the drive to breathe comes from the need to eliminate CO_2. In the blood, CO_2 combines with water (H_2O) to form carbonic acid, which then dissociates into H^+ and HCO_3^- ions. Thus, as CO_2 increases, so does the level of H^+. Recall that pH is a function of H^+ concentration; that is, as H^+ increases, pH decreases. The effects of this change are transmitted across the blood–brain barrier and stimulate the respiratory centers in the brainstem. As a backup mechanism, chemoreceptors located in the aortic arch and carotid arteries are sensitive to changes in oxygen levels. When the Pao_2 level drops below 60 mm Hg, these receptors are subjected to their maximal stimulation and subsequently trigger increased breathing.

The body’s respiratory centers are located in the medulla and pons areas of the brainstem **FIGURE 6-9**. In the medulla, the dorsal respiratory group regulates impulses to the diaphragm. The ventral respiratory group controls expiratory impulses, the upper airway muscles, and the intrinsic pattern of breathing. The pontine respiratory group and the pneumotaxic center fine-tune the respiratory pattern. The innervation of the diaphragm comes from the phrenic nerve, which branches from the spinal cord at the level of C3 to C5. Spinal cord injury near this level dramatically affects the ability to breathe adequately.

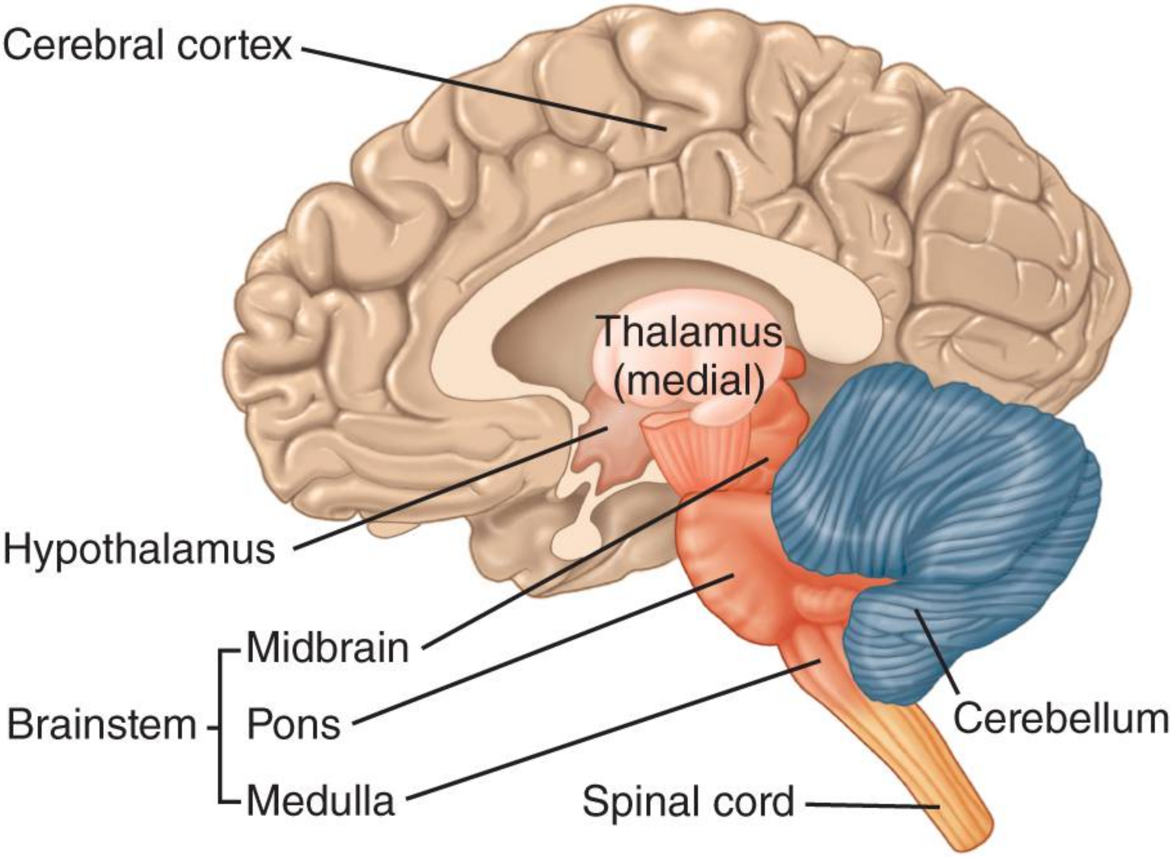

FIGURE 6-9 The pons and medulla are involved in neurocontrol of respiration.

© Jones & Bartlett Learning.

Putting It All Together

The proper functioning of the respiratory system can be explained by five factors:

- **Ventilation.** There must be an adequate bulk flow of gas into and out of the lung.
- **Distribution.** The gas must be delivered into the areas of the lung that are able to engage in gas exchange. Changes in compliance or resistance will send the gas to areas of the lung with an unsuitable $\dot{V}/\dot{Q}$ ratio.
- **Diffusion.** The alveolar-capillary membrane must be able to engage in gas exchange. Widening of the space (as in pulmonary edema) or disease (such as fibrosis) results in a decreased diffusion capacity.
- **Perfusion.** Blood flow through the pulmonary vasculature and contact with the alveolus is essential.
- **Circulation.** The heart must be able to not only pump blood to the lung, but also distribute blood through the systemic circulation. In addition, levels of hemoglobin must be adequate to ensure delivery of oxygen to the cells.

Respiratory Volumes and Capacities

The lungs of a healthy male adult can hold between 5 and 6 L of gas. This so-called total lung capacity (TLC) can be divided into different lung volumes and capacities **FIGURE 6-10**. A spirometer measures these respiratory capacities and volumes of air in liters **FIGURE 6-11**.

Description

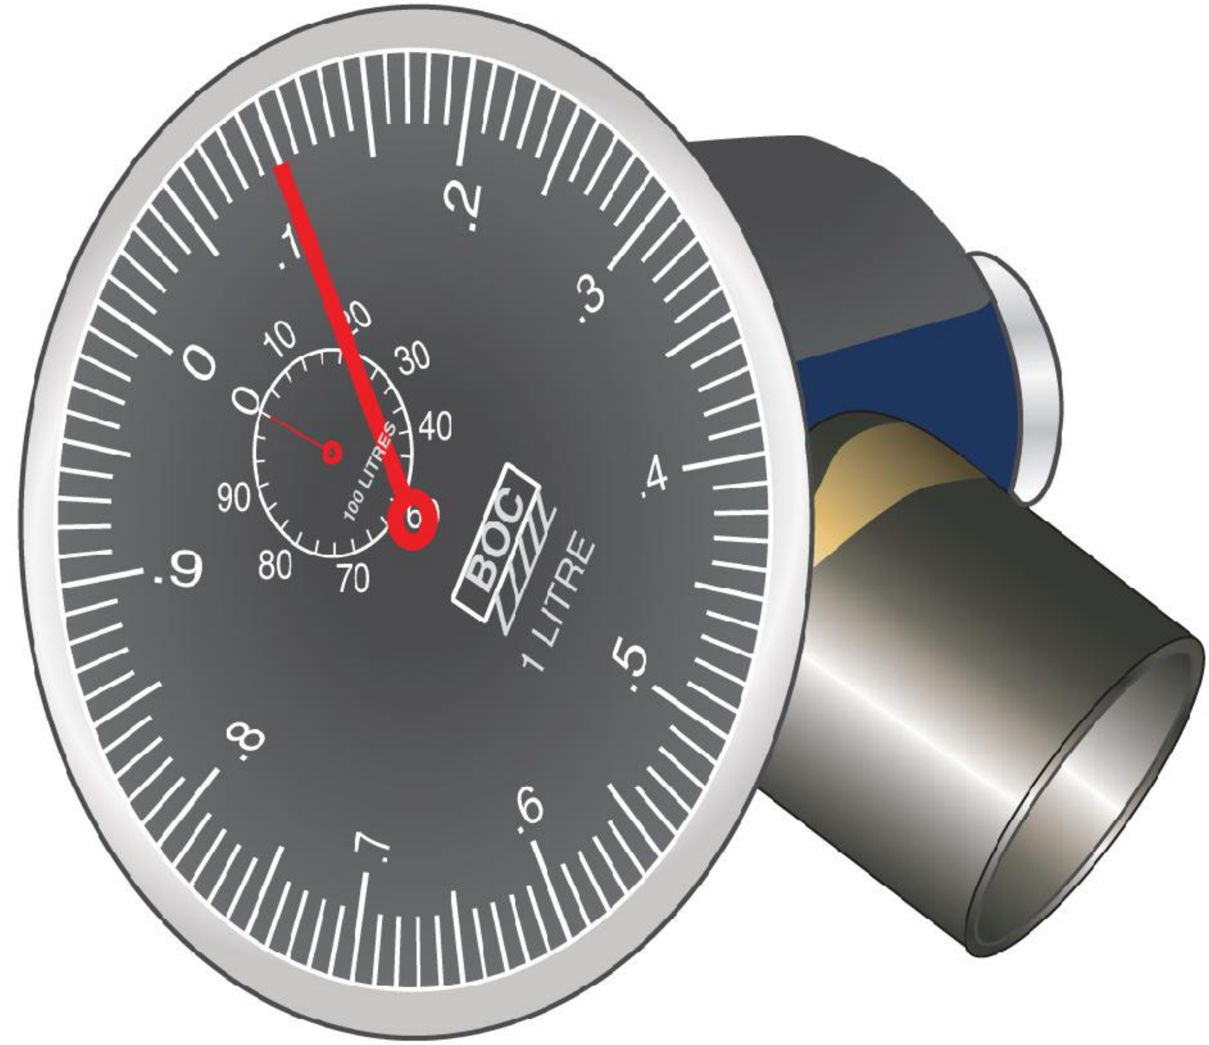

FIGURE 6-11 A spirometer.

Courtesy of Smiths Medical.

Tidal volume (V_t) is the amount of air inhaled and exhaled during each normal breath. **Minute volume** is the amount of air breathed in 1 minute, which is calculated by multiplying the respiratory rate per minute by the average tidal volume. The adequacy and stability of minute ventilation maintain normal oxygen and CO_2 levels; normal minute ventilation is 5 to 8 L/min. The amount of air that can be inhaled after tidal volume is inhaled is the **inspiratory reserve volume (IRV)**, whereas the air that can be expelled from the lungs after a normal exhalation is the **expiratory reserve volume (ERV)**.

The **inspiratory capacity (IC)** is the sum of IRV and V_t. **Vital capacity (V_c)**, also known as the pulmonary reserve, represents the total amount of air that can be exhaled following a maximal inspiration. Normal V_c is 60 to 70 mL/kg of ideal body weight. This value varies with sex, age, and height: Women have a smaller V_c than men do, and V_c decreases with greater age (approximately 20 mL/kg per year for persons older than 20 years) and increases with greater height. A decrease in vital capacity to less than 10 to 15 mL/kg indicates poor pulmonary reserve and an inability to cough effectively. Persons with this condition almost always require some form of mechanical ventilation.

At the end of a maximal forced exhalation, the volume of air remaining in the lungs constitutes the **residual volume (RV)**. RV added to ERV gives the **functional residual capacity (FRC)**. The FRC allows for gas exchange between breaths; it is also targeted during the application of **positive end-expiratory pressure (PEEP)**. Specifically, applied PEEP recruits collapsed alveoli and stents them open. This expansion of the alveoli makes an increased surface area available for gas exchange, facilitating improved oxygenation and increased FRC.

One other volume of note is the **anatomic dead space (V_d)**. This space, found in the upper airway, comprises areas that do not participate in gas exchange. The volume in this space is normally approximately 2 mL/kg.

Pathophysiology: Obstructive and Restrictive Disease States

Respiratory disease states can be categorized in several ways. Disease states that make it more difficult to move air out of the lungs can be classified as **obstructive diseases**. These conditions, which include asthma, COPD, cystic fibrosis, and bronchiectasis, involve an increase in airway resistance. Diseases that result in difficulty moving air into the lungs are classified as **restrictive diseases**. These conditions result in the loss of chest or lung compliance, either individually or together. Restrictive diseases include occupational lung diseases (asbestosis, mesothelioma), idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and the various neuromuscular diseases that affect breathing (eg, Guillain-Barré syndrome and amyotrophic lateral sclerosis).

Both diseases and temporary conditions can alter the $\dot{V}/\dot{Q}$ ratio. Ventilation that exceeds the capacity of blood flow to absorb the gases and carry them to the tissues creates a dead space effect, in which gas exchange is impaired (such as in tachypnea in the setting of a pulmonary embolism). Gas exchange is also impaired when blood flow is in excess of ventilation, as this condition creates a **shunt** effect. For example, in pneumonia, a lobe of the lung is perfused but not ventilated because of infection in the parenchymal air spaces. Anatomic shunts may also prevent blood from participating in gas exchange. Some anatomic shunts are congenital heart defects; others, such as those that involve the bronchial and thebesian veins, are normal and occur in the lung. The extent of the shunt effect (abbreviated Qt) varies: The normal Qt range is 3% to 5%, whereas a value greater than 20% indicates that the patient’s condition is critical.

Because oxygen is vital to the life and metabolism of every cell in the body, evaluating the patient for the presence of hypoxia and treating this condition when it is identified are crucial. It is important to understand the mechanisms underlying hypoxia as well as the causes of hypoxemia:

- **Hypoxic hypoxia.** Defined as insufficient oxygen in the blood. It affects all of the body’s tissues. It may be caused by hypovolemia, airway obstruction, decreased cardiac output, or coronary artery disease.
    - Low oxygen tension may occur in the alveolus itself, such that sufficient amounts of oxygen cannot diffuse across the alveolar-capillary membrane. This condition may be caused by hypoventilation, high altitude (low barometric pressure), and suffocation.

    - Diffusion defects may include fibrosis or edema.
    - Shunting can be intrapulmonary, as when it is caused by atelectasis, bronchospasm, and pneumonia, or extrapulmonary, as occurs with a congenital heart defect.
- **Anemic hypoxia (hypemic hypoxia).** Caused by a reduced level of hemoglobin or dysfunctional hemoglobin. Hypemic hypoxia interferes with the transportation phase of respiration, causing a reduction in oxygen-carrying capacity. Specific causes of hypemic hypoxia include anemias, hemorrhage, hemoglobin abnormalities, use of certain medications (sulfa drugs), and intake of chemicals. It may also be caused by carbon monoxide poisoning. Carbon monoxide is present in exhaust fumes—from ambulances and both conventional and jet-engine aircraft—as well as in cigarette smoke.
- **Stagnant hypoxia.** Reduced cardiac output resulting in tissue hypoxia due to lack of circulation. Specific causes include heart failure, shock, continuous positive-pressure breathing, acceleration (*g* forces), and pulmonary embolism. A reduction in regional or local blood flow may be caused by extremes of environmental temperatures, postural changes, tourniquets, hyperventilation, embolism by clots or gas bubbles, and cerebral vascular accidents.
- **Histotoxic hypoxia.** Occurs when cells are unable to use oxygen due to inactivation or destruction of key enzymes, such as in cyanide and strychnine poisoning as well as in later stages of carbon monoxide poisoning.

Determining the mechanisms underlying hypoxemia can dramatically affect the course of the patient’s treatment. Notably, simply providing supplemental oxygen may not always be sufficient in alleviating hypoxia.

Patient Assessment

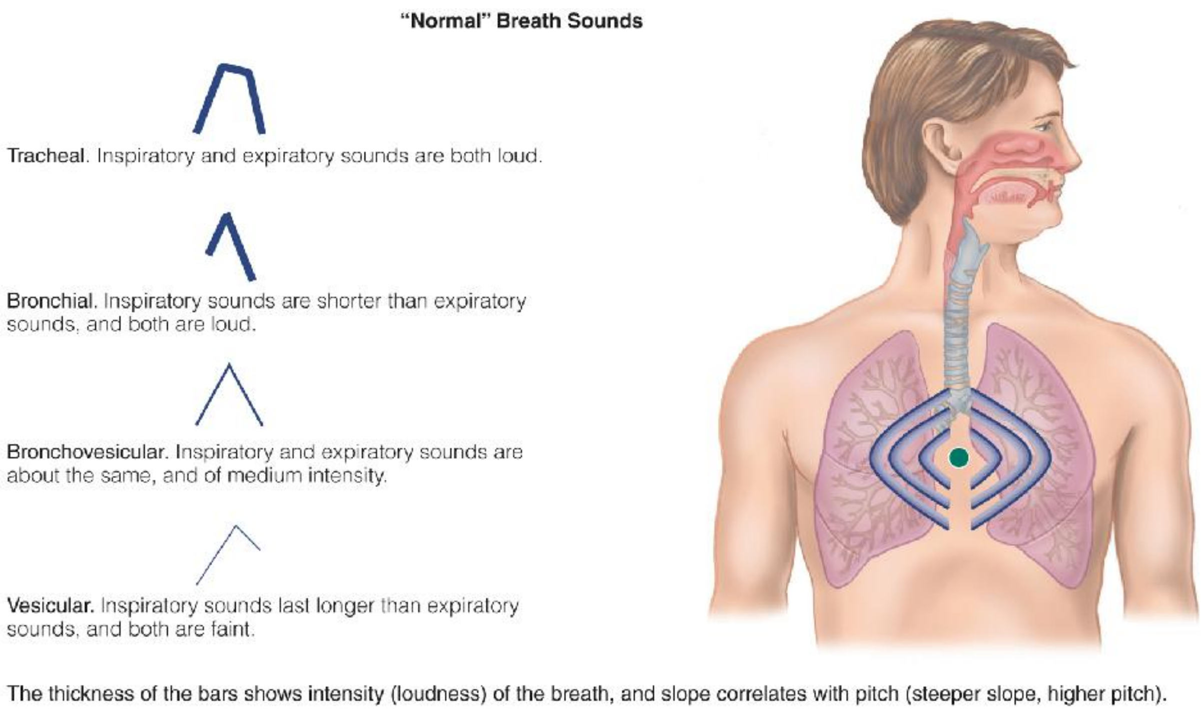
Chapter 5, *Patient Assessment*, covers the techniques of inspection, auscultation, and palpation. This section covers respiratory-specific considerations during the assessment process.

Breath Sound Assessments

After an adequate airway is in place and secured, assessment of breath sounds is vital. Breath sounds are created as air moves through the tracheobronchial tree and the alveoli, and can be auscultated using a stethoscope. The size of the airway determines the type of sound that is produced. (Recall that there are significant differences in the proportional sizes of adult and pediatric airways.)

- The trachea and bronchi have large diameters, so the sound produced there is higher in pitch and is heard during inspiration and expiration. To hear the **tracheal breath sounds** (also called bronchial breath sounds), place the stethoscope diaphragm over the trachea or over the sternum. Assess breath sounds for duration, pitch, and intensity.
- **Vesicular breath sounds** are softer, muffled sounds and have often been described as wind blowing through the trees. The expiratory phase is barely audible. Breath sounds are heard over the majority of the chest, representing airflow in the alveoli.
- **Bronchovesicular sounds** are a combination of the tracheal and vesicular breath sounds. They are heard in places where airways and alveoli are found—that is, the upper part of the sternum and between the scapulae.

FIGURE 6-12 describes the normal breath sounds. The locations where these sounds may be heard are shown in **FIGURE 6-13**.



"Normal" Breath Sounds
Tracheal. Inspiratory and expiratory sounds are both loud.
Bronchial. Inspiratory sounds are shorter than expiratory sounds, and both are loud.
Bronchovesicular. Inspiratory and expiratory sounds are about the same, and of medium intensity.
Vesicular. Inspiratory sounds last longer than expiratory sounds, and both are faint.
The thickness of the bars shows intensity (loudness) of the breath, and slope correlates with pitch (steeper slope, higher pitch).

FIGURE 6-12 Normal breath sounds are heard over different parts of the chest. As you move away from the largest airways, breath sounds become softer. The character of inspiration versus exhalation also changes.

© Jones & Bartlett Learning.

Description

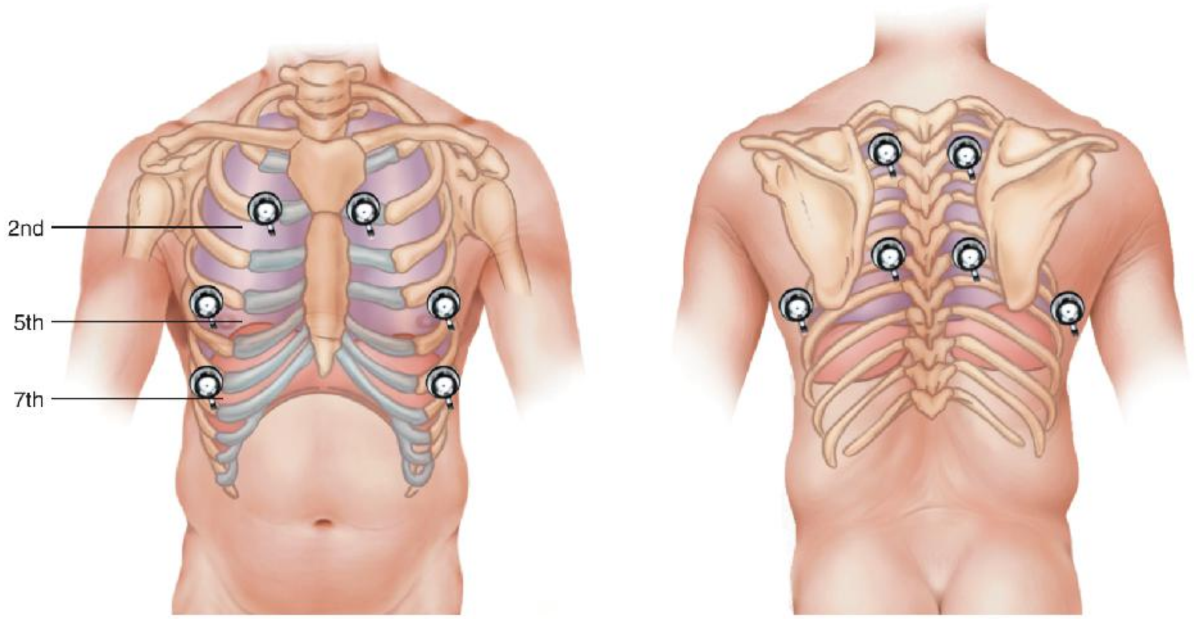


FIGURE 6-13 Commonly assessed auscultation sites, indicated by numbered intercostal spaces.

© Jones & Bartlett Learning.

Bronchovesicular sounds should be assessed for duration, pitch, and intensity. *Duration* refers to the length of time for the inspiratory or expiratory phase of the breath. Normally, expiration is at least twice as long as inspiration. This relationship is expressed by the **I:E ratio**, where a normal I:E ratio is 1:2. When a patient's airway is obstructed and the patient has difficulty getting air out, the expiratory component is prolonged and may be four to five times as long as inspiration; in such a case, the I:E ratio would be 1:5. In patients who are tachypneic, the expiratory cycle is short and approaches that of inspiration, and the I:E ratio may be 1:1. During mechanical ventilation, manipulation of the I:E ratio (such that expiration is longer than inspiration, or inverse I:E) may be used to improve ventilation and hypoxemia in patients with severe lung injury. Extreme caution must be exercised when caring for this patient population.

Pitch of breath sounds is described as either higher or lower than normal, as in patients with stridor or wheezing. The intensity of sound depends on the airflow rate, the constancy of flow throughout inspiration, the patient's position, and the site selected for auscultation.

The thickness of the chest wall may affect the *intensity* of breath sounds. Sounds that are less intense are said to be diminished. A common error in assessing the intensity of breath sounds occurs when auscultation is performed over the patient's clothing.

Sounds that might be classified as normal, but are present in an unexpected area, can indicate an abnormal condition. For example, tracheal sounds in areas that should produce vesicular sounds may indicate consolidation or pneumonia.

The terminology regarding abnormal breath sounds, referred to as **adventitious breath sounds**, varies from one text to another. Such sounds are usually classified as continuous or discontinuous. **Wheezes** and **rhonchi** are continuous sounds that are heard as air flows through a constricted airway. Wheezes are usually high pitched. Rhonchi are low pitched, indicating the airway is not as obstructed as when wheezing is heard.

Crackles (formerly known as rales) occur when airflow causes mucus or fluid in the airways to move, such as when collapsed airways or alveoli pop open. These discontinuous sounds may occur early or late in the inspiratory cycle. Early inspiratory crackles usually occur when larger, proximal bronchi open; they are common in patients with COPD and tend not to clear with coughing. Late inspiratory crackles are heard when peripheral alveoli and airways pop open; these sounds are more common in the dependent lung regions. Late inspiratory crackles are common in patients with reduced lung volumes.

Stridor results from foreign body aspiration, infection, swelling, disease, or trauma within or immediately above the glottic opening. It is associated with a loud, high-pitched sound ("seal bark"), particularly in pediatric patients.

A **pleural friction rub** results from inflammation that causes the lung pleura to thicken, also referred to as pleurisy. The pleural space can decrease as a result, allowing the surfaces of the pleura to rub together. This decrease often creates stabbing pain with breathing or any movement of the thorax. Pleurisy can be caused by viral or bacterial infections as well as autoimmune conditions.

Auscultation

Baseline breath sound assessment is discussed in Chapter 5, *Patient Assessment*. To assess breath sounds in a patient with an invasive airway device, such as an ET tube or supraglottic airway (SGA), listen over the epigastrium and sternal notch **FIGURE 6-14**, over the six recommended sites on the anterior chest wall, and in the axillae (see Chapter 5, *Patient Assessment*). Assess these areas for proper device placement and airflow. The baseline respiratory assessment establishes the standard against which subsequent assessments will be compared.

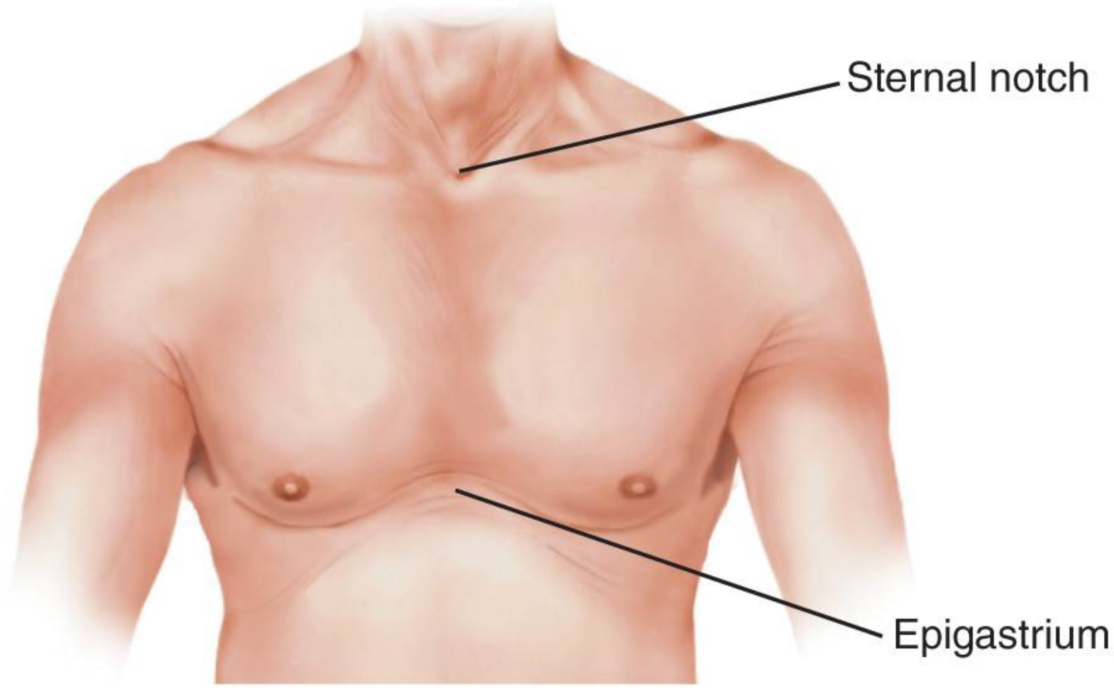

FIGURE 6-14 In patients with an invasive airway, listen for breath sounds over the epigastrium and sternal notch.

© Jones & Bartlett Learning.

Breath sounds are best evaluated while the patient is taking slow, deep breaths through an open mouth and while seated in a semi-Fowler or high Fowler position. Because of clinical circumstances, however, such an assessment may not be possible. If the patient cannot be elevated, auscultate as many of the six recommended sites as possible. Place the diaphragm of the stethoscope firmly against the patient's bare skin. Remember, to avoid misinterpretation of lung sounds, do not perform auscultation through clothing. Be aware of the patient's comfort while assessing breath sounds. Rushing the patient through the process may cause hyperventilation or exacerbate existing dyspnea.

Document the sites chosen for auscultation in the patient care report and the status (patency, appearance, integrity) of any artificial airway. In addition to performing periodic monitoring of breath sounds during transport (though they may be difficult to hear in the sometimes-noisy setting of the transport vehicle), evaluate breath sounds at the following times: immediately on arrival at the patient's bedside, after any patient movement, and immediately before transferring the patient's care to other providers.

Palpation

Palpation of the patient's chest wall enables the CCTP to evaluate the status of the lungs, skin, and subcutaneous tissues and chest expansion. A snap, crackle, pop sensation indicates the presence of subcutaneous emphysema, in which air escapes from the pleural space and dissects through the subcutaneous tissues. Although subcutaneous emphysema itself is benign, its underlying cause may be life threatening. If subcutaneous emphysema is detected, it is important to inquire about recent trauma or invasive procedures (ie, intubation, central line placement) and to determine whether these are new findings.

When a person is speaking, the vibrations of the vocal cords are transmitted to the chest wall, a phenomenon called vocal fremitus. Vocal fremitus is assessed by performing tactile fremitus, which is done by placing the hands bilaterally on the upper thorax and asking the patient to say "ninety-nine." This procedure is repeated in a methodical way down the chest. An increase in the fremitus, or vibration, indicates that the underlying lung tissue is more solid (consolidated) and contains less air than normal, which may be attributable to pneumonia or atelectasis. In addition, if secretions are present in the airways, the vibrations will increase. This finding may indicate that the patient needs to cough or be suctioned. The procedures of vocal fremitus and tactile fremitus are useful in patient assessment but are usually not practical in the transport setting.

Ultrasonography

Point-of-care lung ultrasonography can be a useful assessment tool, especially in a patient with undifferentiated shortness of breath, as described in greater detail in Chapter 9, *Laboratory Analysis and*

Diagnostic Studies. For example, lung ultrasonography can show the relationship of the parietal and visceral lung pleura. An absence of shimmering as these two layers slide past each other (sliding lung sign) suggests poor lung ventilation, which can be seen with a pneumothorax. Additionally, different acoustic artifacts can be used to distinguish well-aerated lungs (A lines) from lungs with alveolar-interstitial syndromes (B lines) such as pulmonary edema or pneumonia.

Normal and Abnormal Respiratory Patterns

When you are assessing respiratory patterns, consider three characteristics of the patient’s respirations: rate, depth, and pattern.

Rate

Eupnea is normal breathing at a rate of approximately 12 to 20 breaths/min in the adult patient. Pediatric norms range from 30 to 50 breaths/min in the newborn to 12 to 20 breaths/min in the adolescent. A number of factors can cause **tachypnea** (an abnormally fast respiratory rate), including fever, pneumonia, metabolic acidosis, hypoxemia, some poisonings and drug uses (aspirin overdose, stimulant use), and lesions of the respiratory center in the brain. Stress, anxiety, and pain can also result in tachypnea. Although tachypnea is a compensatory mechanism, it has negative effects as well. Because rapid respiratory rates usually result in shallower breaths, the amount of **alveolar ventilation (V_a)**—that is, the volume of air that comes into contact with the alveolar-capillary membrane surfaces and participates in the exchange of gases between the lung and the blood—decreases in the patient with tachypnea. More muscle work is used to generate “wasted” ventilation, and the increased work also results in increased oxygen consumption.

Numerous factors can also lead to **bradypnea** (a slower than normal respiratory rate), including use of narcotic or sedative drugs, alcohol, metabolic disorders, respiratory system decompensation or fatigue (particularly in pediatric patients), and traumatic and nontraumatic central nervous system (CNS) lesions. Mild bradypnea is normal in certain stages of sleep.

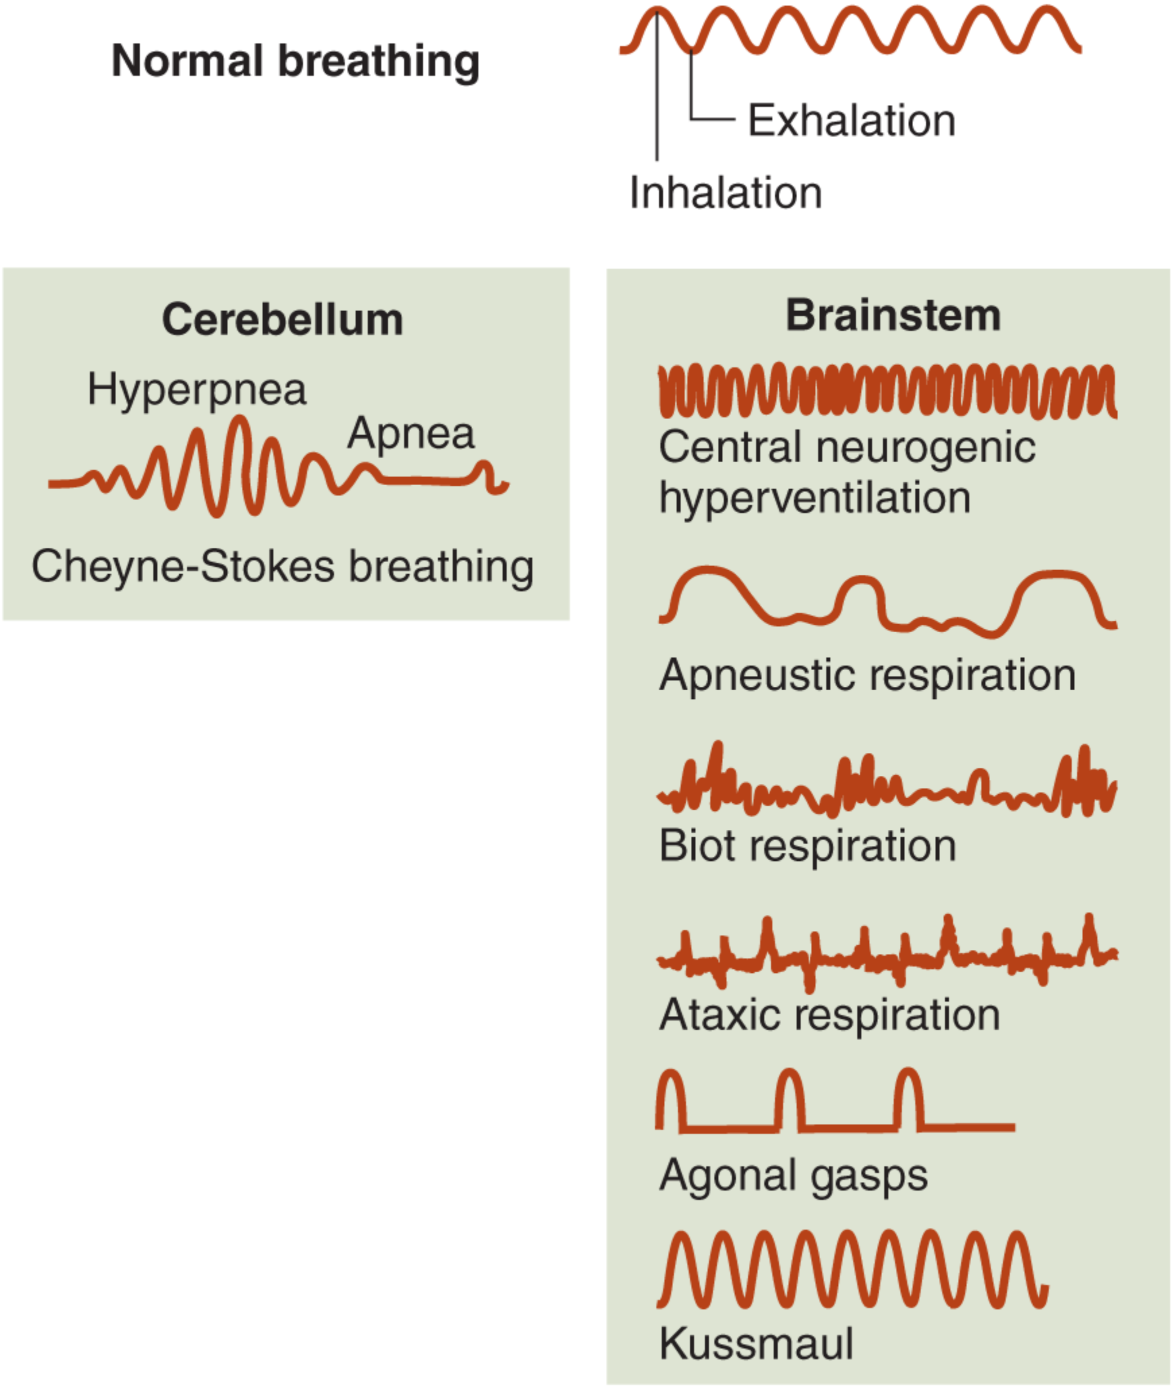
Apnea, the absence of respiration, may be episodic or periodic. Periods of apnea longer than 15 seconds require immediate intervention. The patient with apnea may need ventilatory support or other resuscitative efforts.

Depth

In addition to measuring the respiratory rate, always assess the patient’s depth of respiration. Assessment of depth can be achieved by direct observation or by palpation. **Hyperpnea** describes a deeper than normal breath, whereas **hypopnea** refers to a shallow breath. Hyperpnea can lead to low levels of CO_2, thereby increasing pH and resulting in respiratory alkalosis. Hypopnea can result in increased CO_2 levels, thereby decreasing pH and resulting in respiratory acidosis, as well as decreased oxygen values.

Pattern

Several abnormal respiratory patterns present with characteristic alterations of the respiratory rate, depth, or regularity **FIGURE 6-15**.



Normal breathing
Exhalation
Inhalation
Cerebellum
Hyperpnea
Apnea
Cheyne-Stokes breathing
Brainstem
Central neurogenic hyperventilation
Apneustic respiration
Biot respiration
Ataxic respiration
Agonal gasps
Kussmaul

FIGURE 6-15 Abnormal breathing patterns.

© Jones & Bartlett Learning.

Description

Cheyne-Stokes respiration features a cyclic pattern of increased respiratory rate and depth with periods of apnea. Following the apnea, the patient begins breathing with slow, shallow breaths that increase in rate and depth until apnea returns. This condition can be caused by increased intracranial pressure, renal failure, meningitis, drug overdose, or hypoxia secondary to congestive heart failure. Otherwise, healthy individuals may breathe in a Cheyne-Stokes pattern following exposure to altitude changes or with hyperventilation syndrome. Acidosis, particularly when caused by CO_2 levels, can also trigger Cheyne-Stokes respirations.

Cluster breathing is another abnormal respiratory pattern, in which a cluster of irregular respirations that vary in depth are followed by a period of apnea at irregular intervals.

Biot (ataxic) respiration is similar to Cheyne-Stokes respiration, but the pattern is irregular. While Cheyne-Stokes respiration features repeating patterns of gradual increases concluding with apnea, three patterns occur in Biot respiration: (1) slow and deep, (2) rapid and shallow, and (3) apnea without any predictable pattern. Causes of Biot respiration may include meningitis, increased intracranial pressure, and central nervous system dysfunction. This condition often indicates the presence of lesions higher in the respiratory center in the brainstem than those that produce Cheyne-Stokes respirations.

Kussmaul respiration is fast and deep without periods of apnea. The rate and depth are greater than the normal rate expected for the patient's age group. Breathing is labored, with periods of deep breaths punctuated by sighs. The Kussmaul pattern may indicate metabolic acidosis, including diabetic ketoacidosis, or renal failure. It generally represents a compensatory mechanism to blow off CO_2 during conditions that cause severe acidemia, such as diabetic ketoacidosis.

Apneustic breathing indicates lesions in the respiratory center of the brainstem. The patient exhibits a prolonged, gasping inspiration, followed by an extremely short, ineffective expiration at a rate between 1 and 2 breaths/min. Over a period of several minutes of ineffective exhalation, the patient's lungs may hyperinflate. This pattern results in severe hypoxemia and, if uncorrected, rapid death.

Central neurogenic hyperventilation is a pattern of deep, rapid respirations at rates of 40 to 60 breaths/min. It is caused by a midbrain lesion or dysfunction. Patients exhibiting central neurogenic hyperventilation are generally comatose, with Glasgow Coma Scale scores of less than 8. These patients require intubation and ventilatory assistance to stabilize their ABG parameters.

Hyperventilation syndrome presents with increases in both the rate and depth of respiration. It can result from exertion, fear, anxiety, fever, hepatic coma, acid–base imbalance, or midbrain lesions. A respiratory rate between 20 and 30 breaths/min in the adult is classified as moderate hyperventilation. A prolonged respiratory rate greater than 30 breaths/min is considered severe, and ventilatory support is often necessary in such a case to prevent respiratory muscle fatigue. Use caution when assessing the underlying cause of hyperventilation before initiating any corrective treatment. Never withhold oxygen from a patient showing signs or symptoms of hypoxia.

A state of hyperventilation may also develop in a patient who is intubated or being ventilated. Closely monitor vital signs, pulse oximetry, capnometry readings, end-tidal CO_2 ($ETCO_2$) levels, mental status, and skin color in any patient receiving ventilatory support.

Agonal respirations are also abnormal. This pattern of deep, slow, shallow, irregular, “all-or-none” breaths or occasional gasping breaths is accompanied by a slow respiratory rate.

Another abnormal respiratory pattern is seen in patients with obstructive diseases such as COPD and asthma. The pathology of these diseases leads to airway collapse and hyperinflation of the lungs. Affected individuals have difficulty exhaling completely, which leads to air trapping in the lungs and shallow compensatory respirations. To facilitate exhalation, these individuals exhale for longer periods and with the lips pursed. Pursed-lip breathing applies a back pressure to the airways in an effort to prevent airway collapse. This breathing technique represents an attempt to maintain PEEP (the amount of pressure above ambient pressure present in the airway at the end of the respiratory cycle). The I:E ratio in patients with obstructive disease is usually abnormal.

The appropriate level of intervention for patients with these breathing abnormalities is directly related to the work of breathing and the patient's ability to maintain that work. Remember that all muscle activity uses oxygen to metabolize glucose and manufacture adenosine triphosphate; CO_2, in turn, is produced as a waste product. This process increases the need for further ventilation, which may then exacerbate muscle fatigue. Remember also that the diaphragm is the most efficient of the respiratory muscles. By comparison, the accessory muscles (the scalene, sternocleidomastoid, and external intercostal muscles) use more oxygen. The patient's ability to maintain the increased workload associated with the use of the accessory muscles for breathing depends on age, physical conditioning, degree of cardiopulmonary reserve, and other combined medical conditions. Failure to adequately manage the work of breathing can lead to cardiopulmonary arrest.

Descriptions of Breathing

Do not confuse *shortness of breath* with *work of breathing*. Shortness of breath is a subjective complaint, whereas work of breathing is a physical exam finding.

Assessment in Preparation for Transport

Prior to transport, the CCTP should review the patient care report, noting any medications, disease processes, or trauma that might compromise ventilation. Also note the results of any lab or imaging studies, and review the patient's vital signs. Take special note of when the last ABG measurement was performed and whether the data are valid; for example, consider whether there have been any changes in patient status or interventions since the ABG analysis was performed. If an artificial airway is in place, note its size, type, and depth, and confirm its proper placement before continuing with transport. If the patient requires mechanical ventilation, note the ventilator settings and patient response. If any doubt arises about the placement of tracheal tubes, nasogastric (NG) tubes, orogastric (OG) tubes, or central lines, the CCTP should communicate these concerns to hospital personnel.

If the transport will take place by ground in a mountainous region or by air, remember that altitude-induced pressure changes can occur during travel by helicopter or fixed-wing aircraft. Remember Boyle's law: At a fixed temperature, the volume of a gas varies inversely with the pressure surrounding it. This relationship may cause air or gases within the body to expand as altitude increases (and barometric pressure decreases). Such pressure changes are particularly important for air within the pleural space (pneumothorax). In equipment with air-filled spaces, such as the balloon of an ET tube, the air may need to be replaced with fluid to prevent problems with expansion during ascent in an air transport. During these transports, monitor the patient closely for evidence of dyspnea or the development of an air embolus.

When assessing the respiratory system, begin with the basics:

1. Assess the ABCs.
2. Determine the stability of the airway.
3. Observe the rate, pattern, depth, and character of respiration.
4. Inspect the chest, looking for symmetric rise and fall with each respiratory cycle. Note any accessory muscle use. Note the presence of any central lines or Hickman catheters, nitroglycerin or other medication patches, or indwelling devices such as pacemakers, implanted defibrillators, chest tubes, or medication delivery devices.
5. Note any wounds, abrasion, or bruising. Note the presence and location of bony crepitus or subcutaneous emphysema.
6. Examine any dressings on the chest (eg, wounds, central venous access, chest tubes) and confirm that they are dry and intact.

7. Observe any drainage being collected and note its color and consistency.
8. Auscultate the chest, noting the presence or absence, quality, and type of breath sounds heard. Compare the breath sounds from one side of the chest to the sounds on the other side.
9. If the patient requires oxygen, assess the oxygen delivery device and confirm that the delivered **fraction of inspired oxygen (F_{IO_2})** meets the patient's needs and adequately maintains the desired Sp_{O_2} as measured by pulse oximetry. Recall Henry's law about gas solubility and apply the following formula to determine the required oxygen adjustment for altitude changes:

$$P_1/A_1 = P_2/A_2$$

where P_1 is the partial pressure of gas overlying a solution initially, A_1 is the corresponding amount of gas dissolved in solution at that pressure, P_2 is the ratio of the same gas at a different pressure, and A_2 is the corresponding amount of dissolved gas at this new pressure. Because the two sides of the equation are set equal, a change in P_2 requires a corresponding change in A_2.

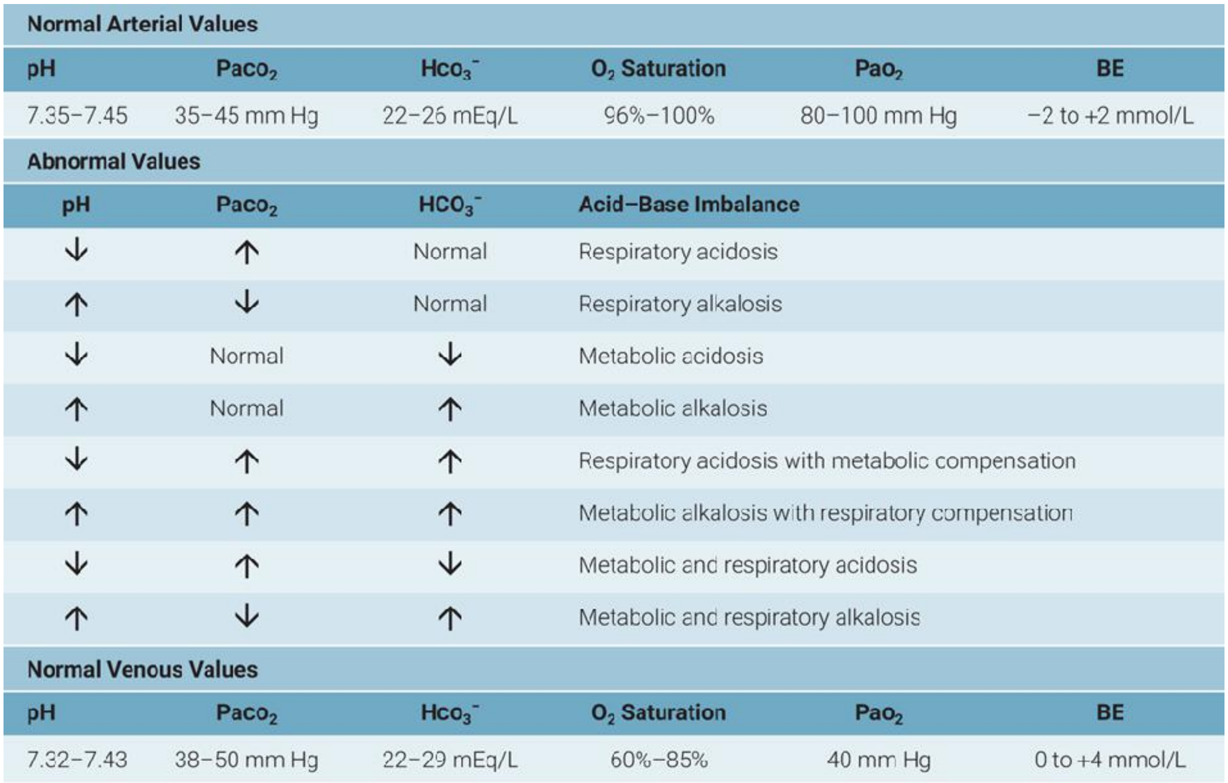
Because cardiac and respiratory functions are intimately linked, assess the patient's circulation to obtain a complete clinical picture. Check the patient's blood pressure, pulse rate, capillary refill time, skin color, and temperature. Mental status is another important consideration, because hypoxia directly affects mental status and level of consciousness.

ABG Monitoring

The gold standard for assessing the functioning of the respiratory system is an ABG measurement. In this procedure, using a heparinized syringe, blood is obtained from a superficial artery, such as a radial or brachial artery, or an arterial line. The blood is then analyzed for pH, $Pa\text{CO}_2$, $Pa\text{O}_2$, HCO_3^- (concentration of bicarbonate ion), base excess (BE, indicating whether the patient has acidosis or alkalosis), and $Sa\text{O}_2$.The technique for obtaining an ABG value is covered in Chapter 9, *Laboratory Analysis and Diagnostic Studies*.

The values for pH, $F\text{IO}_2$, and HCO_3^- are used to evaluate the patient's acid–base status. In contrast, $Pa\text{CO}_2$ is an indicator of the effectiveness of ventilation. The $Pa\text{O}_2$ and $Sp\text{O}_2$ values are indicators of oxygenation. If an ABG sample cannot be obtained, a venous blood gas (VBG) analysis can be useful to assess pH, $Pa\text{CO}_2$, and HCO_3^- (see **TABLE 6-1** for a comparison of values). Further discussion of blood gas interpretation and abnormalities appears in Chapter 7, *Ventilation*; Chapter 9, *Laboratory Analysis and Diagnostic Studies*; and Chapter 17, *Gastrointestinal and Genitourinary Emergencies*.

TABLE 6-1 **Normal Blood Gas Values**



Normal Arterial Values

pH	Paco$_2$	Hco$_3^-$	O$_2$ Saturation	Pao$_2$	BE
7.35–7.45	35–45 mm Hg	22–26 mEq/L	96%–100%	80–100 mm Hg	−2 to +2 mmol/L

Abnormal Values

pH	Paco$_2$	HCO$_3^-$	Acid–Base Imbalance
↓	↑	Normal	Respiratory acidosis
↑	↓	Normal	Respiratory alkalosis
↓	Normal	↓	Metabolic acidosis
↑	Normal	↑	Metabolic alkalosis
↓	↑	↑	Respiratory acidosis with metabolic compensation
↑	↑	↑	Metabolic alkalosis with respiratory compensation
↓	↑	↓	Metabolic and respiratory acidosis
↑	↓	↑	Metabolic and respiratory alkalosis

Normal Venous Values

pH	Paco$_2$	Hco$_3^-$	O$_2$ Saturation	Pao$_2$	BE
7.32–7.43	38–50 mm Hg	22–29 mEq/L	60%–85%	40 mm Hg	0 to +4 mmol/L

© Jones & Bartlett Learning.

Description

To maintain normal blood gas values, the appropriate relationship between alveolar ventilation and perfusion of the alveolar capillaries must be maintained. This relationship is expressed as the $\dot{V}/\dot{Q}$ ratio. Recall that $\dot{V}/\dot{Q}$ mismatch is the most common cause of hypoxemia.

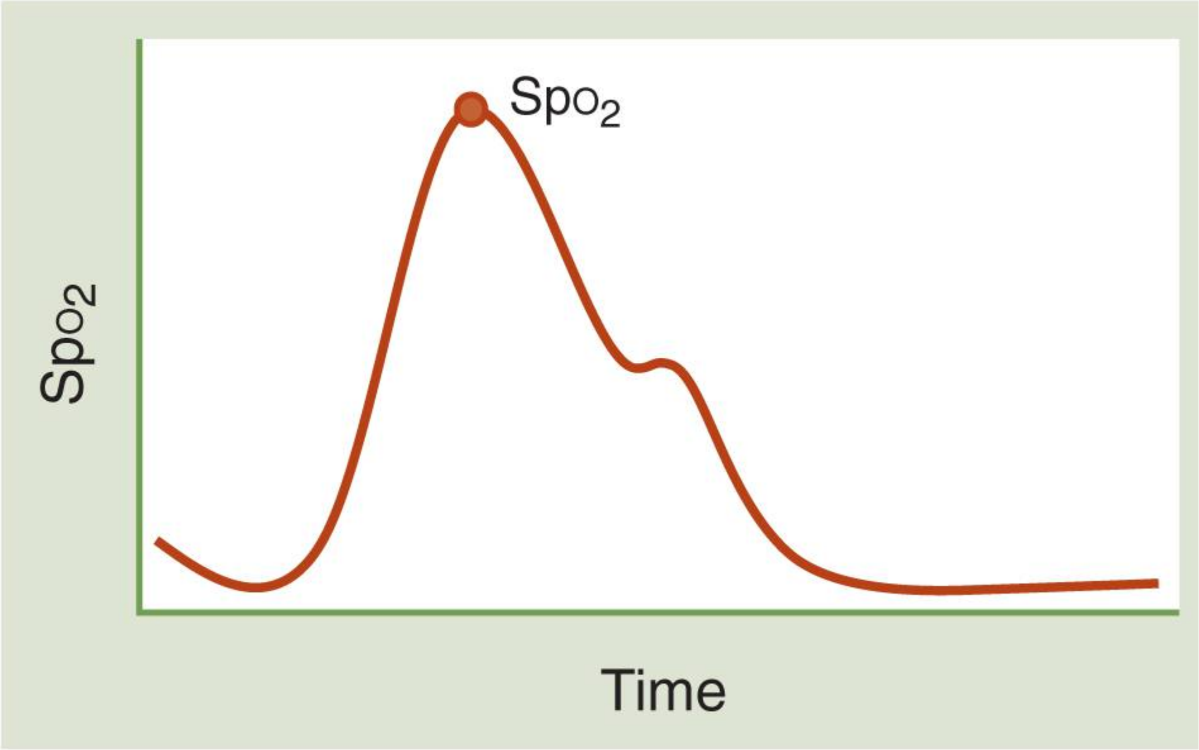
Noninvasive Ventilatory and Oxygenation Monitoring

In addition to ABG analysis, continuous hemodynamic monitoring of critically ill patients, such as via pulse oximetry and capnography, is essential not only in evaluating the patient’s current clinical status, but also in determining how the patient is responding to adjustments in treatments.

Pulse Oximetry

Pulse oximetry provides information about arterial Spo_2 and the pulse **FIGURE 6-16**. Normal pulse oximetry readings should be greater than 92%, but can vary with underlying diseases such as COPD.

A



B

FIGURE 6-16 A. A pulse oximeter. **B.** The characteristic shape of the waveform when the pulse oximeter is properly sensing. Oxygen saturation (SpO_2) indicates the percentage of available hemoglobin that is saturated with oxygen.

© Jones & Bartlett Learning.

All pulse oximetry models work on a similar principle. The machine's diode directs two wavelengths of light, red and infrared, through body tissues toward a photoreceptor. Bound hemoglobin alters light absorption; the degree of change in light transmission indicates the level of arterial Spo_2. Most detectors also supply the monitor with a pulsatile waveform that shows beat-to-beat changes in pulse amplitude and regularity. Commonly used monitoring sites include the finger, pinnae of the ear, toe, and forehead, and sometimes the bridge of the nose.

The pulse oximetry reading reflects the relationship between oxygen and hemoglobin in the body. A number of factors can alter this relationship. Abnormal hemoglobin levels, such as are seen in conditions that produce carboxyhemoglobin, methemoglobin, and sulfhemoglobin, significantly reduce the reliability of pulse oximetry. Conventional pulse oximetry cannot differentiate between normal oxyhemoglobin and the dyshemoglobinemias. Because the dysfunctional hemoglobin is still bound, the pulse oximetry reading will be normal. A newer technology, pulse carbon monoxide oximetry, uses additional wavelengths of both infrared and visible light to measure and differentiate oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, methemoglobin, and hemoglobin itself.

Decreased tissue perfusion (eg, hypotension, cardiogenic shock) to the periphery may also result in impaired light absorption and inaccurate pulse oximetry readings. Hypothermia may alter pulse oximetry readings because of peripheral vasoconstriction. Peripheral vascular disease (PVD) and vasopressor use may alter blood flow to the periphery and pulse oximetry readings.

Capnography

Capnography (a graphic representation of exhaled CO_2) and **capnometry** (a numeric value) are both essential adjuncts to determining airway patency and appropriateness of ventilation **FIGURE 6-17**. CO_2 is produced intracellularly as a by-product of cellular metabolism and is transported to the lungs for diffusion and subsequent ventilation. Capnography and capnometry devices monitor the CO_2 concentration within the patient’s exhaled air by analyzing air samples obtained directly from the airway through nasal prongs in the spontaneously breathing patient or by insertion of a sampling port into the ventilator circuit. Because CO_2 readily diffuses across the alveolar-capillary membrane and quickly equilibrates in the alveolar gases, exhaled gases—particularly those present near the end of exhalation—closely approximate arterial CO_2 levels (35 to 45 mm Hg).

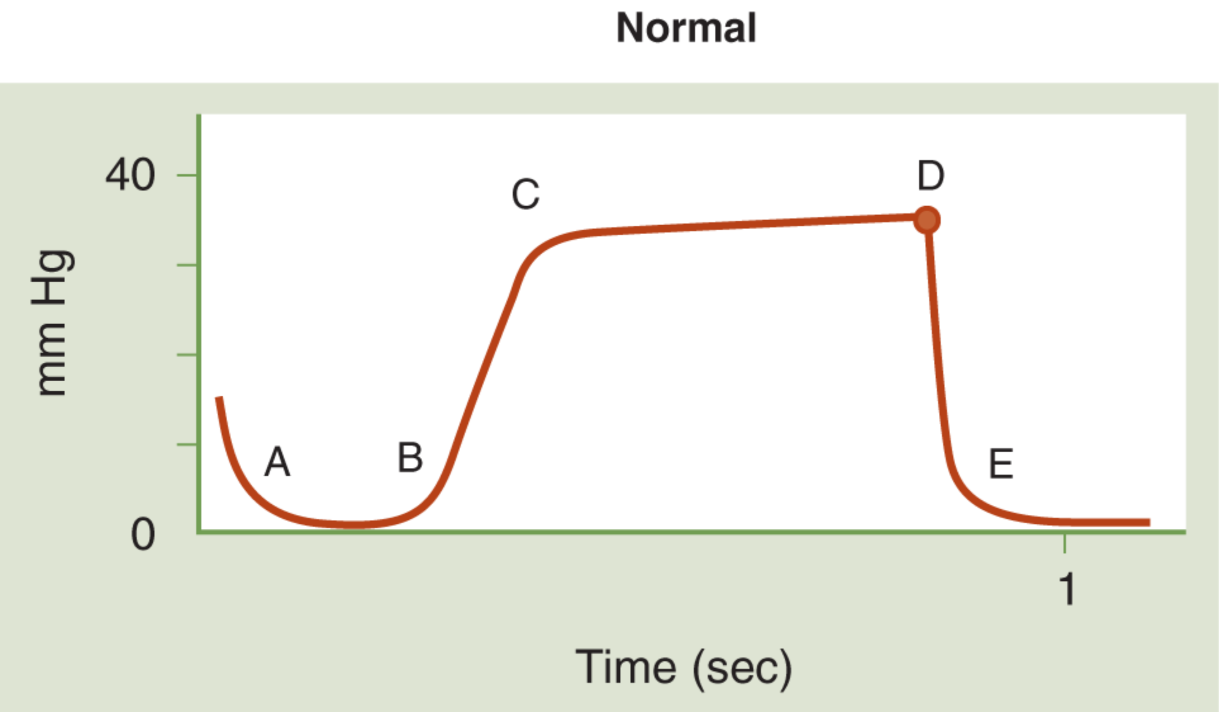
Description

In normal respiratory physiology, because of the diffusion gradient across the alveolar membrane, the $Pa{O_2}$ level is expected to be 2 to 5 mm Hg higher than the $ETCO_2$ value. The CCTP should be aware of gradient trends between these two values. A widening gradient may indicate a perfusion issue and worsening $\dot{V}/\dot{Q}$ mismatch, suggestive of a condition such as a pulmonary embolism. A narrowing gradient may indicate a ventilation issue and developing shunt pathology.

Waveform capnography morphology can inform the astute CCTP of changes in the patient's respiratory status and metabolism, provide diagnostic information, and help establish the differential diagnosis. Capnography will depict respiratory rate and tidal volume changes almost instantaneously, compared to pulse oximetry, which is a lagging indicator of the patient's condition. The normal capnography waveform **FIGURE 6-18** is rectangular with rounded corners and is divided into four phases:



Normal

FIGURE 6-18 Normal capnographic waveform with points A through E shown.

© Jones & Bartlett Learning.

Description

- Phase I (A–B) begins on inspiration, when there are low levels of CO_2. It is considered the baseline.

- Phase II (B–C) begins with the movement of PCO_2 from the anatomic dead space at the beginning of exhalation. It is represented by the first expiratory upstroke.
- Phase III (C–D) is the alveolar plateau. It ends with the last alveolar gas sampled, referred to as PETCO_2.
- Phase IV (sometimes referred to as phase 0; D–E) is depicted by the inspiratory downstroke. It is caused by the sudden reduction in PCO_2 on inspiration.

Given these phases, the capnograph reflects changes in PCO_2 over time during ventilation. If the normal flow of PCO_2 is disrupted, the capnography will display the abnormalities as a modified waveform. In cases involving obstructive pathology, PCO_2 becomes trapped in the alveoli, thereby causing prolonged exhalation. This prolongation would be represented on the capnograph in the phase II expiratory upstroke and the phase III plateau by curving the initial upward deflection, producing a characteristic shark-fin pattern **FIGURE 6-19**. **Figures 6-20** through **6-23** represent other abnormal capnographic waveforms.

Waveform Morphology

When interpreting waveform morphology and trends in values, remember that capnography depends on cellular metabolism and patient ventilation.

Respiratory and Ventilation Abnormalities

Respiratory insufficiency is the inability of the respiratory system to keep up with the body's metabolic demands. Careful respiratory assessment can help the CCTP to determine whether the insufficiency stems from ventilation or oxygenation problems. Treatment depends on the cause of the insufficiency. For example, thoracic, head, or spinal cord injury; central nervous system depression; use of drugs; and conditions in which fatigue challenges the patient's ability to breathe normally may cause **respiratory depression**. Symptoms of respiratory depression consist of a low respiratory rate (less than 12 breaths/min in adults) for a prolonged time or hypoventilation. In this case, increasing ventilation will resolve the insufficiency. Oxygen therapy is indicated in those patients who cannot maintain normal Spo_2. In general, oxygen therapy should be titrated to a goal Spo_2 level of greater than 92%. Hyperoxygenation should be avoided because it may contribute to nitrogen washout and subsequent damage to alveolar cells, oxygenation toxicity leading to pulmonary dysfunction, and oxidative stress on tissues caused by the release of free radicals.

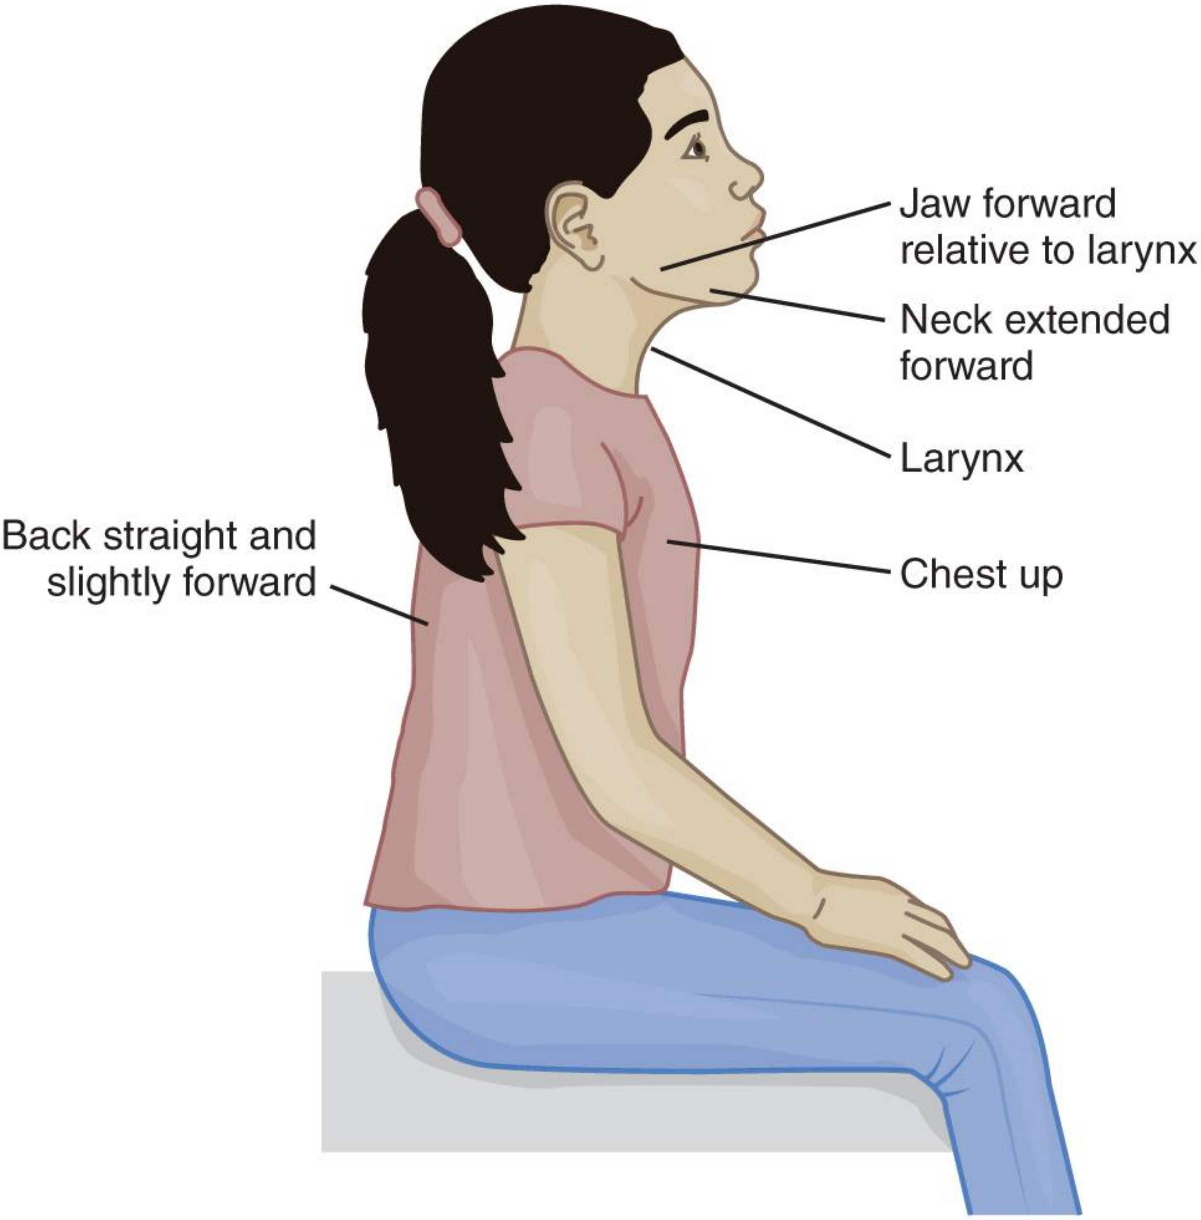
Respiratory failure occurs when the respiratory system fails to meet the body's metabolic needs. Respiratory failure can present with decreasing respiratory effort and depth. The patient may be anxious, confused, or obtunded. If not reversed, respiratory failure will lead to respiratory or cardiopulmonary arrest. Two basic types of respiratory failure are distinguished: oxygenation failure and ventilatory failure. Tachypnea is the hallmark of oxygenation failure. In this case, the ability to sustain a high respiratory rate is related to the amount of accessory muscle use the patient can endure before muscle fatigue occurs. The astute CCTP must intervene before the patient sustains an arrest. Ventilatory failure develops with increased arterial tension of CO_2.

Basic Airway Management

Although intubation is considered the gold standard for airway management, basic airway skills are the starting point in the initial patient assessment and treatment; they are also what CCTPs fall back on in difficult cases. These basic skills may be as simple as placing a nontrauma patient in the recovery position or using the head tilt–chin lift or jaw-thrust maneuver to maintain airway patency. Other basic skills may include use of adjuncts such as the oropharyngeal airway (OPA) or nasopharyngeal airway (NPA).

Positioning

Patients can usually assume the position that makes breathing easiest —typically, sitting upright in the sniffing position **FIGURE 6-24**. In most circumstances, the CCTP should allow the patient to assume this position or be prepared to assist the patient in doing so. Patients with spinal precautions and those with a diminished level of consciousness, however, may not be able to assume this position or adequately protect their airway. As the level of consciousness decreases, control of the muscles located within the oropharynx is lost, causing the tongue to contact the posterior pharyngeal wall or soft palate, which results in airway obstruction. Muscular control of the epiglottis may also be lost, leading to partial or total airway obstruction.



Jaw forward relative to larynx
Neck extended forward
Larynx
Back straight and slightly forward
Chest up

FIGURE 6-24 A patient seated in the sniffing position sits upright with the head and chin thrust slightly forward.

© Jones & Bartlett Learning.

As a patient's level of consciousness diminishes, the ability to control secretions also decreases. This diminished control may result in significant aspiration, especially when patients are found unconscious and supine.

In patients undergoing resuscitation that requires supine positioning, manual airway maneuvers may be used to open the airway:

- **Head tilt–chin lift maneuver.** The most commonly known and used manual method of opening the airway in an unconscious, nontrauma patient **FIGURE 6-25**. Evidence suggests the head tilt–chin lift maneuver is not as effective as the jaw-thrust maneuver.
- **Tongue-jaw lift maneuver.** Most commonly used to open and assess a patient's airway for foreign body obstruction. The patient cannot be ventilated while this maneuver is being used **FIGURE 6-26**.
- **Jaw-thrust maneuver.** Frequently used to ensure a patent airway and provide cervical spine protection in the unconscious trauma patient. In the nontrauma patient, the jaw thrust may be combined with a slight head tilt to provide a better airway opening **FIGURE 6-27**.

Description

Airway Adjuncts

Both the OPA and the NPA are used along with manual airway maneuvers to provide a patent airway. In the unconscious patient, neither can be used independently, as both adjuncts require maintaining manual airway maneuvers.

The OPA is a rigid device made of plastic or similar material that is placed in an unconscious patient's mouth **FIGURE 6-28**. An OPA can be inserted only when the patient does not have a gag reflex; if the gag reflex is working, the airway must be removed immediately because it will induce vomiting. The appropriate size of airway is determined by measuring from the central incisors to the angle of the jaw. Insertion of an airway that is too small or too large will not provide for a patent airway and, in fact, may worsen an already compromised airway. Insertion of an OPA does not replace the need for manual methods to maintain the airway, but rather supplements them.

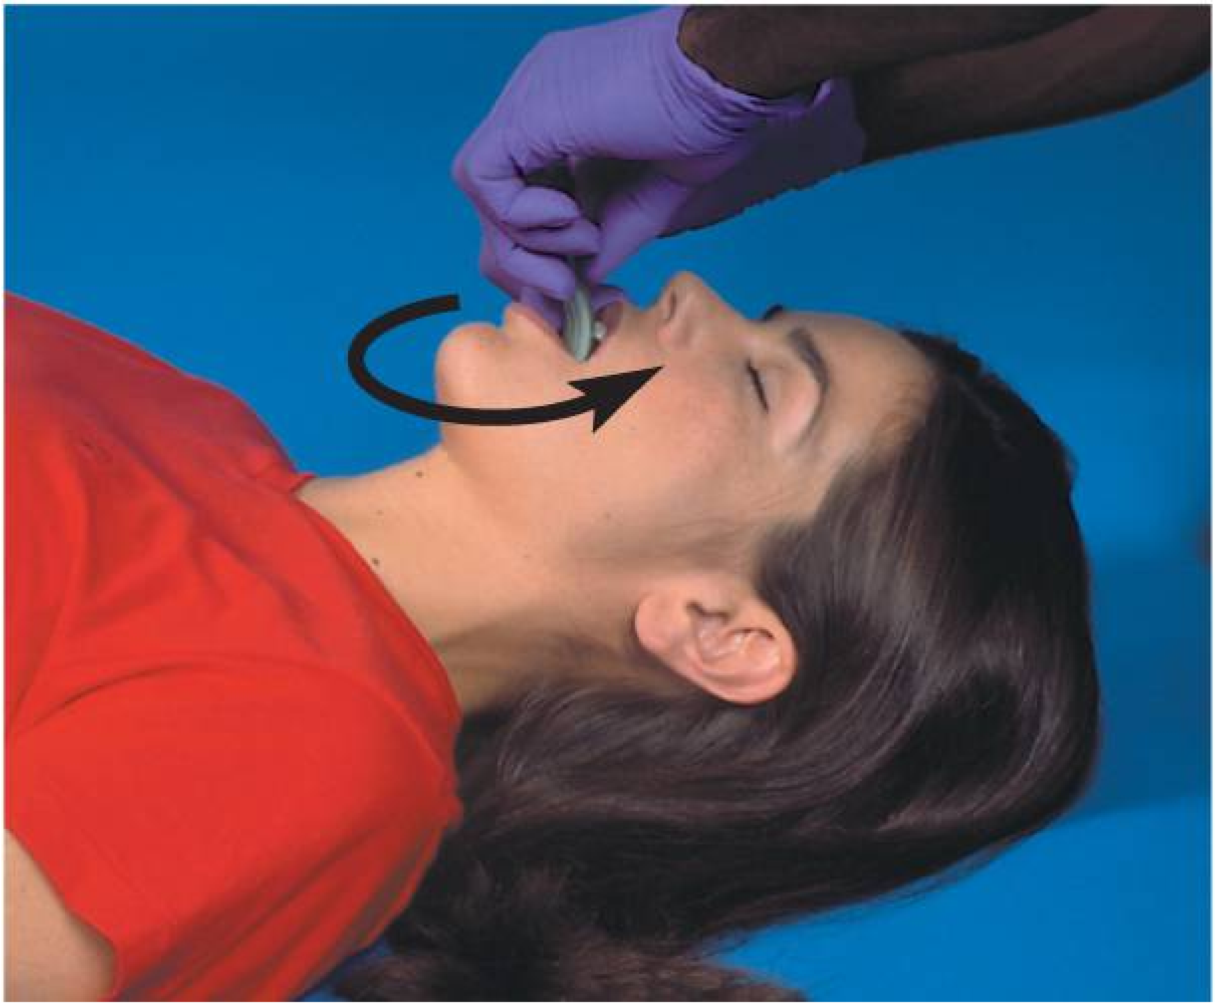

FIGURE 6-28 Use of an oropharyngeal airway.

© Jones & Bartlett Learning.

The NPA is a flexible rubber or silicone device that is placed in one of the nares and extends to the oropharynx **FIGURE 6-29**. It is better tolerated than the OPA in semiconscious patients. To select the appropriate size (length) of airway, measure from the tip of the patient's nose to the tragus of the ear. The diameter of the NPA should be the largest possible, but not large enough to cause blanching of the naris. Its placement should not be forced, as the mucosa of the nose is easily lacerated, which can lead to significant bleeding. Application of a non–petroleum-based lubricant might be helpful in inserting the NPA. Head trauma with evidence of basilar skull fracture or facial fracture is a contraindication to insertion of this device. Like the OPA, the NPA does not take the place of manual methods to maintain the airway, but rather supplements them.

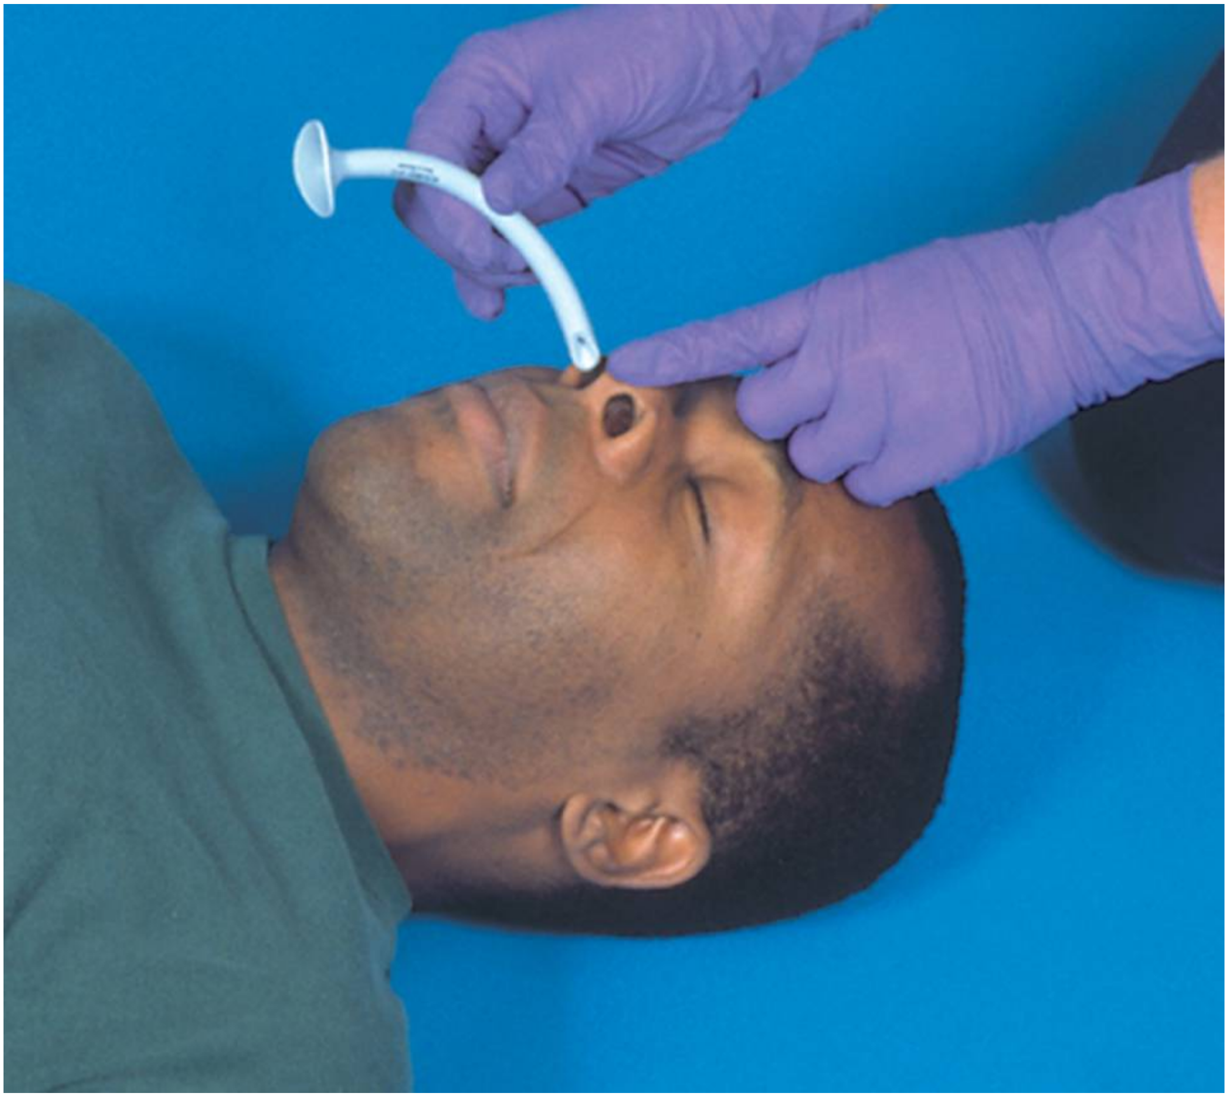

FIGURE 6-29 Use of a nasopharyngeal airway.

Suction

One principle of airway management is to presume that a patient has a full stomach and will vomit and potentially aspirate. The prehospital provider’s ability to clear debris (eg, vomit, blood) from a patient’s airway, while a basic skill, may be lifesaving. Clearing the airway can restore airway patency and minimize the potential for aspiration. In the context of upper airway suctioning, a large-bore suction apparatus can be used. There are various types of these devices, both fixed and portable. These suctioning devices use rigid suction catheters (Yankauer, tonsil tip, DuCanto) to remove debris. In a patient with large volumes of debris or vomit, turning the patient to their side while using a large-bore suction device works best **FIGURE 6-30**. Adequate suction should be immediately available during all airway procedures.

FIGURE 6-30 Suctioning.

© Jones & Bartlett Learning.

Flexible or soft suction catheters are used for suctioning the nasopharynx, oropharynx, and lower airways in patients with an artificial airway in place. These suction catheters, which are not designed to remove large volumes or large particulate matter, come in a variety of sizes, measured using the French scale.

Suctioning of the nasopharynx, oropharynx, and lower airway may cause hypoxemia and hemodynamic instability. Patients should be preoxygenated before suctioning begins, and suction attempts should be limited to 10 seconds or less while withdrawing the catheter. Patients should be oxygenated and ventilated if necessary between suction attempts.

In the critical care transport setting, you will often use suctioning while an ET tube is in place. Indications for suctioning in this scenario include the following:

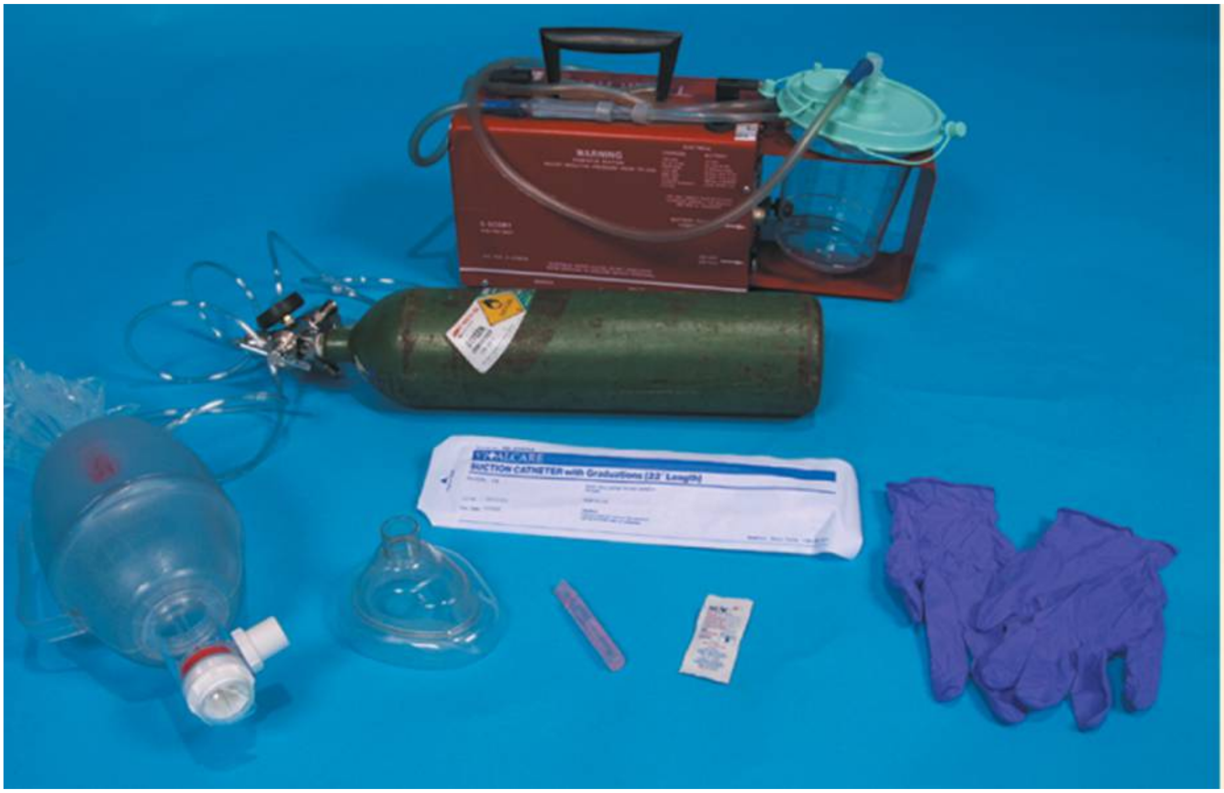
- Dyspnea
- Obstruction
- Excessive secretions

Several complications are possible with suctioning:

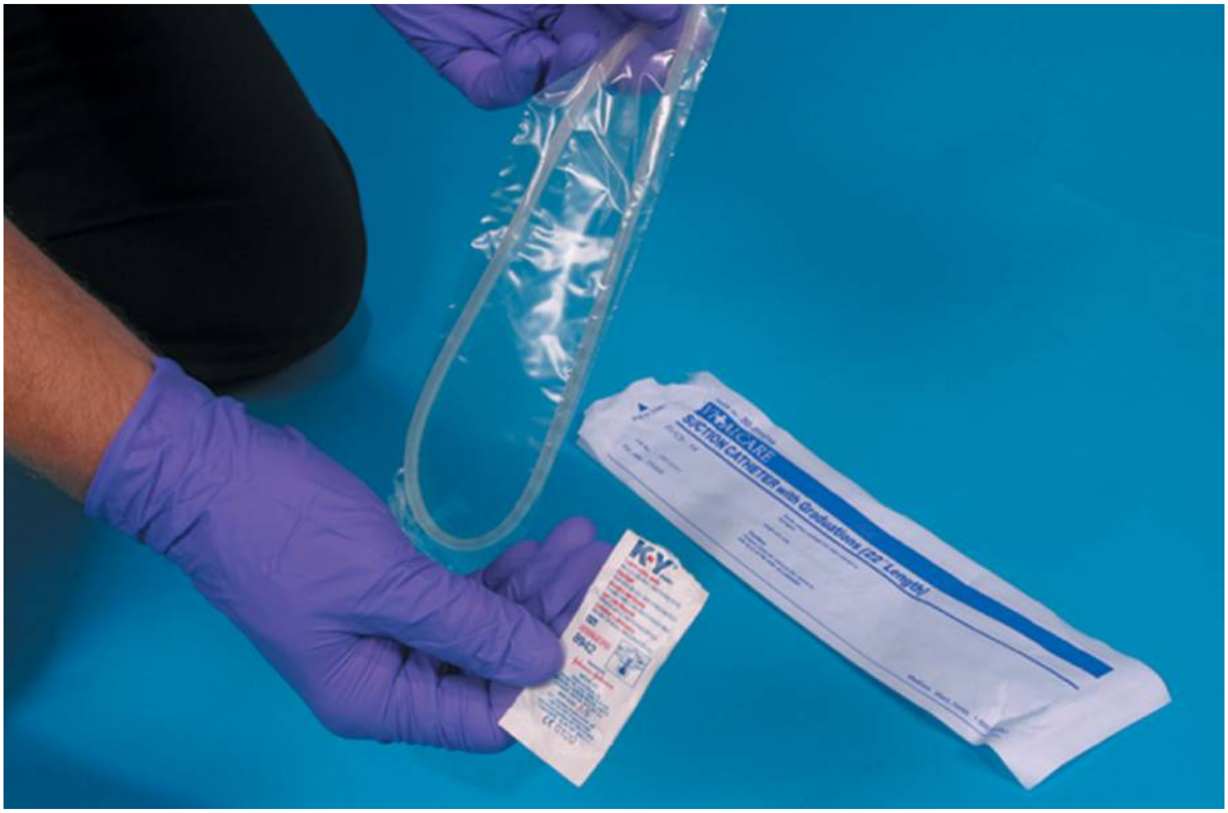
- Hypoxemia
- Cardiac arrhythmias
- Mechanical trauma
- Infection
- Increased intracranial pressure
- Inability to remove material due to a mucus plug or dried crusting

Skill Drill 6-1 shows the steps for suctioning a patient with an ET tube in place, which are also described here:

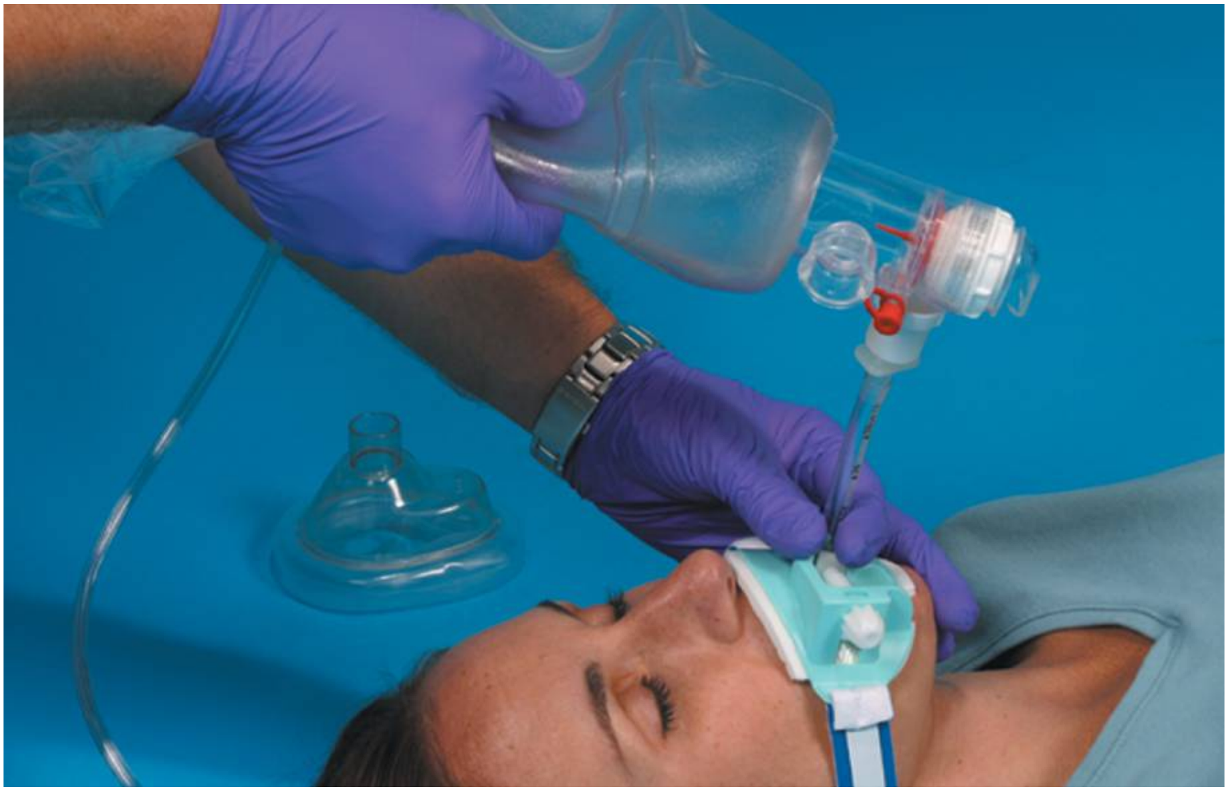
SKILL DRILL 6-1 Suctioning a Patient With an ET Tube in Place



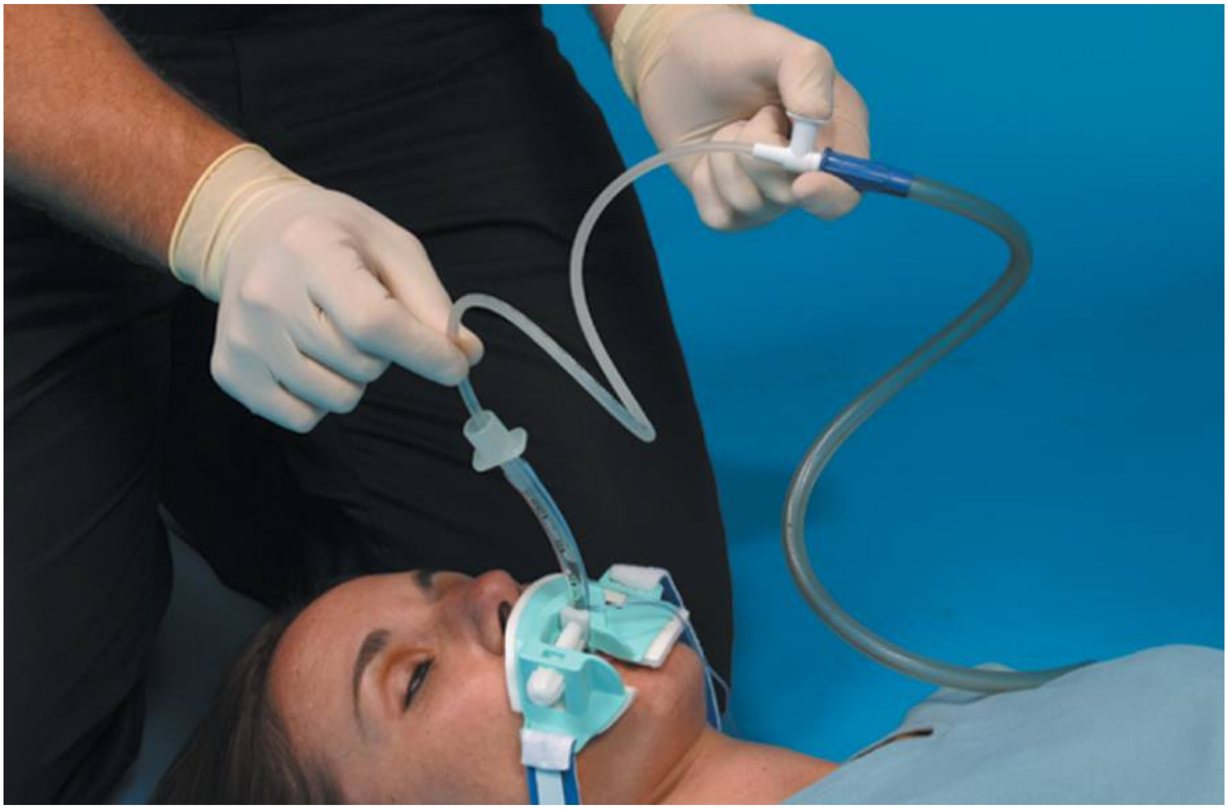
Step 1
Check, prepare, and assemble your equipment.



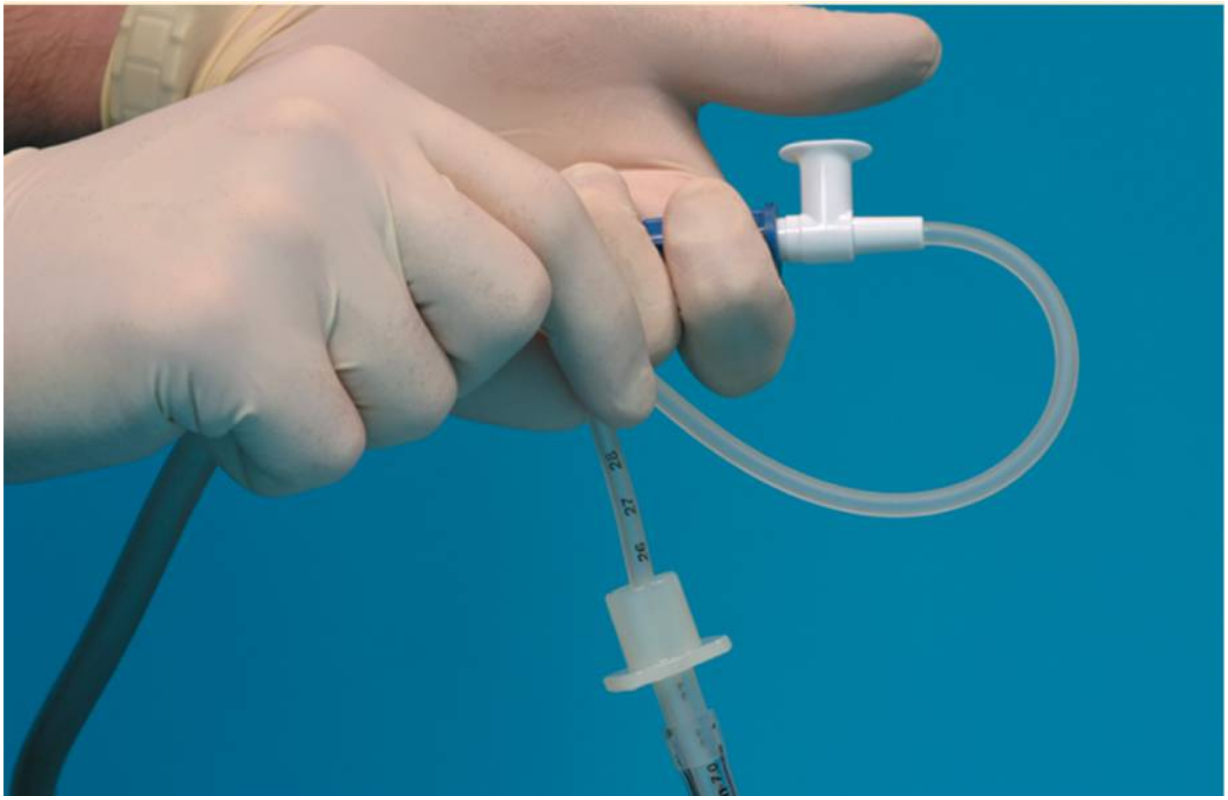
Step 2
Lubricate the suction catheter.



Step 3
Preoxygenate the patient.



Step 4
Gently insert the catheter into the ET tube until the patient coughs.



Step 5
Suction in a rotating motion while withdrawing the catheter. Monitor the patient's cardiac rhythm and SpO_2 during this procedure.

Step 6
Reattach the bag-mask device and resume ventilation and oxygenation.

© Jones & Bartlett Learning.

1. Choose an appropriate suction adjunct: a Yankauer or DuCanto catheter for larger objects, or a French (“whistle tip”) catheter for fluid or ET tube obstructions.
2. Check, prepare, and assemble your equipment **STEP 1**.
3. Maintain universal precautions.
4. Use a sterile technique.
5. Lubricate the suction catheter **STEP 2**.
6. Preoxygenate the patient for 1 to 2 minutes with 100% oxygen **STEP 3**.
7. Measure the suction catheter tip from the corner of the patient’s mouth to the angle of the jaw or insert it through the ET tube until the patient coughs **STEP 4**.
8. Suction for no longer than 5 to 10 seconds as you remove the suction catheter with a twisting motion **STEP 5**.

9. Continuously observe the patient’s response to suctioning (vital signs).
10. Rinse the catheter with sterile water.
11. Assess the airway, ET tube, and lungs to determine the effectiveness of the suctioning. Reattach the bag-mask device and resume ventilation and oxygenation **STEP 6**.

Oxygen Administration

Oxygen is the most commonly administered drug in the hospital and prehospital environments. Oxygen administration has potentially significant benefits when this therapy is used appropriately. As a general rule, hypoxic patients should receive supplemental oxygen to maintain an Spo$_2$ level of greater than 92%. Unnecessary oxygen administration, resulting in a supranormal Spo$_2$ level (hyperoxia), has been associated with increased morbidity and mortality in critically ill patients. Remember, it is possible for a patient to have an Spo$_2$ of greater than 92% and still be hypoxic at the cellular level.

Low-flow oxygen devices such as a nasal cannula can safely and comfortably deliver an Fio$_2$ up to approximately 40% **TABLE 6-2**. Flow rates ranging from 6 L/min up to a flush rate may be indicated for patients with apneic oxygenation during airway procedures. Patients in significant respiratory distress and those with significant hemodynamic instability require higher oxygen flow rates, usually through a nonrebreathing mask, which can deliver an Fio$_2$ closer to 1.0 (100%). Remember, with a critical patient, too much oxygen is better than too little oxygen.

TABLE 6-2 Oxygen Versus Approximate Fio$_2$

Oxygen, L/min	Approximate Fio$_2$, %
Nasal cannula	

Oxygen, L/min	**Approximate $\mathrm{FIO_2}$, %**
1	24
2	28
3	32
4	36
5	40
6	44
Simple face mask, 10	40–60
Nonrebreathing mask, 12–15	80–100

Abbreviation: $\mathrm{FIO_2}$, fraction of inspired oxygen
Data from Federal Aviation Administration.

The appropriate oxygen delivery device should be chosen based on the physical assessment of the patient. Patients in significant respiratory distress require high-flow oxygen via a nonrebreathing mask or bag-mask device. Patients with agonal respirations or those who are apneic require bag-mask ventilation with supplemental high-flow oxygen. The device chosen must fit the patient’s overall assessment.

When gas flow is inadequate, positive-pressure ventilation is required to ensure the patient is appropriately oxygenated. Indeed, delivery of positive-pressure ventilation when the patient’s spontaneous respiration is inadequate may be life-saving care. A bag-mask device is commonly used to deliver supplemental oxygen via positive-pressure ventilation, and can be used in combination with a face mask or an invasive airway device such as a SGA or ET tube **FIGURE 6-31**.

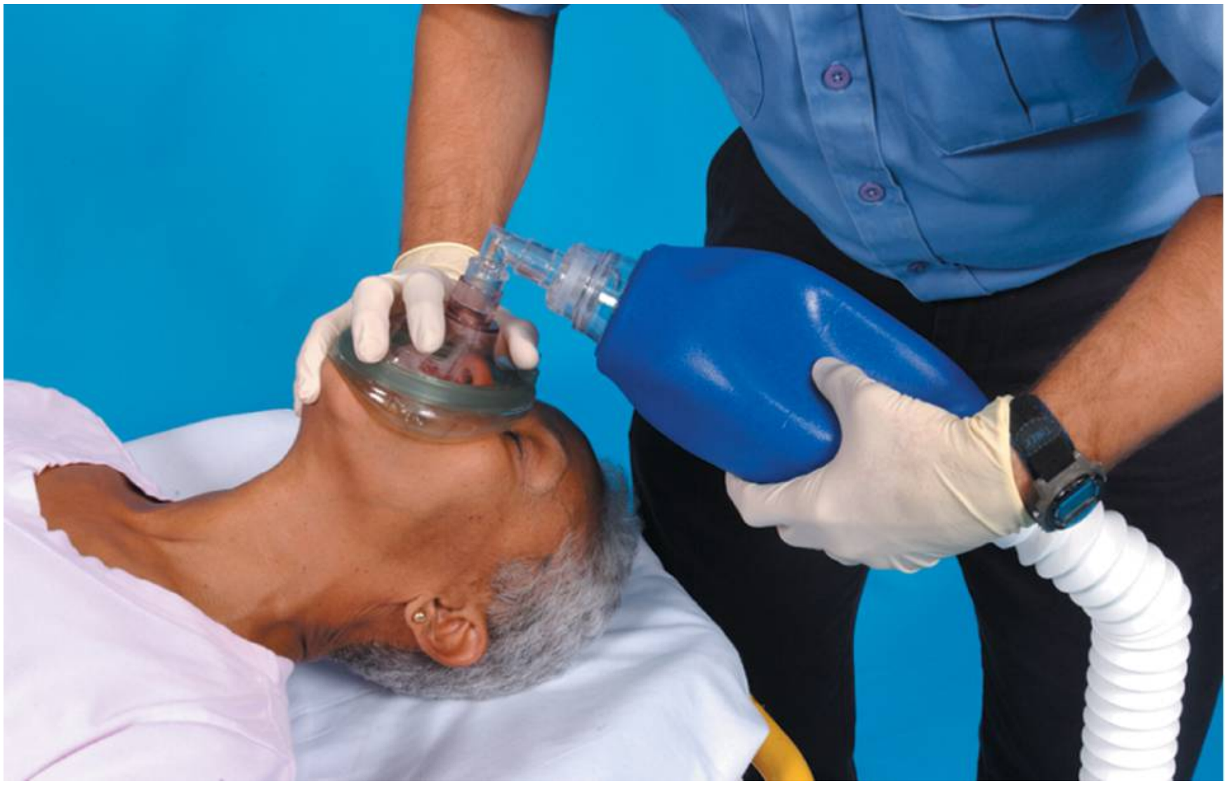


FIGURE 6-31 Use of a bag-mask device.

Advanced Airway Management

Although basic airway maneuvers are a starting point in the CCTP's assessment and patient care, they are not considered to be definitive airway management. Instead, definitive airway management entails the placement of an ET tube or tracheostomy tube within the trachea. Insertion of such a tube facilitates adequate oxygenation and ventilation. Patients primarily require intubation for two reasons:

- Failure to maintain a patent airway
- Failure to adequately oxygenate or ventilate

When an ET tube is present in the trachea, the upper airway structures, such as the tongue and epiglottis, do not affect airway patency. With a cuffed ET tube, aspiration of upper airway secretions and vomitus is minimized, albeit not entirely prevented. A properly placed and maintained ET tube virtually ensures that the airway will remain patent. It also facilitates delivery of oxygen and adequate ventilation. Some indications for ET intubation are as follows:

- Diminished level of consciousness with loss of airway control
    - Absent or diminished gag reflex
    - Glasgow Coma Scale score of 8 or less
    - Potential for aspiration (eg, secretions, blood, vomitus)
- Respiratory failure (eg, hypoxemia, hypercarbia)
- Cardiac arrest, after adequate CPR or bag-mask ventilations have been provided

Predicting the Difficult Airway

In the prehospital environment, an estimated 20% of all emergency intubations are classified as difficult. In such a case, the prehospital provider has to decide how to accomplish airway management. Ask yourself, “Can I manage this airway at the BLS level? Can I intubate this patient’s trachea?”

History is one factor to consider when treating a difficult airway. Anatomic findings suggestive of a difficult airway may include congenital abnormalities, recent surgery, trauma, infection, or neoplastic disease (cancer). Two commonly used mnemonics to guide assessment of the difficult airway are LEMONS and HEAVEN. The elements of LEMONS mnemonic are described here:

L Look externally

E Evaluate 3-3-2

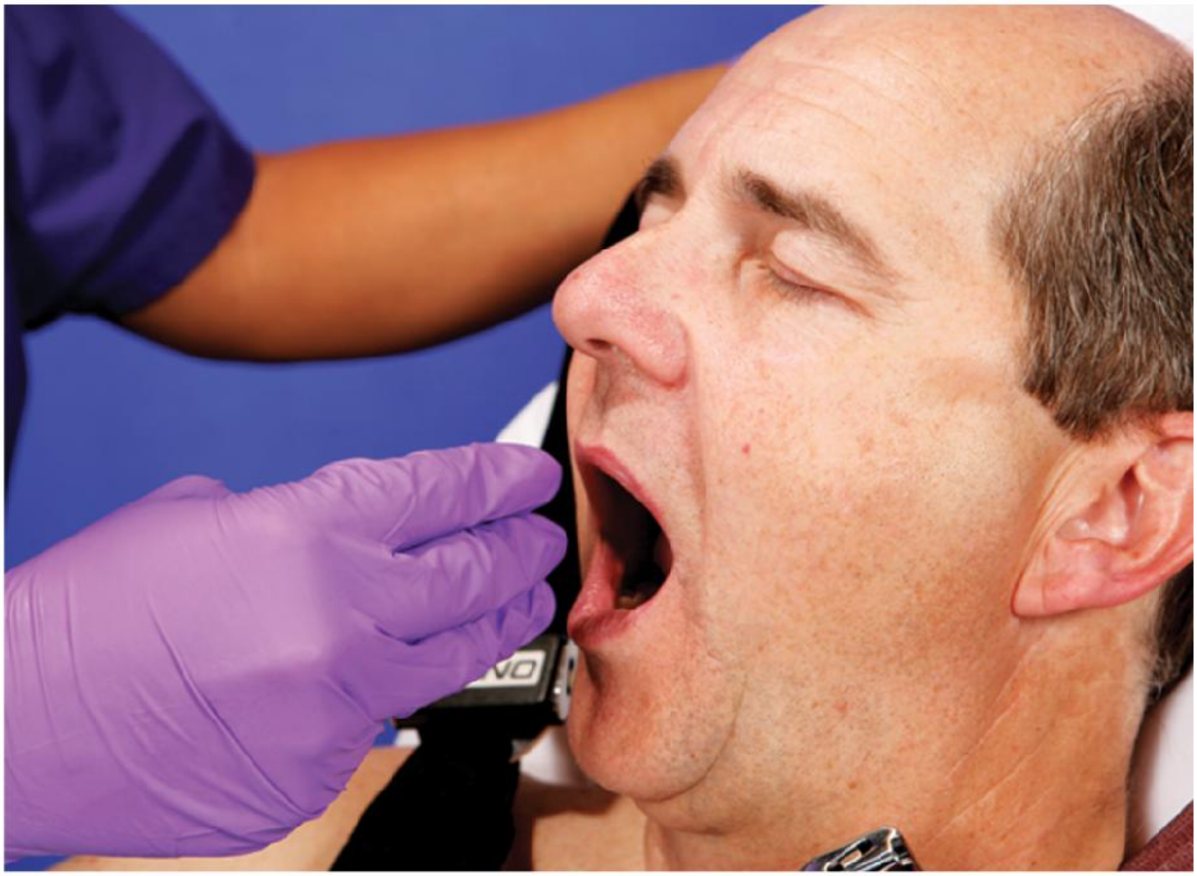
M Mallampati

O Obstruction

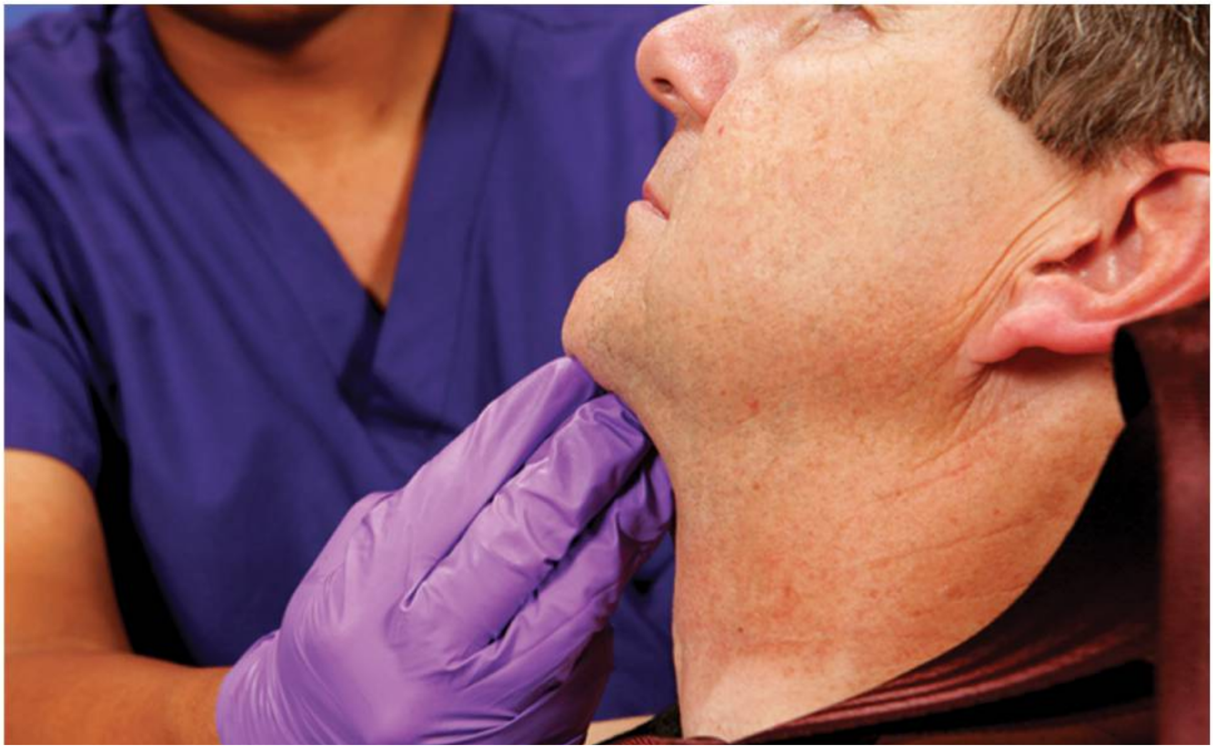
N Neck mobility
S Saturation

As indicated by the *L* in the LEMONS mnemonic, simply looking at the patient may suggest the relative difficulty that may be encountered during airway management. Patients with short, thick necks may be difficult to intubate. Morbid obesity significantly complicates intubation. Dental conditions such as overbite, or buck teeth, may make intubation difficult.

The *E* stands for “evaluate 3-3-2.” Three different anatomic measurements are assessed using the **3-3-2 rule** **FIGURE 6-32**. The first 3 refers to mouth opening. Ideally, a patient’s mouth will open at least three fingerbreadths (approximately 5 cm) wide. Conversely, a width of less than three fingers indicates a possibly difficult airway. The second 3 refers to the length of the mandible, measured from the tip of the chin to the hyoid bone: At least three fingerbreadths is optimal. Smaller mandibles have less room for displacement of the tongue and epiglottis, which can make airway management more difficult. The 2 part of this rule refers to the ideal distance (two fingerbreadths) from the hyoid bone to the thyroid notch.



A



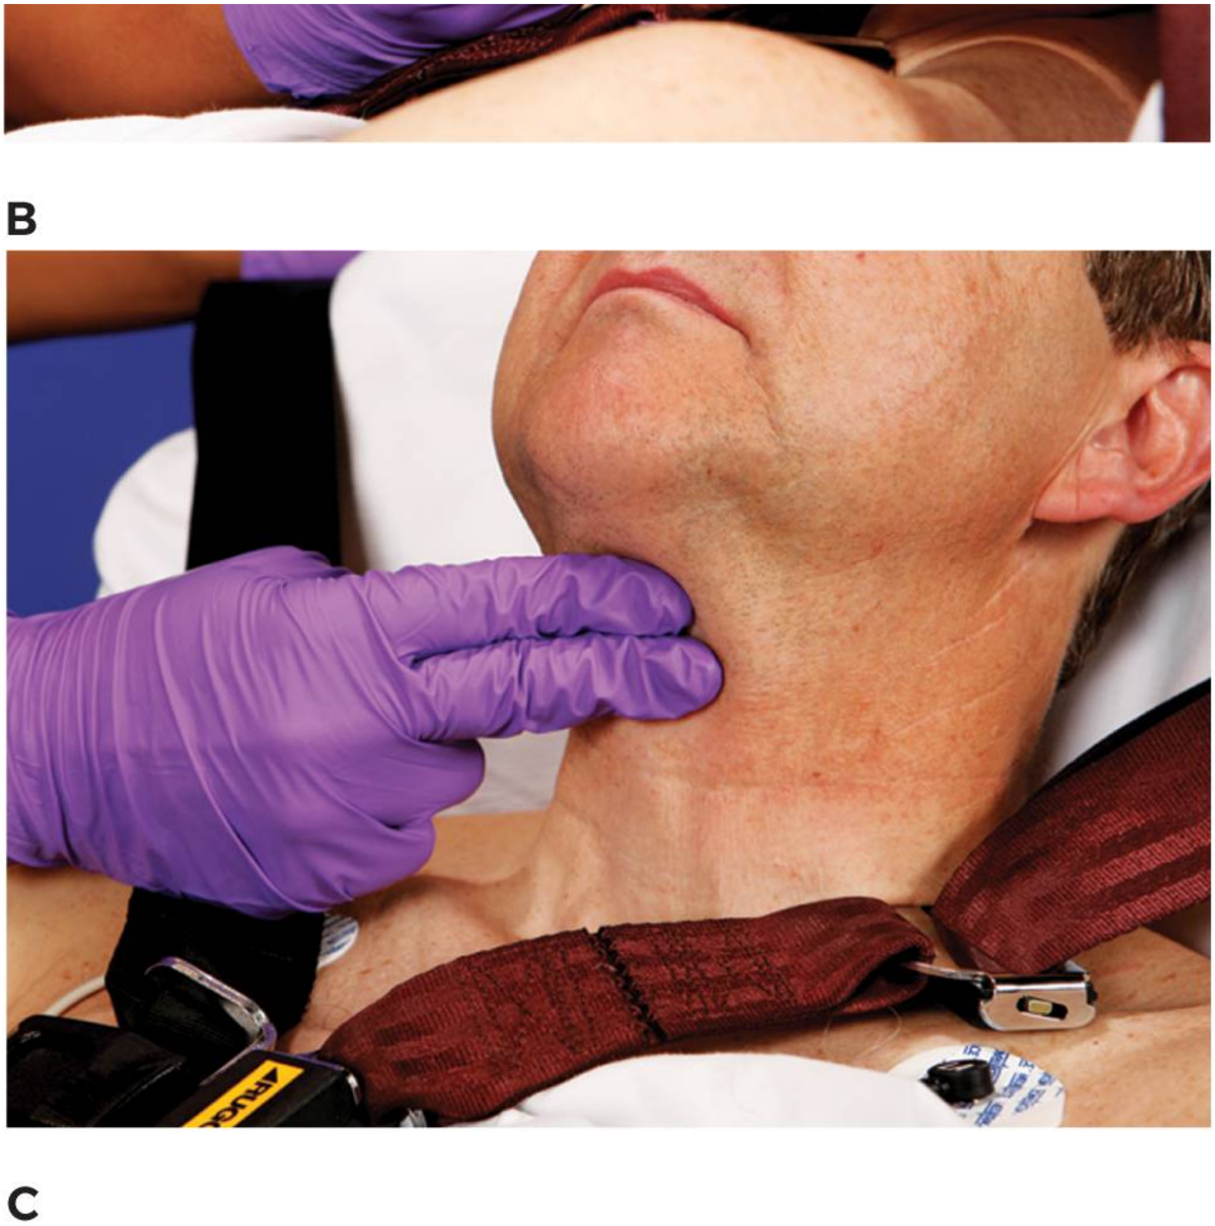


FIGURE 6-32 The 3-3-2 rule. **A.** The mouth should be at least three fingers wide when open. **B.** The space from the chin to the hyoid bone should be at least three fingers wide. **C.** The distance from the hyoid bone to the thyroid notch should be at least two fingers wide.

© Jones & Bartlett Learning.

The *M* stands for Mallampati, an anesthesiologist who developed the **Mallampati classification** to predict the relative difficulty of intubation **TABLE 6-3**. This classification is based on the oropharyngeal structures visible in an upright, seated patient who can fully open their mouth. Although this system is an accurate predictor of difficult intubation, it has limited utility in unconscious patients and in patients who cannot follow commands. If a patient is cooperative and able to comply with this evaluation, emergent prehospital intubation is probably not necessary, but the evaluation is important in that it can provide useful information should intubation be needed.

TABLE 6-3 Mallampati Classification

Mallampati Class	Description
I	Entire posterior pharynx fully exposed **FIGURE 6-33A**
II	Posterior pharynx partially exposed **FIGURE 6-33B**
III	Posterior pharynx cannot be seen; base of uvula exposed **FIGURE 6-33C**
IV	No posterior structures can be seen **FIGURE 6-33D**

Description

The *O* represents obstruction. Anything that might interfere with visualization or tracheal tube placement should be noted. Foreign bodies, obesity, hematoma, and masses are all examples of obstructive situations that can create a difficult airway.

The *N* stands for neck mobility. The ideal position for visualization and intubation is the sniffing position, in which the adult head is slightly elevated and extended **FIGURE 6-34**. The two types of patients who most commonly have neck mobility problems are trauma patients (due to use of cervical collars and/or injury) and older patients (due to osteoporosis or arthritis). The inability to place the patient in the sniffing position can significantly impact the ability to visualize the airway.

Description Description

The *S* in LEMONS stands for saturation or situation. Unlike the other components of this mnemonic, which assess anatomic features, the *S* reminds providers to consider the physiologic presentation.

As an alternative to LEMONS, the HEAVEN mnemonic lists criteria that help predict a difficult airway. This approach combines anatomic and physiologic assessments and suggests a course of action. It does not require the patient to be conscious. HEAVEN is described as follows:

H Hypoxemia
E Extreme of size
A Anatomic disturbance or obstruction
V Vomit, blood, or fluid
E Exsanguination
N Neck mobility or neurologic injury

The *H*, for hypoxemia, reminds providers that patients will desaturate rapidly during intubation if their initial oxygenation is low. Providers must maximize oxygenation before making any intubation attempt.

The first *E* stands for extreme of size. It includes pediatric patients younger than 8 years and adults who are clinically obese.

The *A* stands for anatomic disruption or obstruction. Such a finding may limit direct visualization during laryngoscopy. Consider nonintubation management and provide support to achieve oxygenation.

The *V* stands for vomit, blood, or fluid noted in the pharynx or hypopharynx before laryngoscopy. Suction clinically significant fluids before attempting intubation.

The second *E* stands for exsanguination. Blood loss raises concerns of anemia and reduced oxygen-carrying capacity. Consider not intubating such patients to reduce the apnea time for them.

Finally, the *N* stands for neck mobility or neurologic injury. Consider performing a hyperacute video laryngoscopy in patients with these issues.

Orotracheal Intubation

Once the decision to intubate a patient has been made, the CCTP needs to determine how to most effectively accomplish the procedure. The goal is to intubate the patient on the first attempt (first-pass success) without induction of hemodynamic compromise or aspiration. Important questions that must be answered before undertaking orotracheal intubation include the following: Does direct laryngoscopy or indirect (video) laryngoscopy offer the greatest chance of successful intubation on the first attempt? Which size of blade should be used? Is a hyperacute geometry blade needed? Which size of ET tube should be used? What should be done if the intubation is unsuccessful? Are medications necessary to facilitate intubation? In addition, the CCTP should consider LEMONS or HEAVEN criteria to help determine the best intubation approach.

Multiple techniques, devices, and procedures for airway management are discussed next. As always, it is important to abide by the protocols established by your state and your service when using airway devices. Additionally, routine use of a checklist to aid in the preparation, placement, and postprocedure care of advanced airways is highly recommended.

Equipment

The following equipment is needed to provide advanced, invasive airway management:

- Gloves, mask, and goggles
- ET tubes of various sizes
  - Usual size range of 2.0 to 9.0
  - Most adults accept a size 7.0 to 8.0
- Appropriate-size stylet (adult or pediatric)
- Appropriate-size laryngoscope handle and blades (Miller or Macintosh)
- Suctioning equipment
- 10-mL syringe
- Water-soluble lubricant
- Commercial tube-holding device
- Age- and size-appropriate bag-mask device with reservoir
- Supplemental oxygen
- Stethoscope
- Device able to perform continuous waveform
- Magill forceps
- Topical anesthetic spray (for nasotracheal intubation)
- Rescue airway device (King LT, laryngeal mask airway, i-gel)
- 20-mL syringe
- 40-mL syringe

The laryngoscope handles and blades must also be the appropriate size:

- Straight blades: sizes 00, 0, 1, 2, 3, 4
  - Miller
  - Wisconsin

- Curved blades: sizes 1, 2, 3, 4
    - Macintosh

Many believe the type of blade used can have a significant impact on the success of intubation. For many older children and adults, the choice of the blade is not as important as the comfort and experience of the CCTP with a particular blade type and the technique used in the intubation attempt. For smaller children, because of age-related anatomic differences, choosing a straight blade to actually pick up the epiglottis may facilitate successful intubation. Remember, the curved blade is placed in the vallecula, which is located at the base of the tongue and displaces the epiglottis indirectly via pressure on the underlying hyoepiglottic ligament. However, the curved blade may also be used to pick up the epiglottis to facilitate visualization.

Special Populations

In infants, children, and young adults, many methods may be used to estimate the appropriate size of ET tube for the patient.

- For children older than 1 year, calculate the appropriate size by adding 16 to the child's age in years, then dividing this number by 4:

$$(16 + \text{Child's age in years})/4 = \text{ET tube size}$$

- Use the diameter of the child's pinky finger to estimate the diameter of the tube.
- Use a weight-based chart.

Orotracheal Intubation

Indications for orotracheal intubation include:

- Airway control following coma, respiratory arrest, and/or cardiac arrest
- Ventilatory support prior to impending respiratory failure
- Need for prolonged artificial ventilatory support
- Medication administration (atropine, epinephrine, naloxone)
- Impending airway compromise (burns, trauma)

- Expected complicated clinical course

Relative contraindications for orotracheal intubation include:

- Inability to open the mouth because of trauma, dislocation, or pathologic condition
- Epiglottitis
- Inability to see the glottic opening
- Copious secretions, vomit, or blood in the airway

Direct Laryngoscopy

Orotracheal laryngoscopy can be performed in two ways. The first, more traditional way is via direct visualization of the vocal cords by displacement of the tongue with a laryngoscope blade. Advantages of direct laryngoscopy include high success rates, low equipment cost, and reliability. Disadvantages include difficulty maintaining proficiency, anatomic limitations, and cervical motion restriction precautions.

This procedure begins with airway assessment, equipment preparation, oxygenation, and patient positioning. Each of these processes is key to achieving successful intubation. When performing direct laryngoscopy, the provider must align the oral, laryngeal, and pharyngeal axes to visualize the larynx. In patients without suspected cervical injury, placing the patient’s ears level with the sternal notch, with the face parallel to the plane of the ceiling, may achieve this goal.

Once the patient is positioned, the provider inserts the laryngoscope blade into the oral cavity, sweeps the tongue to the left, and progressively advances the blade until the epiglottis is identified. At this point, if using a straight Miller blade, the provider would use the distal tip of the blade to directly elevate the epiglottis to expose the larynx and vocal cords. The Miller blade is generally preferred in the pediatric population because it allows for direct control of the epiglottis, which may be floppy and more challenging to manage in young patients as compared to adult patients. In the event that a curved Macintosh blade is selected, the tip is inserted into the vallecula to apply pressure to the hyoepiglottic ligament, which in turn lifts the epiglottis to expose the glottic opening.

The view obtained during laryngoscopy can be graded with the Cormack-Lehane system, which scores the view of the glottic opening:

- **Grade 1.** The entire glottic opening is visible.
- **Grade 2.** The arytenoid cartilages or the posterior portion of the glottic opening is visible **FIGURE 6-35**.
- **Grade 3.** Only the epiglottis is visible.
- **Grade 4.** Only the tongue and/or soft palate is visible.

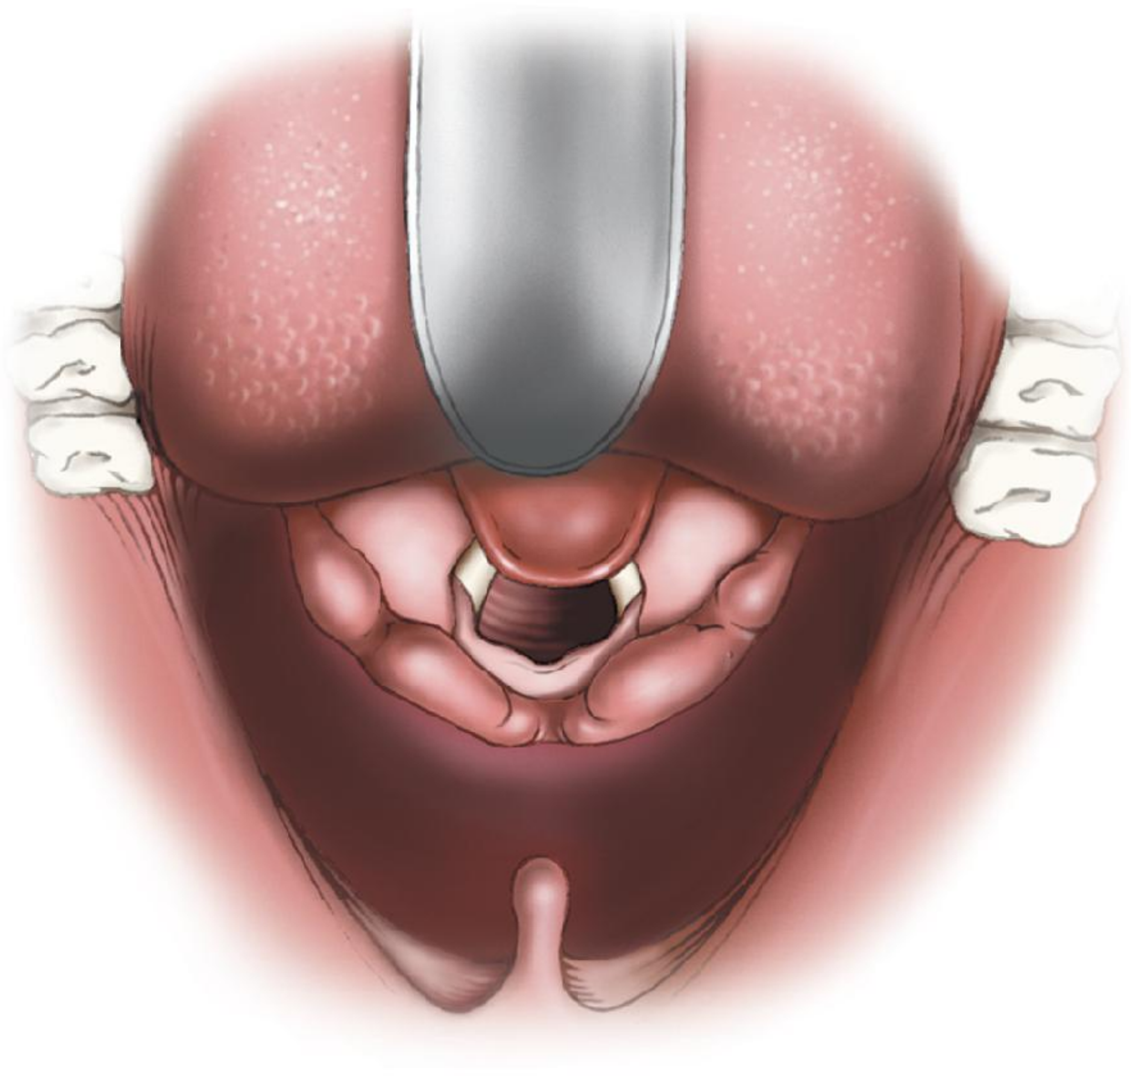

FIGURE 6-35 Laryngoscopic view of the vocal cords (white fibrous bands).

© Jones & Bartlett Learning.

Grade 3 on laryngoscopy can result in significant difficulty intubating the trachea due to the CCTP’s inability to visualize any part of the glottic opening.

When visualization of the larynx is successful, an ET tube may be placed through the larynx and into the trachea. Following successful placement and verification of the ET tube, a small distal cuff is inflated to seal the airway. Note that microaspiration is still a risk even when this seal is in place. Monitor the ET tube’s pilot balloon for proper inflation pressure, which ranges from 20 to 30 mm Hg. If ET tube cuff pressure exceeds the pressure within the superficial capillaries of the trachea (30 mm Hg), the resulting tissue ischemia can lead to tracheal stenosis. If the clinical condition permits, raising the head of the stretcher to 30° allows gravity to help reduce aspiration events.

Indirect (Video) Laryngoscopy

The second way to perform orotracheal intubation is via indirect visualization of the vocal cords using video laryngoscopy. The video laryngoscope provides for indirect viewing of the glottic opening via a video camera at the distal end of the blade, which sends a video feed to a screen that is either a separate handheld tablet **FIGURE 6-36** or attached to the handle of the device **FIGURE 6-37**. Advantages of video laryngoscopy include the ability to visualize the vocal cords without needing to align the airway axes, minimal need for significant tongue displacement, and, although somewhat device specific, often a greater distance between the CCTP's face and the patient's face. Disadvantages include the cost of purchasing and maintaining the devices, the need for space to store the device, and the potential for fluids in the airway to obscure the video camera. The use of video laryngoscopy has expanded exponentially in the past several years due to reduced unit costs, recognition of its effectiveness, and greater education on use of these devices.

Two distinct types of video laryngoscopes may be used: those with a **standard geometry blade** and those with a **hyperangulated blade**. The standard geometry blade is inserted using a similar technique as for its direct laryngoscope counterparts. As previously described, the procedure begins with airway assessment, equipment preparation, oxygenation, and patient positioning. Each of these processes is key to achieving successful intubation. Using the standard geometry video laryngoscope, the CCTP directly visualizes the blade entering the oral cavity, then transitions attention to the device monitor for indirect viewing of the larynx.

Video laryngoscopes often provide excellent visualization of airway structures, but this does not always translate to successful intubation. When using these devices, the CCTP should account for the delta blade angle and camera angle. The larynx should be positioned in the center upper half of the monitor and the blade should not be advanced farther when visualization is achieved. Once this view is obtained, an angulated **rigid stylet** may be necessary to pass the ET tube around the nondisplaced tongue. A Cormack-Lehane grade 2 view may be optimal to facilitate ET tube passage. If the patient has limited neck mobility, either from a preexisting condition or because of the current clinical need for spinal motion restriction, the use of a hyperangulated blade may be beneficial. This blade overcomes the need to align the airway axes due to its anterior viewing angle, but almost always requires the concurrent use of an angulated rigid stylet to guide ET tube advancement.

Bougie-Assisted Intubation

A bougie is a flexible 10–15 French, 60-cm, ET tube introducer with a distal coude tip **FIGURE 6-38**. Its tip angle of 30° to 40° allows this device to transmit a tactile sensation to the user as it passes the tracheal rings and encounters resistance as the airways narrow. This simple device allows the CCTP to perform laryngoscopy in difficult airways and may be considered for all intubations.

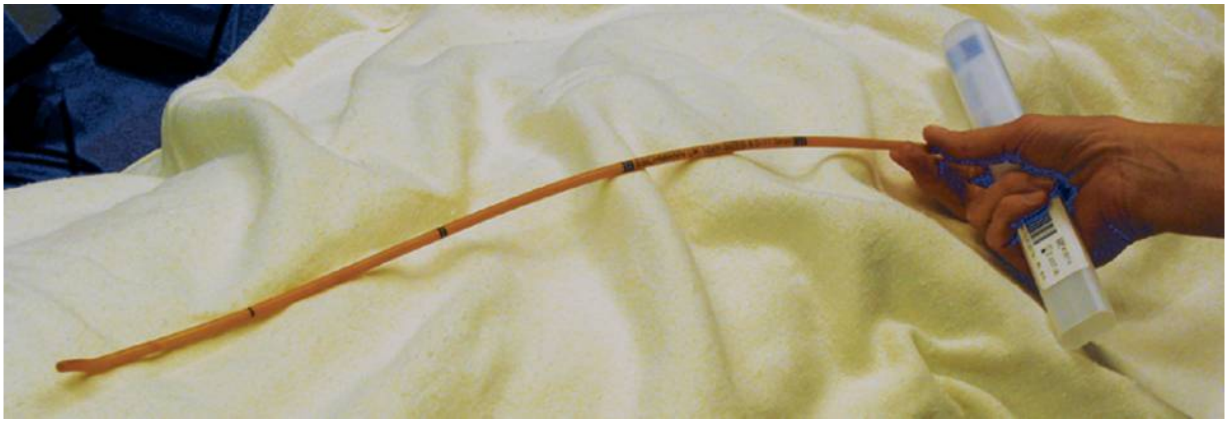

FIGURE 6-38 The bougie.

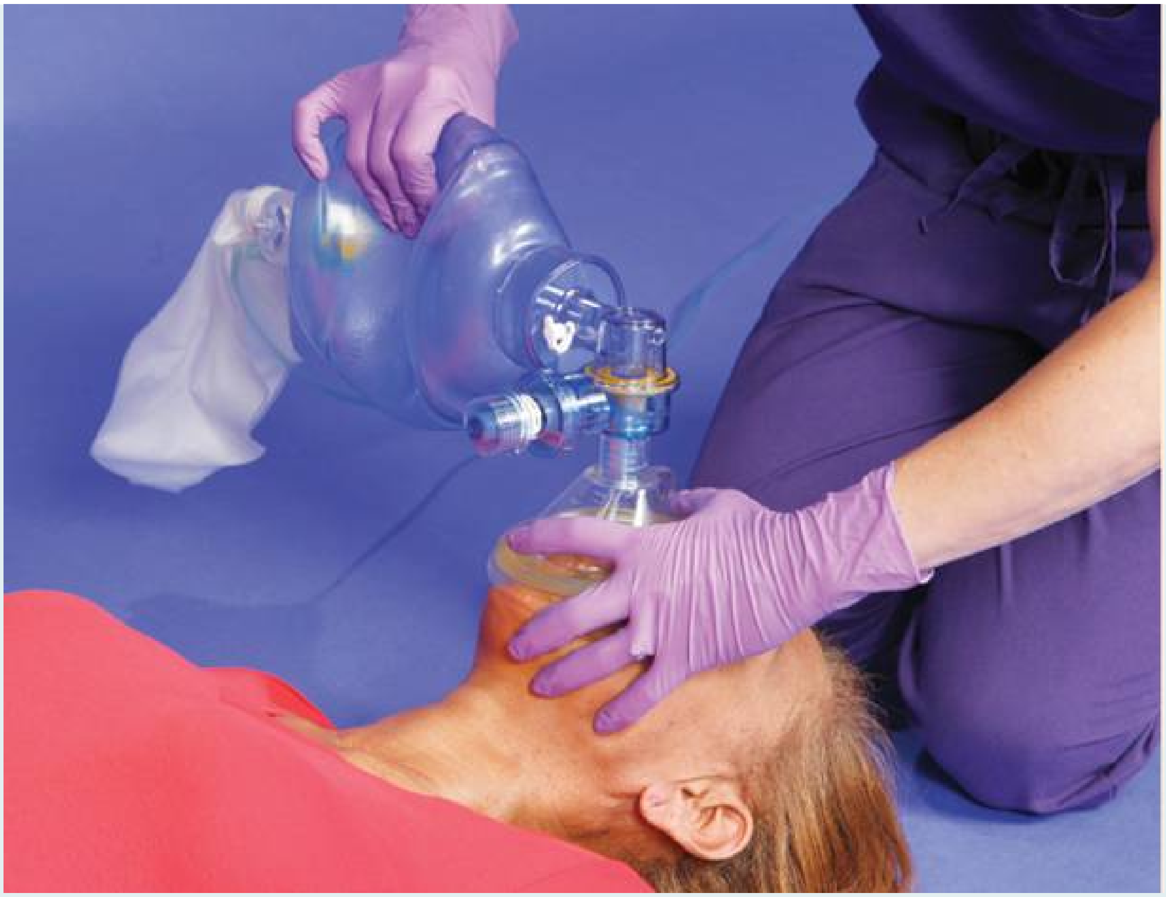
Courtesy of Marianne Gausche-Hill, MD, FACEP, FAAP.

The bougie may be inserted blindly or when the larynx is visualized, at which point the bougie would be passed under the epiglottis. It is inserted from the side of the patient's mouth and rotated into the trachea until gentle resistance is encountered. Next, an assistant places an ET tube onto the bougie and slides it down the introducer into the trachea. Alternatively, the bougie may be preloaded with the ET tube. The bougie may also be used during ET tube exchange and surgical airway placement.

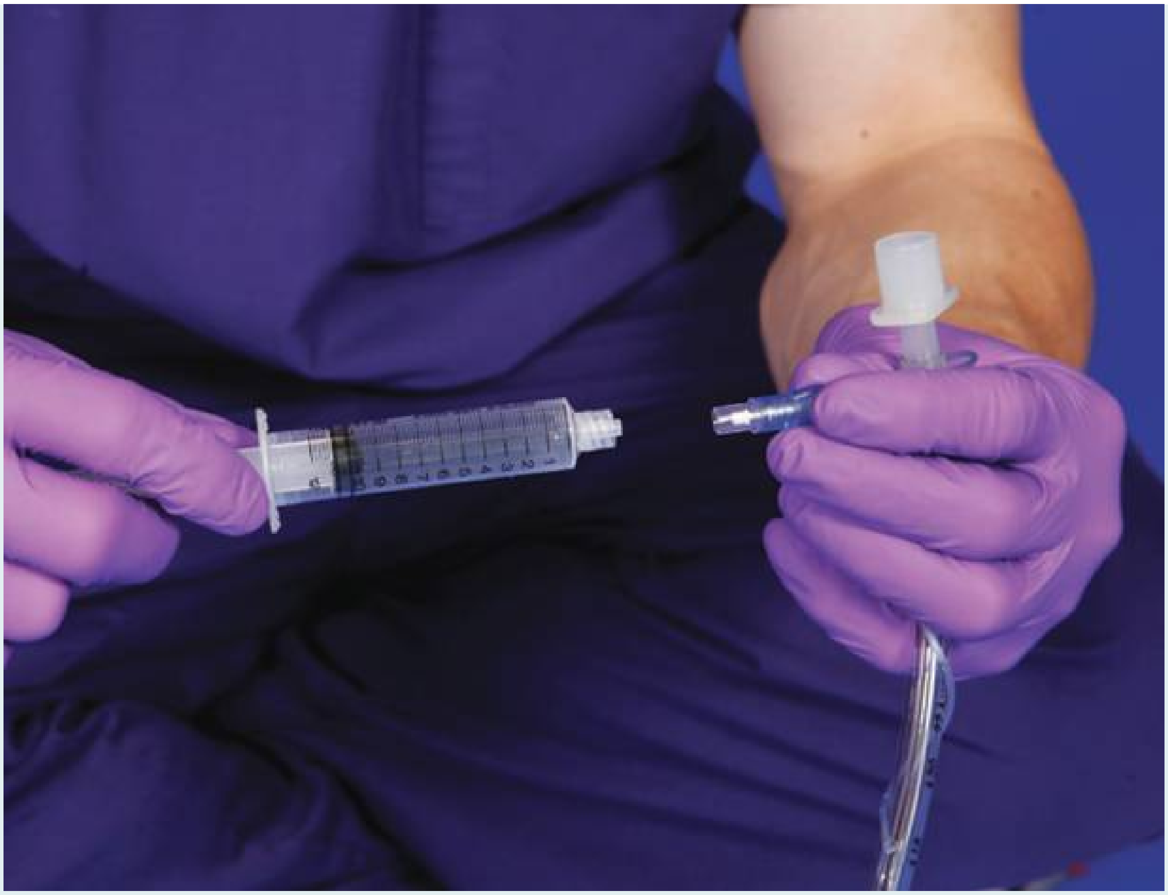
Orotracheal Intubation With Direct Laryngoscopy

Skill Drill 6-2 shows the steps for orotracheal intubation, which are also described here:

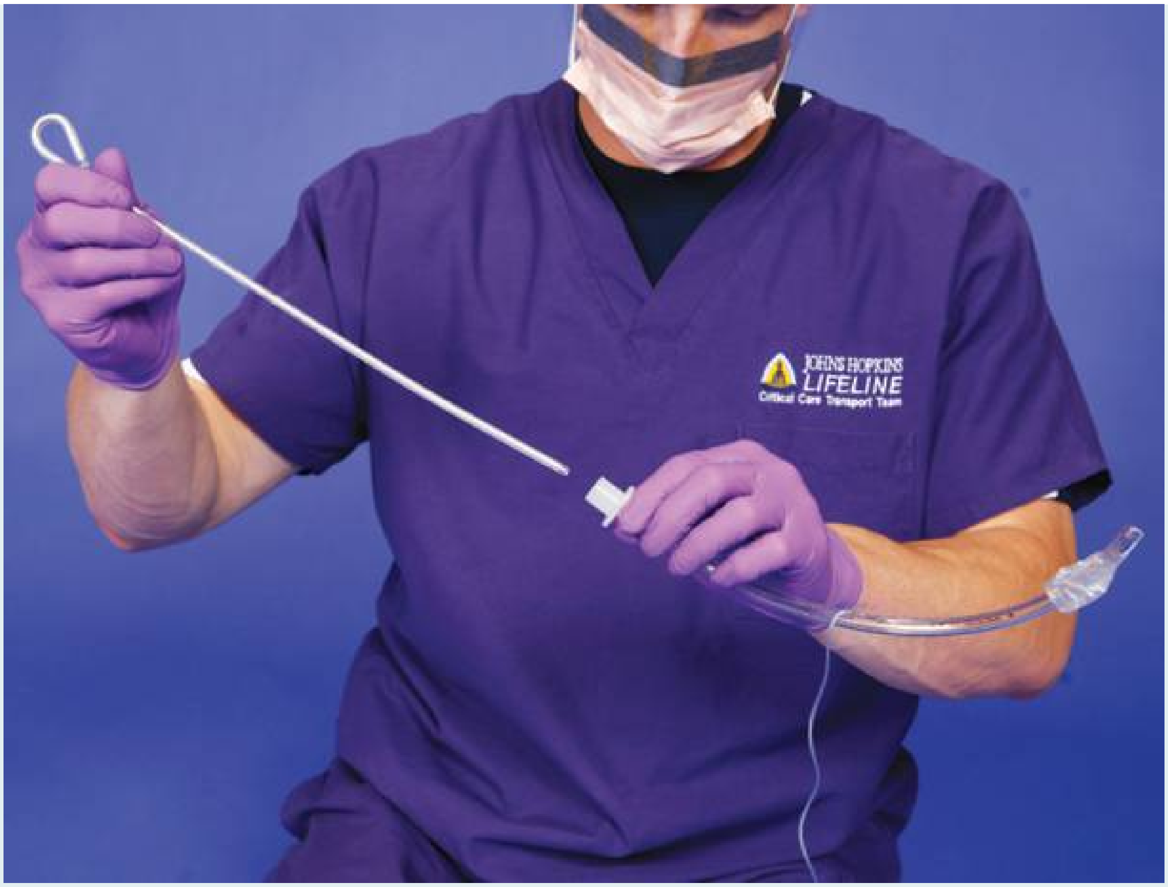
SKILL DRILL 6-2 Performing Orotracheal Intubation



Step 1
Follow standard precautions. Preoxygenate the patient.

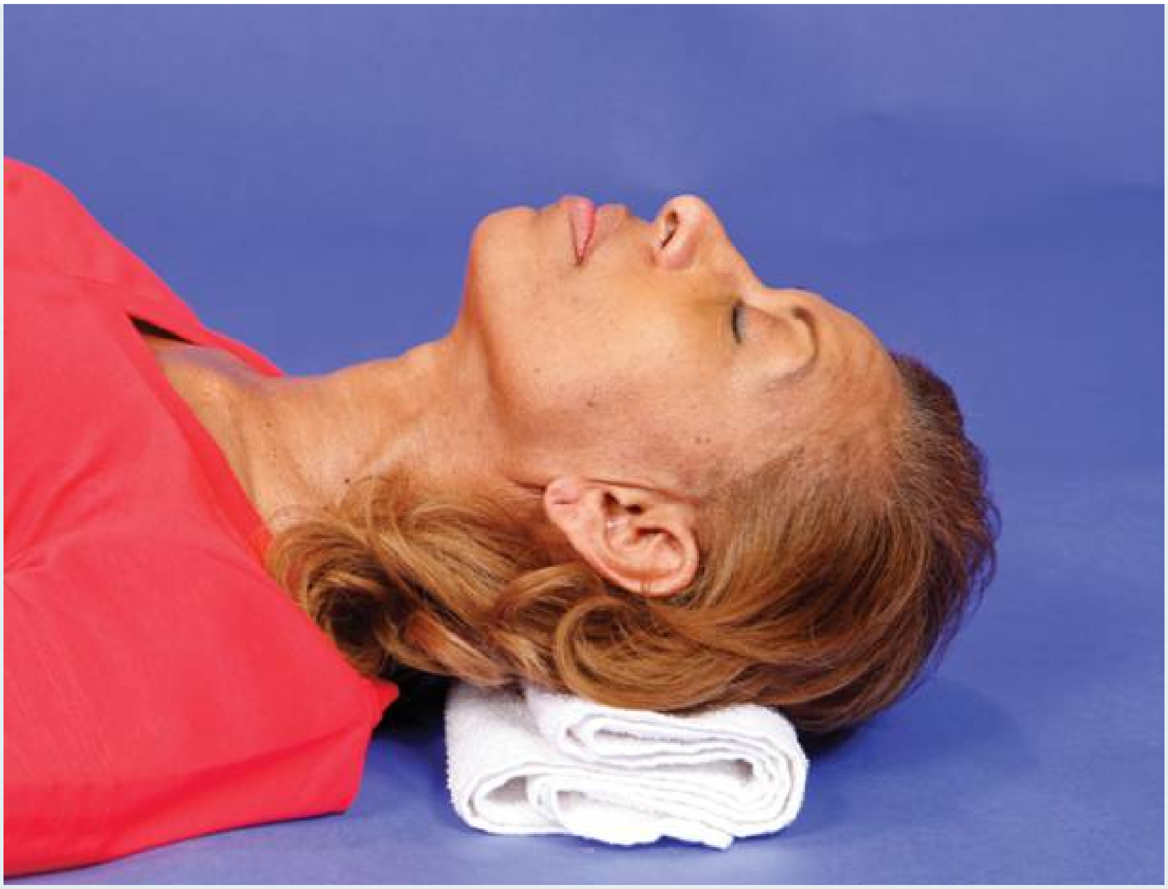


Step 2
Check, prepare, and assemble your equipment.

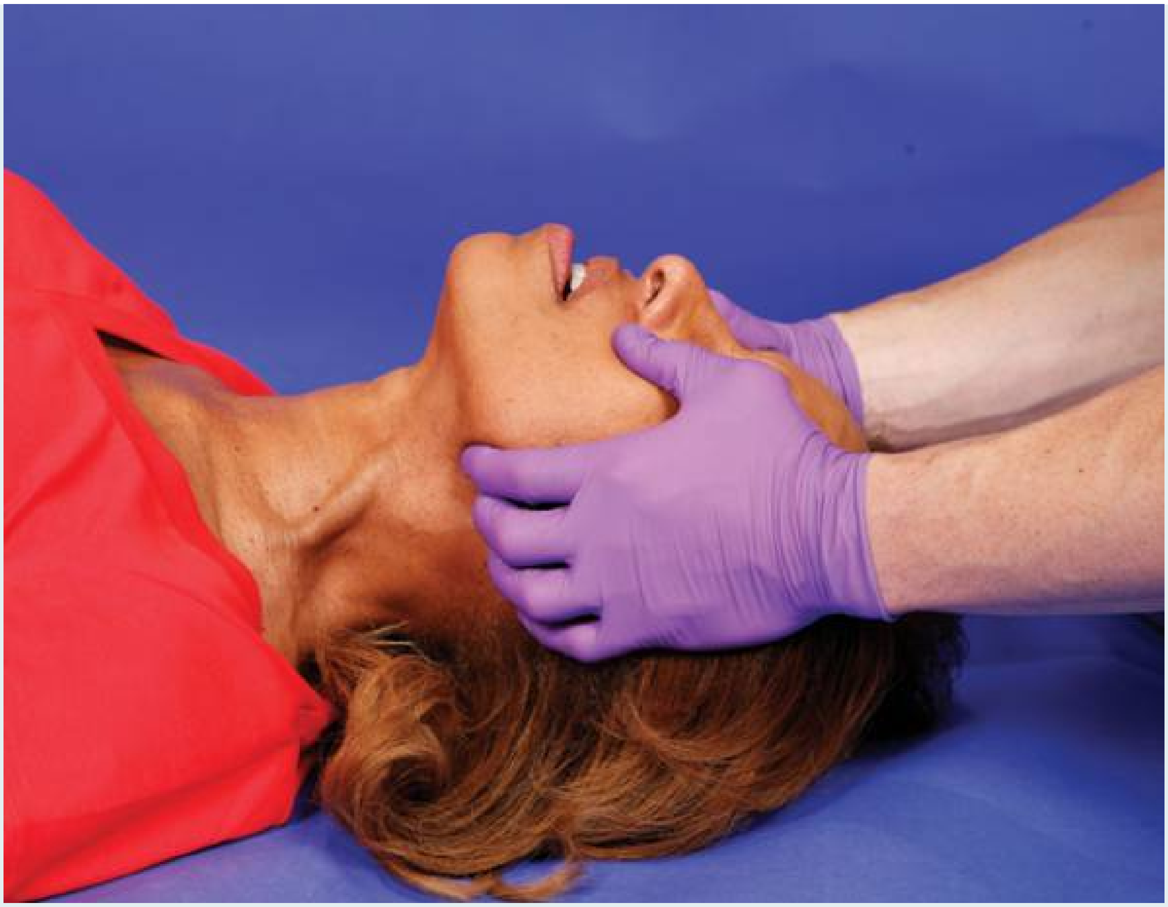


JOHNS HOPKINS
LIFELINE
Critical Care Transport Team

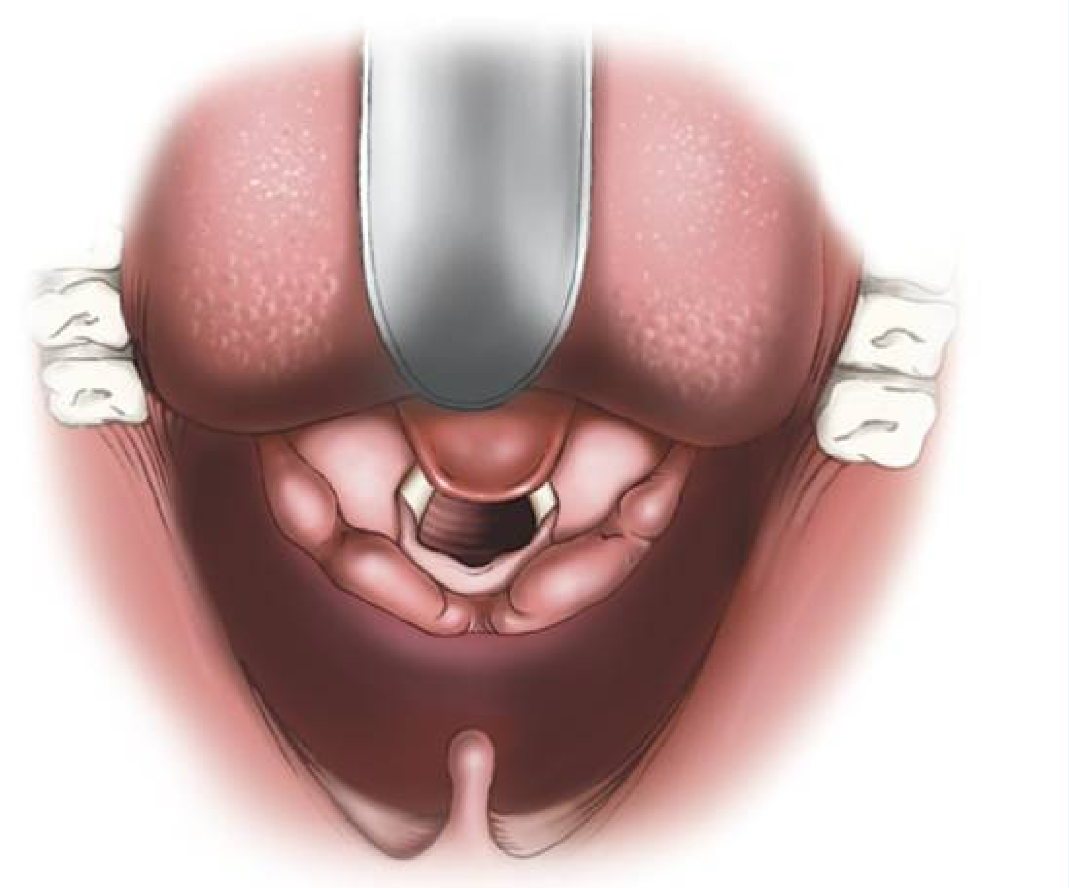
Step 3
Insert the stylet, lubricate the tube, and bend to the desired position. Auscultate breath sounds.



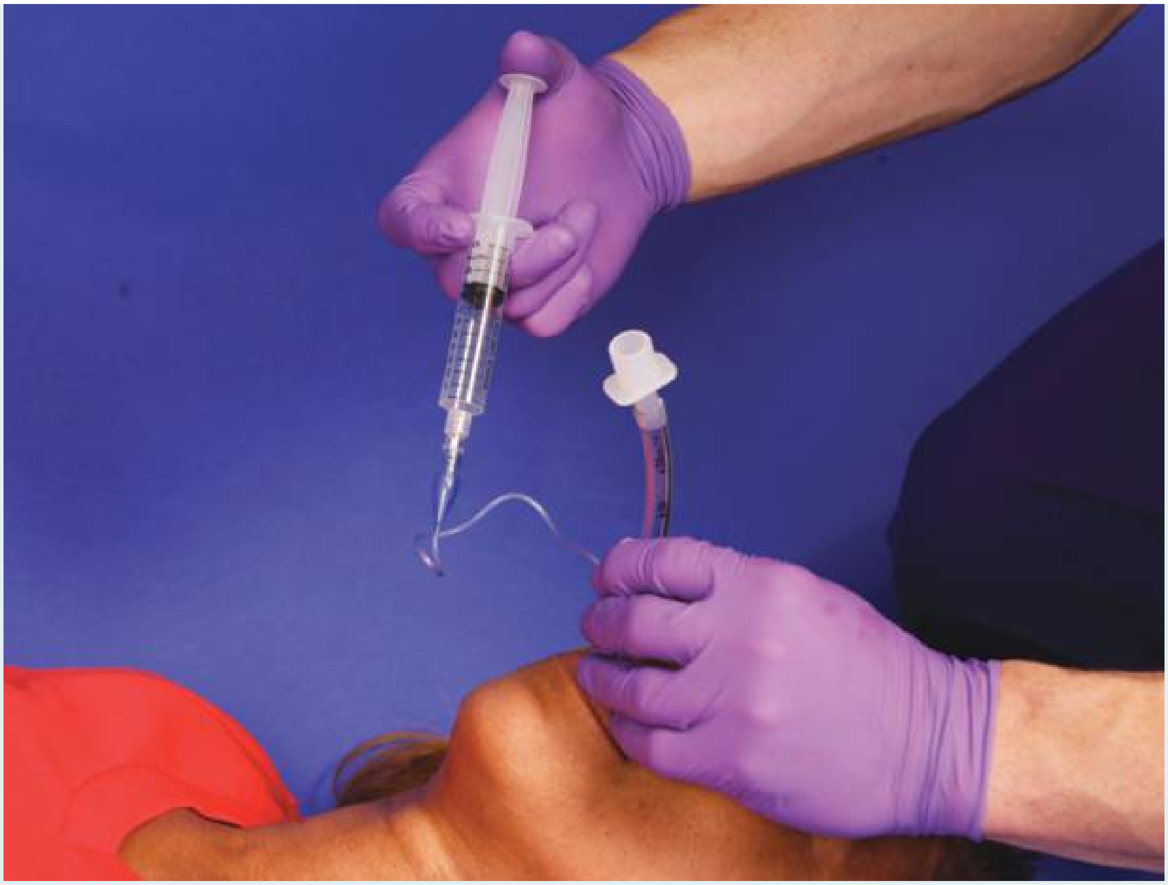
Step 4
Align the airway axes by placing the patient’s ears in line with the sternal notch and the face level to the plane of the ceiling.



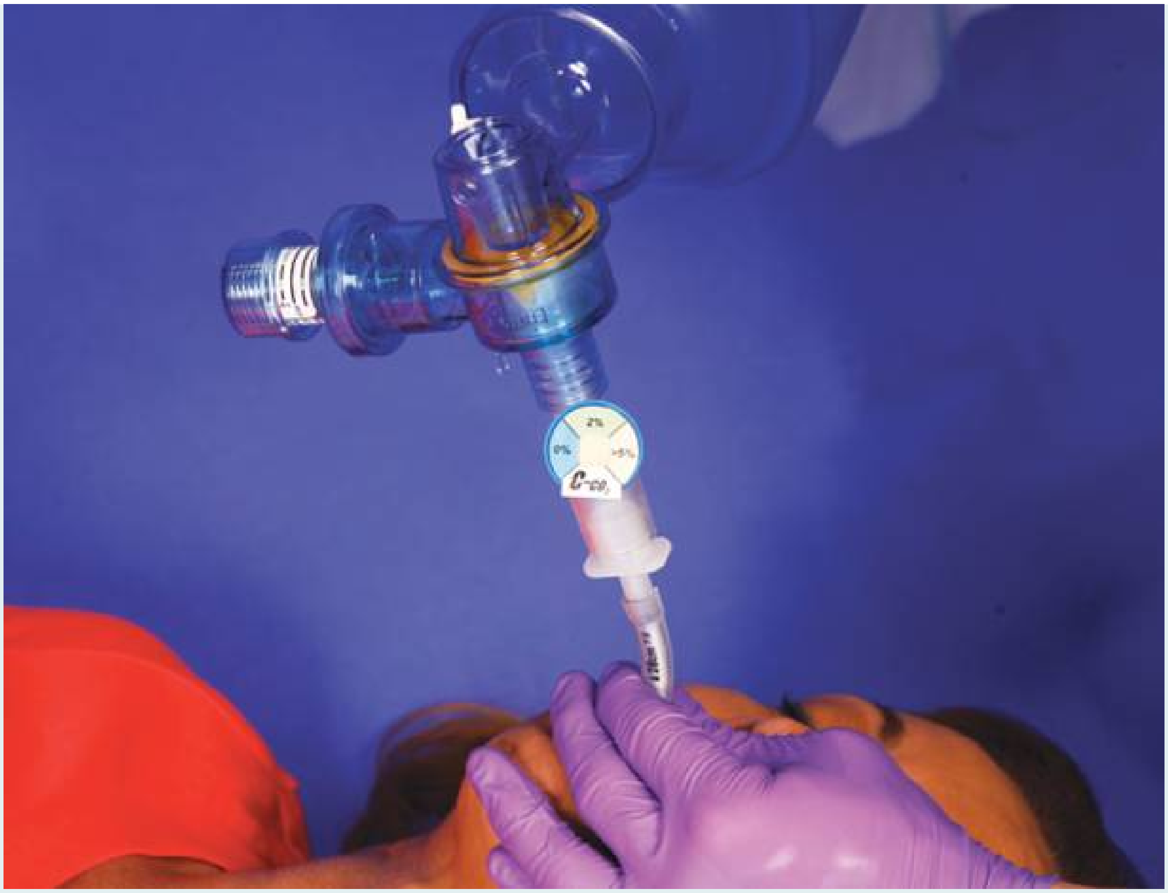
Step 5
With a trauma patient, maintain cervical spine immobilization while intubating.



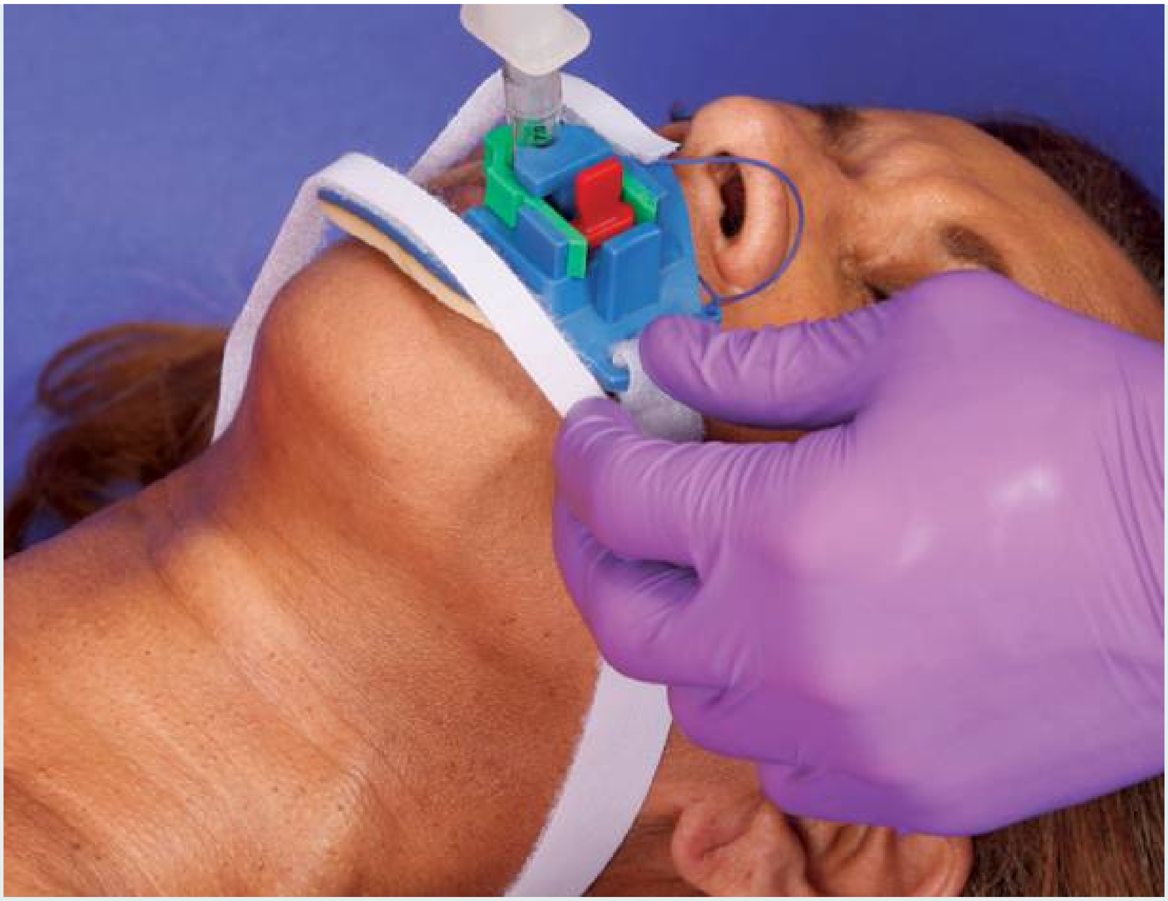
Step 6
Insert the laryngoscope blade into the right side of the patient's mouth, sweep the tongue to the left, and visualize the cords. Insert the ET tube to the appropriate depth until the cuff is just below the vocal cords.



Step 7
Inflate the cuff with 10 mL of air and remove the syringe. Remove the stylet if applicable.



Step 8
Attach the bag-mask device and $ETCO_2$ detector and begin to ventilate. Verify correct tube placement by auscultating the epigastrium and bilateral chest.



Step 9
Secure the ET tube with a commercial device or tape

All images © Jones & Bartlett Learning.

1. Follow standard precautions.
2. Preoxygenate the spontaneously breathing patient for 3 minutes (eight vital capacity breaths) with high-flow oxygen or a nonrebreathing mask. Try to avoid bag-mask ventilations because these devices increase air insufflation of the stomach and, therefore, the potential for regurgitation and aspiration **STEP 1.**
3. Check, prepare, and assemble your equipment **STEP 2**.
4. Choose an appropriate-size tube, with the tube still in the package to maintain sterility. Check the cuff's integrity by inflating it and checking for leaks. Insert the stylet, lubricate the tube, and bend it

to the desired position. It is also a good idea to have a tube of a slightly smaller diameter prepared, in case it is needed **STEP 3**.

5. Auscultate breath sounds prior to intubation.
6. Have Magill forceps and a commercial tube-securing device ready.
7. Have at least one large-bore suction unit at the patient’s side and turned on.
8. Optimize patient positioning for first-pass success. When using direct laryngoscopy or a traditional geometry video laryngoscope, it is critical to align the airway axes by placing the patient’s ears in line with the sternal notch and the face level to the plane of the ceiling **STEP 4**. With a trauma patient, maintain spinal motion restriction precautions while intubating **STEP 5**. Opening the cervical collar to facilitate mandible movement during the laryngoscopy is acceptable as long as spinal motion restriction is manually applied.
9. Consider the use of external laryngeal manipulation to maximize visualization.
10. Insert the laryngoscope blade into the right side of the patient’s mouth, sweep the tongue to the left, and visualize the vocal cords **STEP 6**.
11. Insert the ET tube to the appropriate depth until the cuff is just below the vocal cords.
12. Inflate the cuff, with this pressure not to exceed 30 mm Hg **STEP 7**.
13. Attach the bag-mask device and ETCO$_2$ detector and begin to ventilate **STEP 8**.
14. Verify correct tube placement by auscultating the patient’s epigastrium and bilateral chest.
15. Observe for bilateral chest expansion, compliance of the bag-mask device, condensation in the tube, and the presence of continuous waveform end-tidal capnography.
16. Secure the ET tube with a commercial device or tape **STEP 9**.

7. Frequently verify placement of the ET tube, ideally with waveform capnography. If continuous waveform capnography is not available, the tube position should be verified, at a minimum, each time the patient is moved.

Flight Considerations

When you are performing tracheal intubation in the air medical environment, consider filling the cuff with water equivalent to the volume of air needed for a seal. Another consideration is using a cuff pressure manometer to monitor and adjust pressures as altitude changes, or using the minimal occluding technique. This technique involves placing the stethoscope over the laryngeal area while inflating the cuff until air leak is no longer present at peak inspiratory pressure. The goal is to keep cuff pressures at less than 20 to 30 mm Hg.

Nasotracheal Intubation

Nasotracheal (nasal) intubation was once the preferred airway management technique in patients suspected of having a spinal cord injury. With the advent of rapid sequence intubation (RSI), however, nasal intubation is now used relatively infrequently. Most patients who undergo nasotracheal intubation are receiving care in the prehospital environment where RSI may not be permitted or are spontaneously breathing but present the likelihood of a difficult airway, making RSI inadvisable.

Nasotracheal intubation requires a spontaneously breathing patient. The likelihood of success with this procedure may be enhanced by using ET tubes specifically designed for nasotracheal placement. Even so, this type of intubation carries a fairly high failure rate and takes longer to perform than intubation under direct laryngoscopy. It also frequently requires placement of an ET tube of a smaller diameter compared with the tubes placed during direct laryngoscopy.

Prolonged attempts at nasotracheal intubation may result in significant hypoxemia and glottic edema secondary to trauma. This procedure may also cause significant bleeding and vomiting. The risks of hypoxemia and hypercarbia in a patient with inadequate respirations must be weighed against the risks of performing nasal intubation. Combativeness, facial trauma with suspected basilar skull fracture, coagulopathy, and upper airway infection are a few of the relative contraindications to nasotracheal intubation.

Indications for nasotracheal intubation include the following:

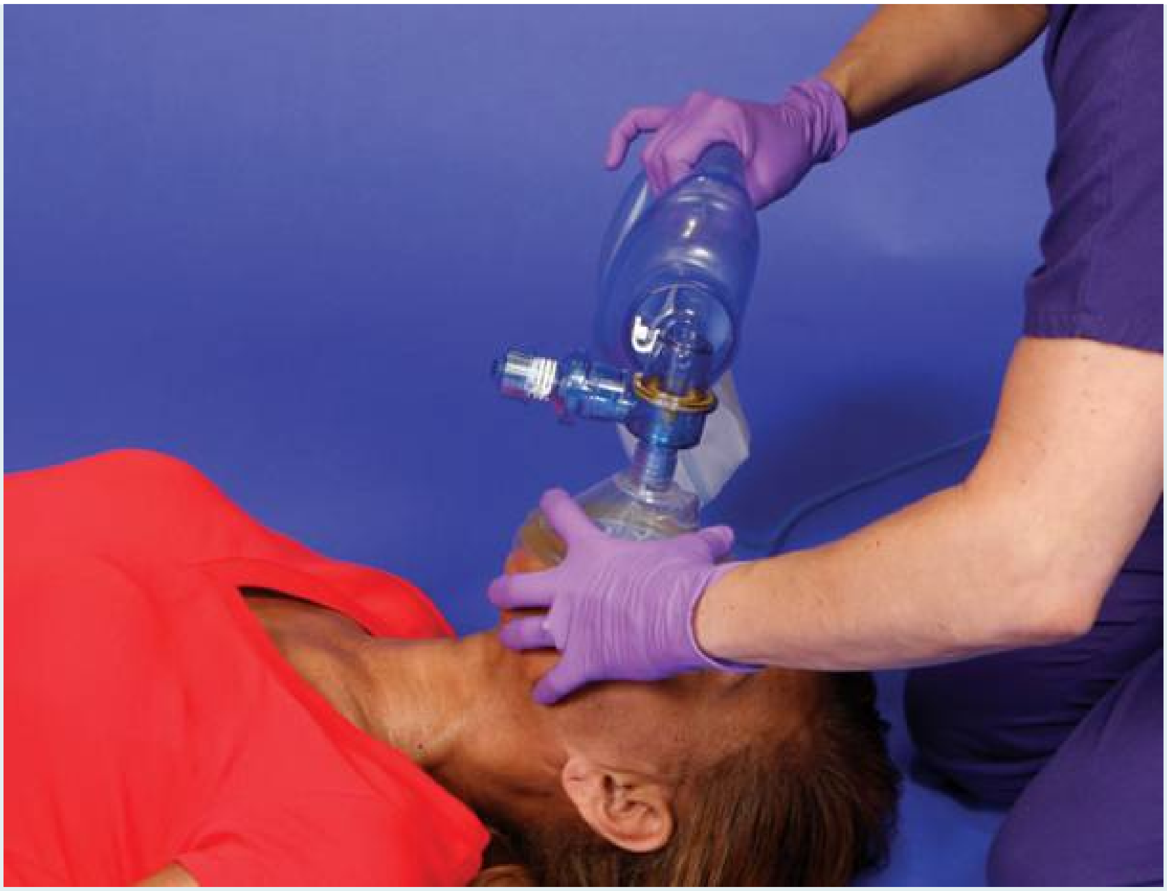
- Patients who are awake and breathing but are in danger of respiratory failure
- Patients with a gag reflex
- Patients who are breathing but cannot open their mouth

Contraindications to nasotracheal intubation include the following:

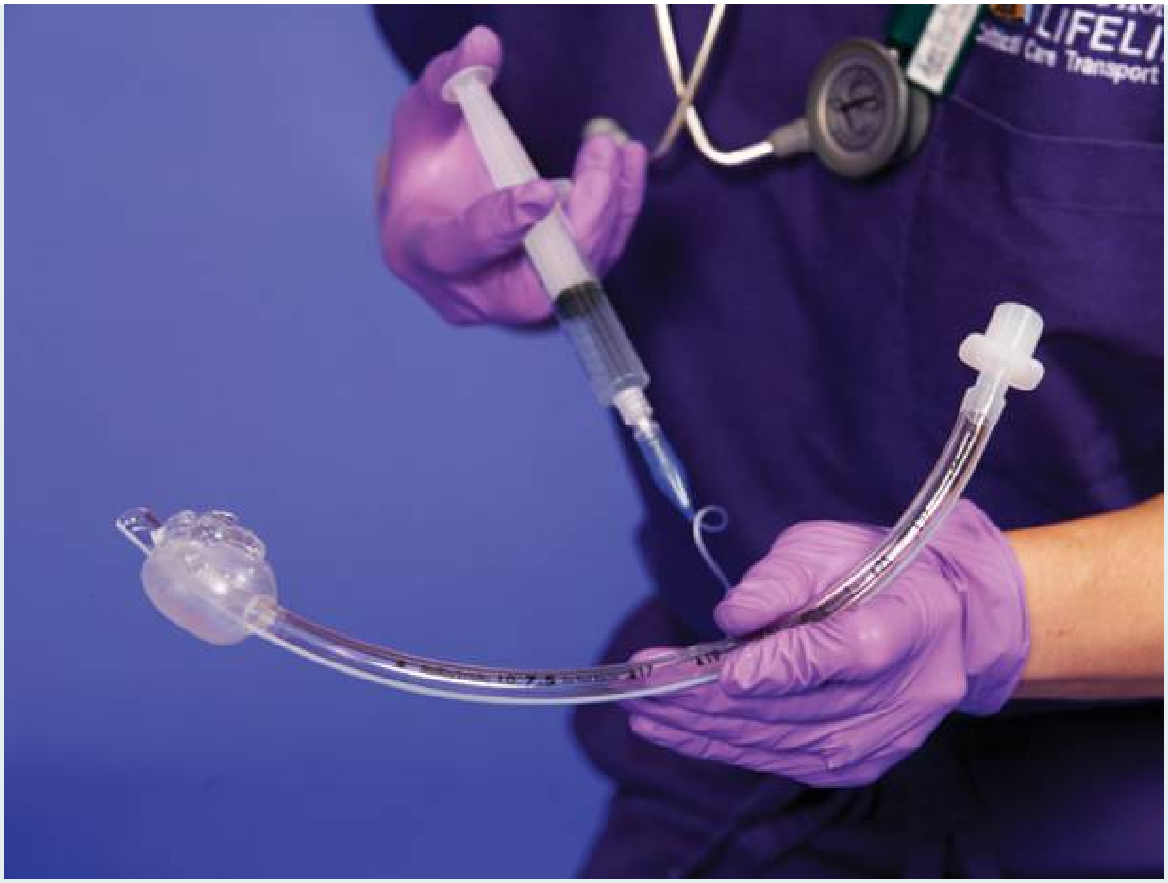
- Apneic or near-apneic patients
- Inability to pass the tube through the nostril
- Blood clotting or anticoagulation therapy
- Severe nasal, facial, or basilar skull fractures

Skill Drill 6-3 shows the steps for nasotracheal intubation, which are described here:

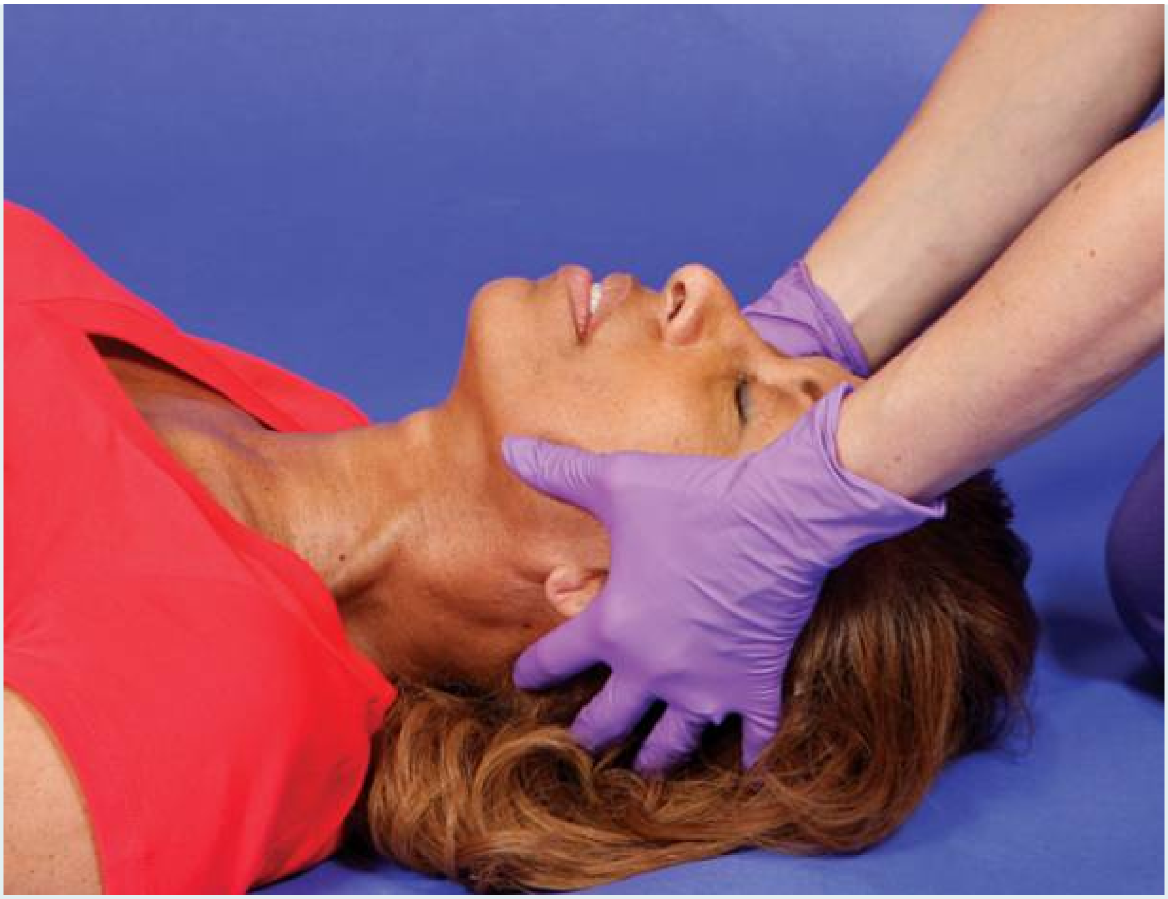
SKILL DRILL 6-3 Performing Nasotracheal Intubation



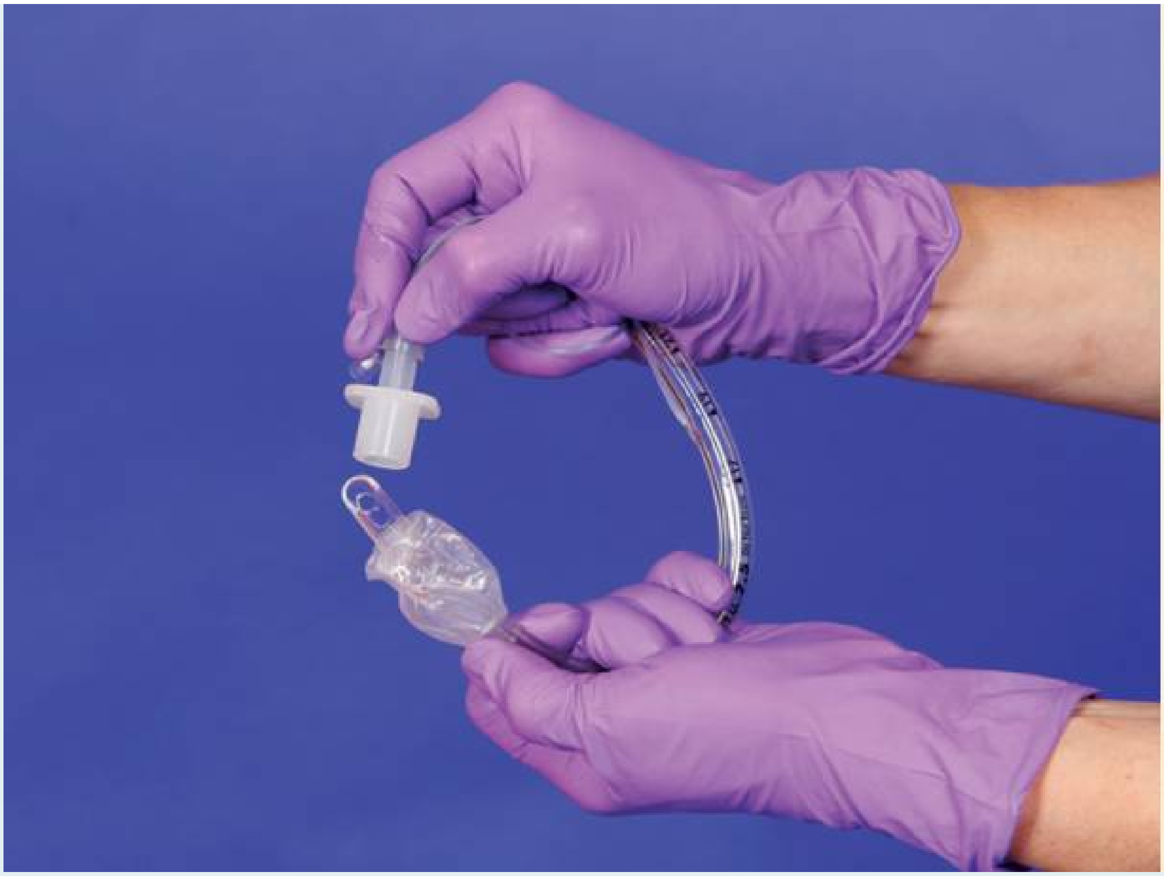
Step 1
Follow standard precautions (gloves and face shield). Preoxygenate the patient.



Step 2
Check, prepare, and assemble your equipment.

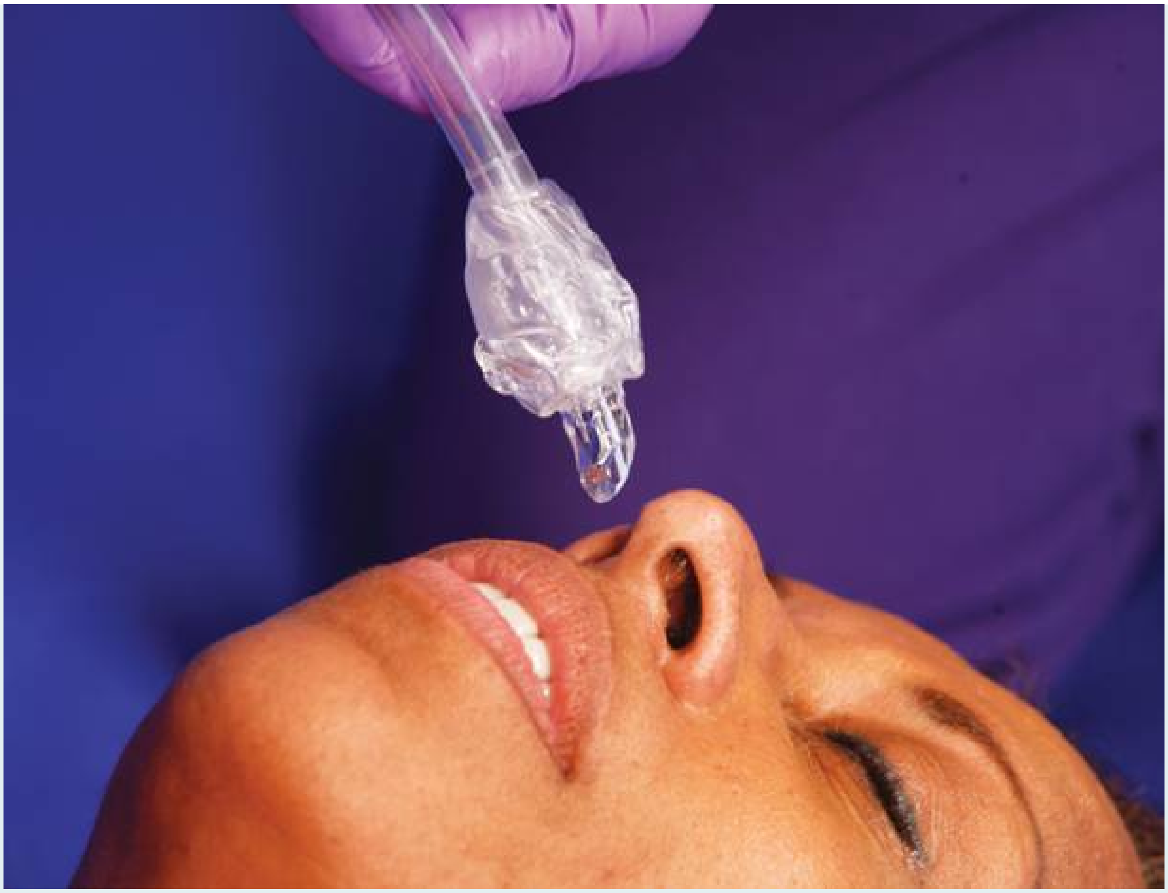


Step 3
Place the patient’s head in a neutral position.

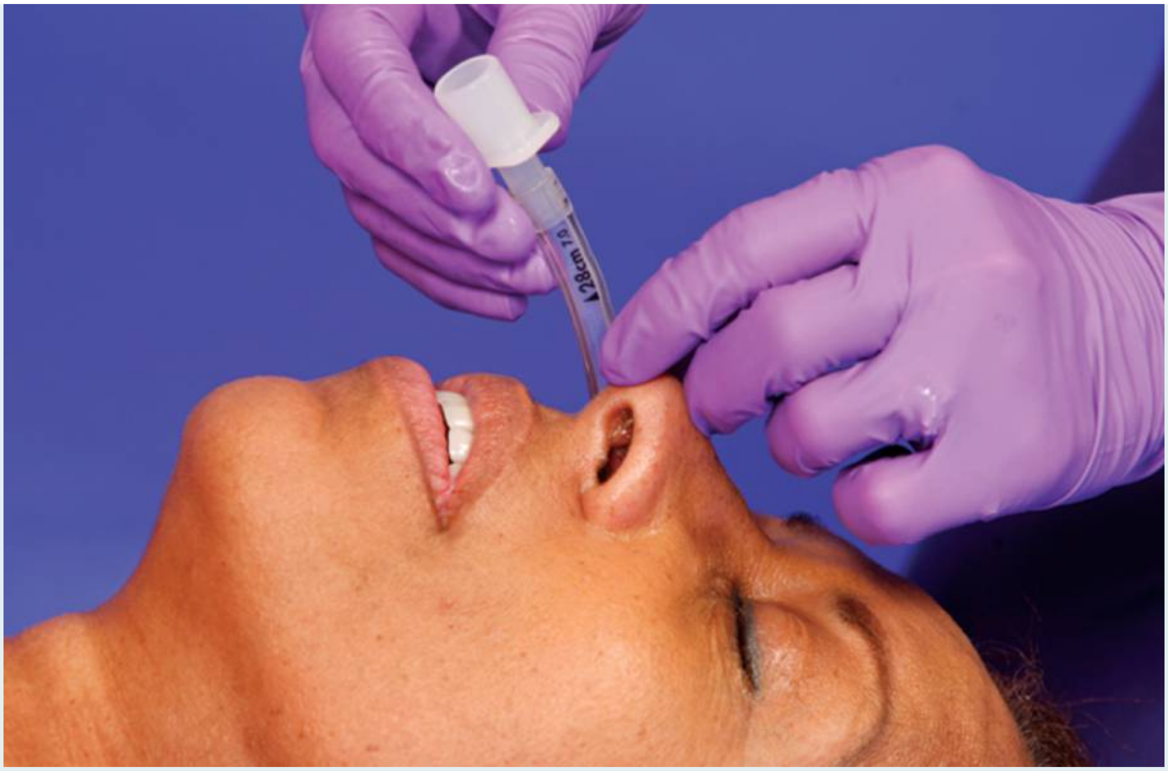


Step 4
Select the proper size of ET tube and form it into a circle.

Step 5
Apply topical anesthetic spray to the patient’s nostrils and pharynx. Lubricate the tip of the tube with a water-soluble gel.

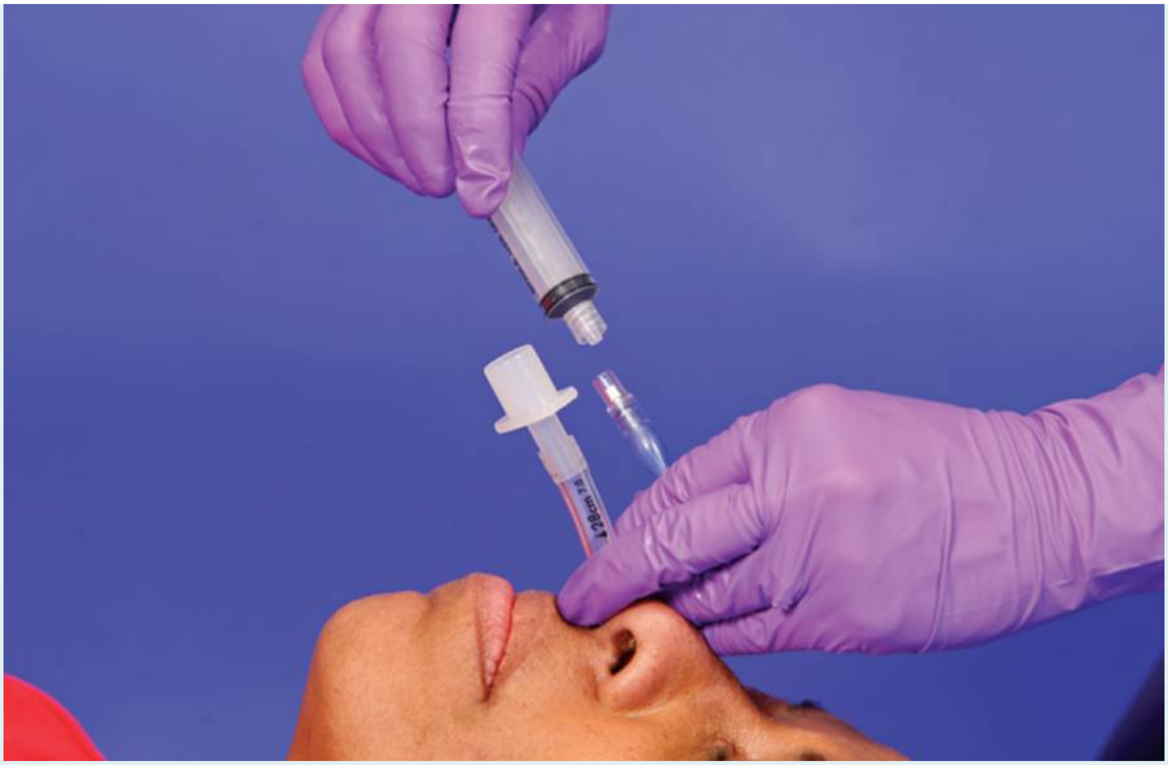


Step 6
Release the circle from the ET tube and gently insert it into either nostril, with the bevel of the tube pointed toward the septum.

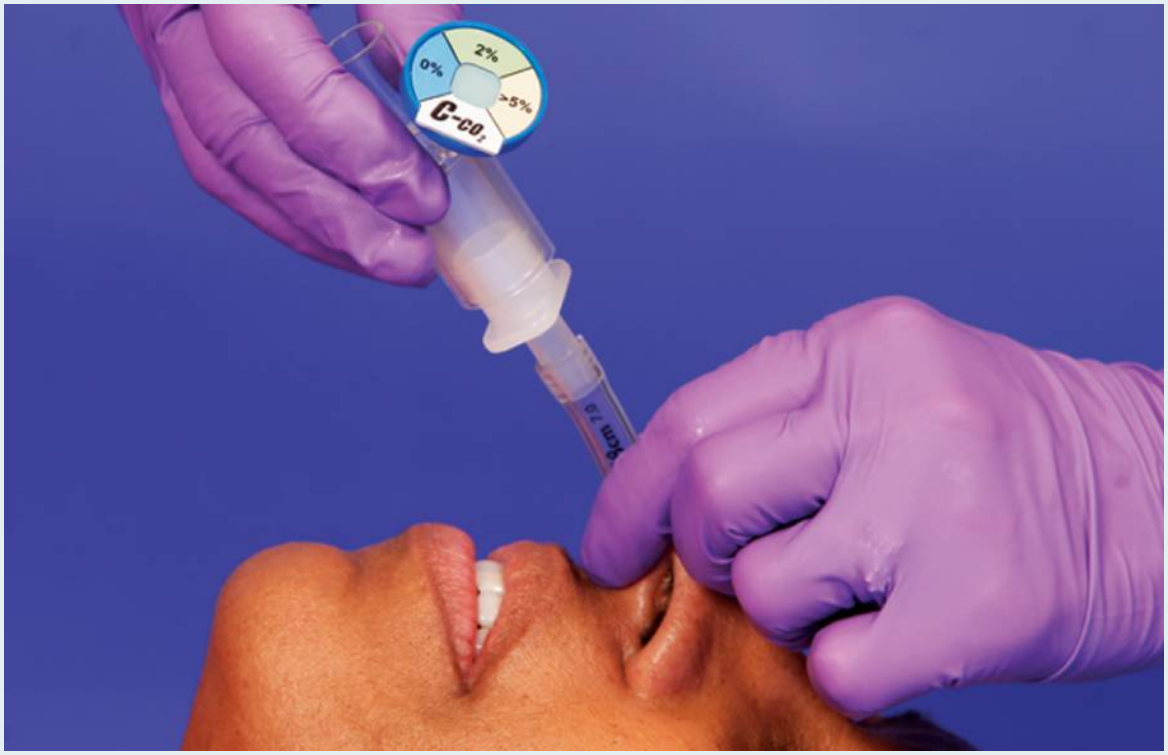


Step 7

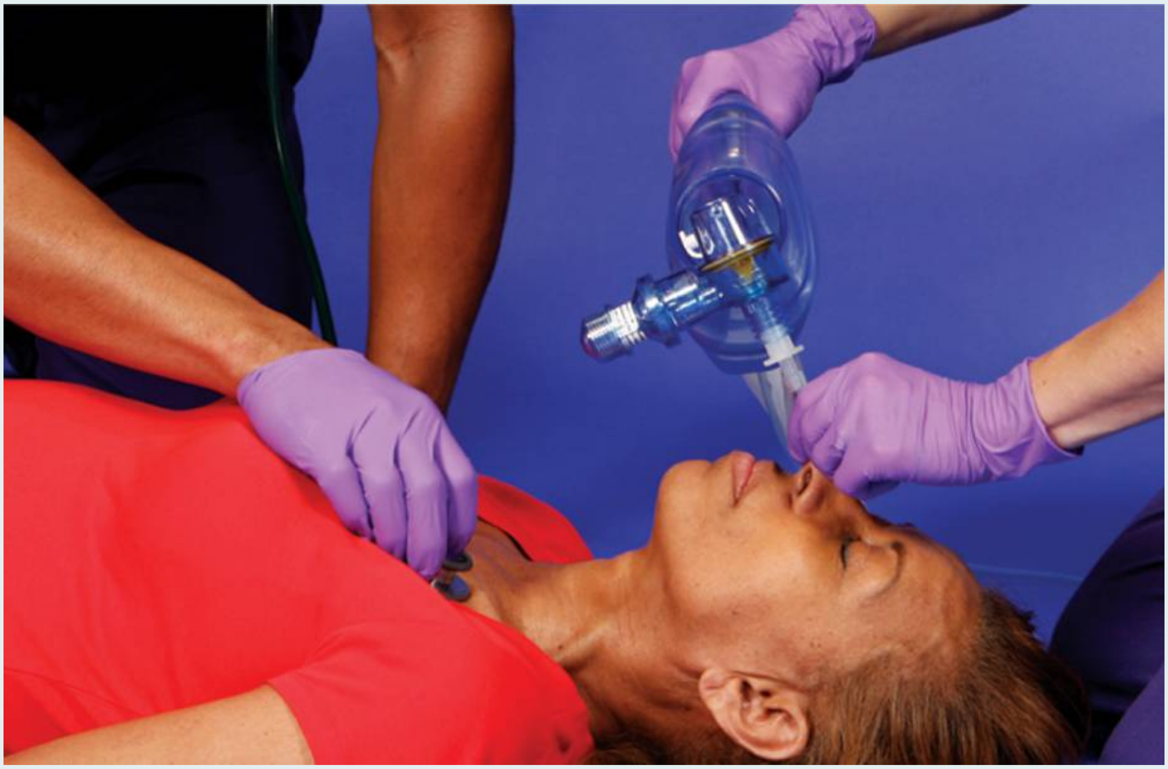
Advance the tube until the tip passes through the nasopharynx. Listen for breath sounds and look for condensation in the tube.



Step 8
Inflate the distal cuff with 5 to 10 mL of air and detach the syringe.



Step 9
Attach an $ETCO_2$ detector to the ET tube.



Step 10
Attach the bag-mask device and ventilate. Auscultate the chest bilaterally and over the epigastrium. Secure the ET tube.

© Jones & Bartlett Learning.

1. Follow standard precautions (gloves and face shield).
2. Preoxygenate the patient whenever possible with 100% oxygen provided by an appropriate delivery device **STEP 1**.
3. Check, prepare, and assemble your equipment **STEP 2**.
4. Place the patient's head in a neutral position **STEP 3**.
5. Select the proper size of ET tube and form it into a circle **STEP 4**.
6. Apply topical anesthetic spray to the patient's nostrils and pharynx.
7. Lubricate the tip of the tube with a water-soluble gel **STEP 5**.

8. Release the circle from the ET tube and gently insert it into either nostril, with the bevel of the tube pointed toward the septum **STEP 6**.
9. Advance the tube until the tip passes through the nasopharynx. Listen for breath sounds and look for condensation in the tube **STEP 7**.
10. As the tube approaches the larynx, the patient's breath sounds will be amplified. Gently and evenly push the tube into the larynx during inspiration.
11. The 15-mm adapter should rest close to the nostril. Passing the tube through the trachea may stimulate the gag reflex, which could result in the patient coughing and bucking. Watch and monitor for vomiting.
12. Inflate the distal cuff with 5 to 10 mL of air and detach the syringe **STEP 8**.
13. Attach an ETCO$_2$ detector to the ET tube **STEP 9**.
14. Attach the bag-mask device and ventilate. Verify tube placement by auscultating the patient's chest bilaterally and over the epigastrium.
15. Secure the ET tube **STEP 10**.

Face-to-Face Intubation

Intubation may be performed with the provider's face at the same level as the patient's face when other positions are not possible, such as in the context of a motor vehicle crash where the patient is in a seated position or in a tight space where the space above the head cannot be accessed. This approach is called **face-to-face intubation**, or the tomahawk method. The procedure is the same as with orotracheal intubation, except for the following points:

- The patient's head cannot be placed in the sniffing position. It is manually stabilized by a second provider during the entire procedure.
- Hold the laryngoscope (with a Macintosh blade) in your right hand with the blade facing downward like a hatchet, while holding

the ET tube in your left hand. Insert the laryngoscope blade into the right side of the patient's mouth, sweep the tongue to the patient's left, and visualize the vocal cords.

- Once the laryngoscope blade has been placed, the provider who is intubating the patient may slightly adjust the patient's head for better visualization by pulling the mandible forward while pressing down.

The Difficult Airway

Attempts at laryngoscopy should be limited to approximately 30 seconds or less, as lengthy attempts at intubation can result in significant hypoxemia, hypercarbia, and hemodynamic instability. Even a single episode of hypoxia may negatively affect the patient's outcome. If the patient is hypoxic or having clinically significant desaturation during a laryngoscopy, the attempt should be aborted and the patient immediately oxygenated. Remember that pulse oximetry is a lagging indicator, and the patient's $Pa\text{O}_2$ may be lower than the displayed $Sp\text{O}_2$.

The intubation strategy should be optimized to realize first-pass success. However, if you are attempting intubation and not visualizing what you need to proceed, stop, ventilate, and try something different. The patient's position is probably the most crucial aspect to reconsider.

1. Reposition the patient's head, if possible, to elevate the ear to the level of the sternal notch, with the face parallel to the ceiling. In some patients, achieving this position may require placing multiple blankets under the head and shoulders and/or elevating the head of the stretcher.
2. If spinal motion restriction precautions have been implemented, remove the front of the collar while maintaining manual spinal precautions to allow for increased mandibular displacement.
3. Consider performing external laryngeal manipulation. In this procedure, the provider uses the right hand to manipulate the larynx and improve the laryngeal view, and then has an assistant maintain

this view while the provider passes the ET tube under direct visualization **FIGURE 6-39**.

4. Consider using a bougie or tracheal tube introducer.

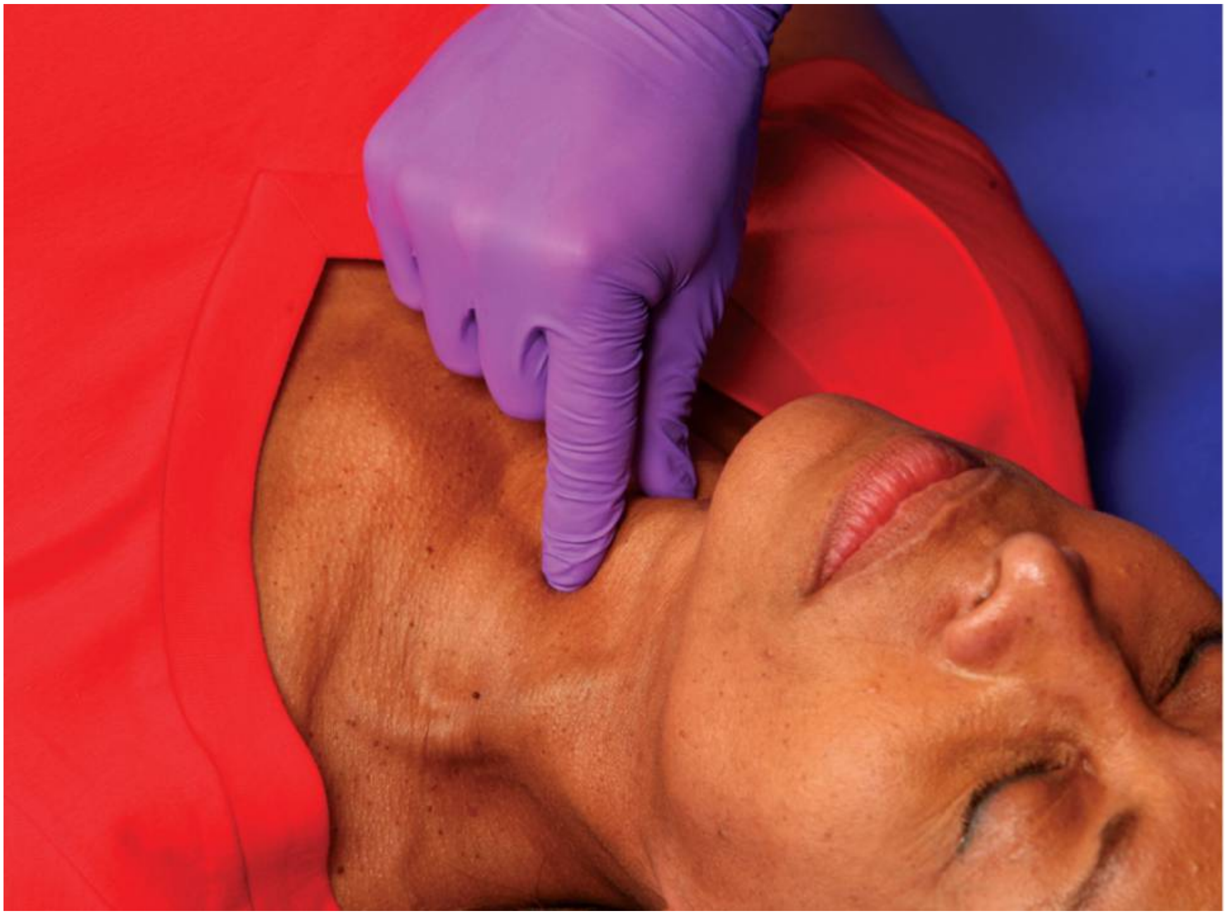


FIGURE 6-39 External laryngeal manipulation.

© Jones & Bartlett Learning.

Difficult Airway Versus Failed Airway

The Difficult Airway Course defines a **failed airway** as one that meets the following three criteria:

1. Failure to maintain an acceptable SpO_2 during or after one or more failed laryngoscopic attempts
2. Three failed attempts at orotracheal intubation by an experienced intubator, even when oxygenation can be maintained

3. The single “best attempt” at intubation fails in the “forced to act” situation

More simply, a failed airway can be defined as “a failure to oxygenate or ventilate the patient.”

With a **difficult airway**, providers can predict complications that might occur while securing the patient’s airway. For example, the CCTP can determine a difficult airway through assessment of the patient using the LEMONS or HEAVEN mnemonic. Both anatomic and physiologic indicators need to be considered in this assessment. Anatomic issues may be overcome with positioning and equipment, whereas physiologic issues may necessitate additional treatment of the patient, optimization, and resuscitation. Failing to predict the difficult airway is a leading cause of preventable airway failures. In other words, you must determine whether the patient will be difficult to ventilate via bag-mask device, whether the patient will be difficult to intubate, whether you can use an SGA, or whether a cricothyrotomy is likely. As emergency medical providers, CCTPs do not have the option of canceling a case due to a difficult or failed airway. Guidance for caring for patients with difficult and failed airways is described in the algorithms in **FIGURE 6-40** and **6-41** , respectively.

Description

Special Populations

Pregnant patients have a four times higher rate of failed intubation as compared with nonpregnant patients. Keep the following facts in mind when you are treating a pregnant patient:

1. The airway in pregnant patients is usually more anterior.
2. The airway tissues of a pregnant patient are often friable and will bleed easily when manipulated.
3. Pregnant patients are at a high risk of aspiration secondary to release of the hormone relaxin.
4. Pregnant patients have more oral secretions and require more suctioning, even after being intubated.

Postintubation Management

Once the ET tube has been passed and the balloon inflated, correct tube placement should be confirmed through the use of continuous waveform end-tidal capnography. Additionally, the chest should be auscultated to ensure the presence of bilateral lung sounds and the absence of epigastric sounds with ventilation. If breath sounds are heard for the right lung only and you believe the ET tube may have been placed too deep, consider deflating the cuff, withdrawing the ET tube slightly, reinflating the cuff, and repeating auscultation. Do not automatically assume the ET tube is too deep when you do not hear breath sounds on the left side of the chest. Other factors may be present that affect left-side breath sounds, including pneumothorax, pneumonia, atelectasis, and pneumonectomy.

If ET tube placement cannot be confirmed with continuous waveform end-tidal capnography, remove the ET tube and remove bag-mask device ventilation.

Once the patient is successfully intubated, provide postintubation analgesia and sedation per your local protocol. Ensure the tube is secured using a commercial tube holder and the patient is connected to the ventilator. If available, obtain a postintubation chest radiograph and ABG analysis. Finally, consider placing an orogastric tube to allow for stomach decompression.

Supraglottic Airways

Several SGAs are available that can be used as rescue airways if orotracheal intubation is unsuccessful or predicted to be difficult. These options include the laryngeal mask airway, King LT airway, and i-gel airway.

Laryngeal Mask Airway

The **laryngeal mask airway (LMA)** was designed for use as an alternative to mask ventilation and intubation in the operating room. The LMA has been advocated for use as a rescue airway in the setting of failed intubation in both the emergency and EMS environments. LMAs have various designs, some of which allow an ET tube to be passed through the airway or a tube to decompress the stomach. The basic design is similar to an ET tube at the proximal end, in that a standard adapter is present to allow ventilation. The distal end is equipped with an elliptical cuff, which, when inflated, covers the supraglottic area and allows ventilation.

An advantage of the LMA is ease of insertion—placement of the device does not require laryngoscopy. It also provides superior oxygenation and ventilation compared with bag-mask ventilation. Some disadvantages associated with LMA use are the risk of aspiration and difficulty with obtaining an adequate seal, allowing a loss of tidal volume and gastric insufflation.

Indications for LMA use include:

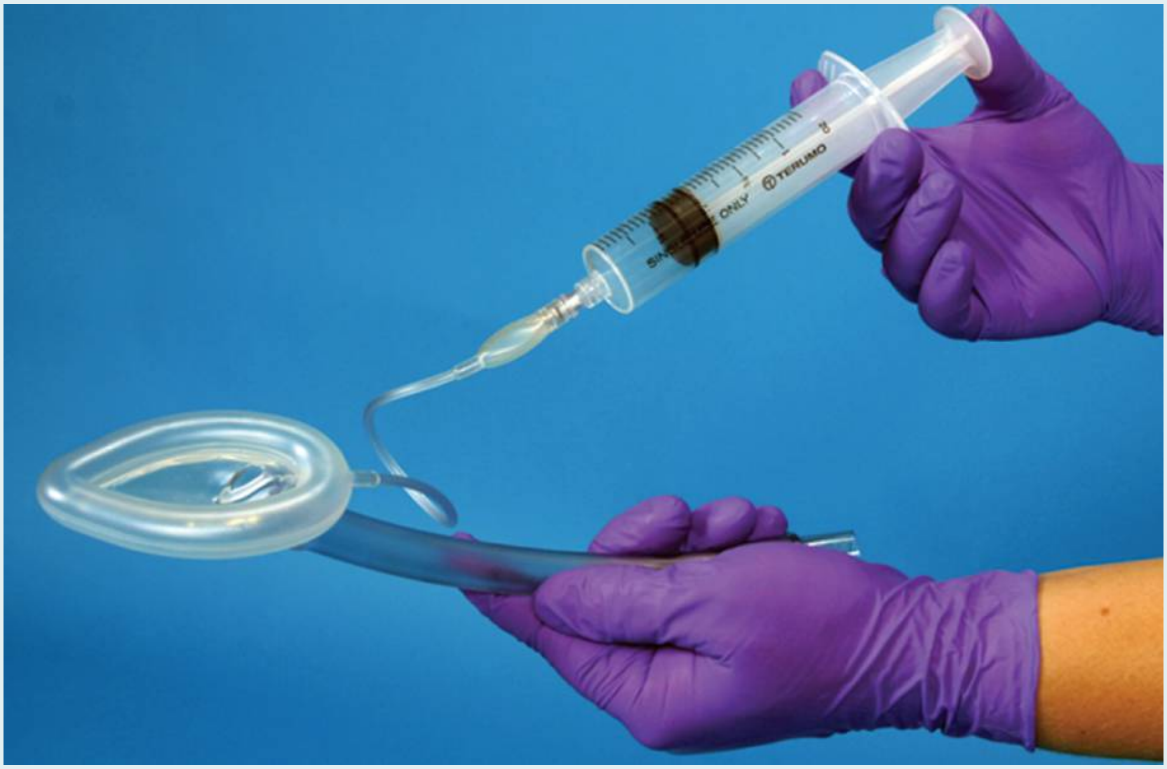
- Deep coma, cardiac arrest, and/or respiratory arrest
- Inability to perform ET intubation (including lack of equipment)

Contraindications to LMA use include:

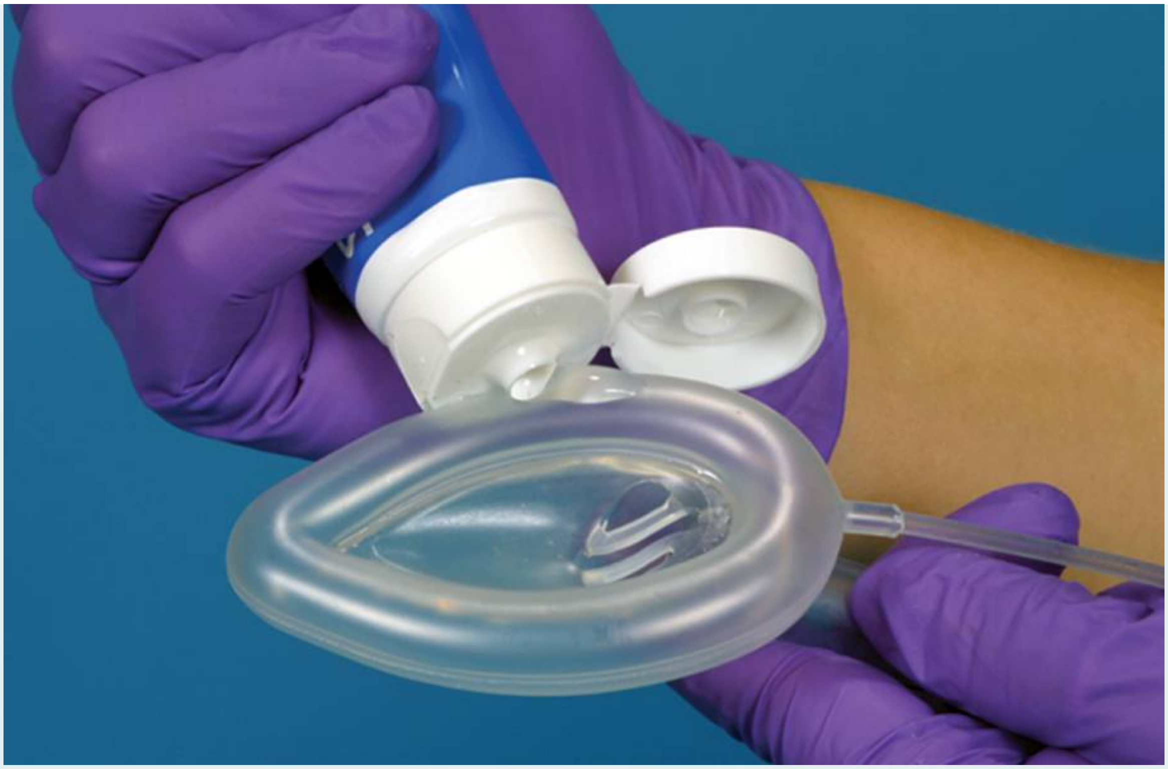
- Patients with a gag reflex
- Facial and/or esophageal trauma
- Suspected foreign body airway obstruction

Skill Drill 6-4 shows the steps for LMA placement, which are described here:

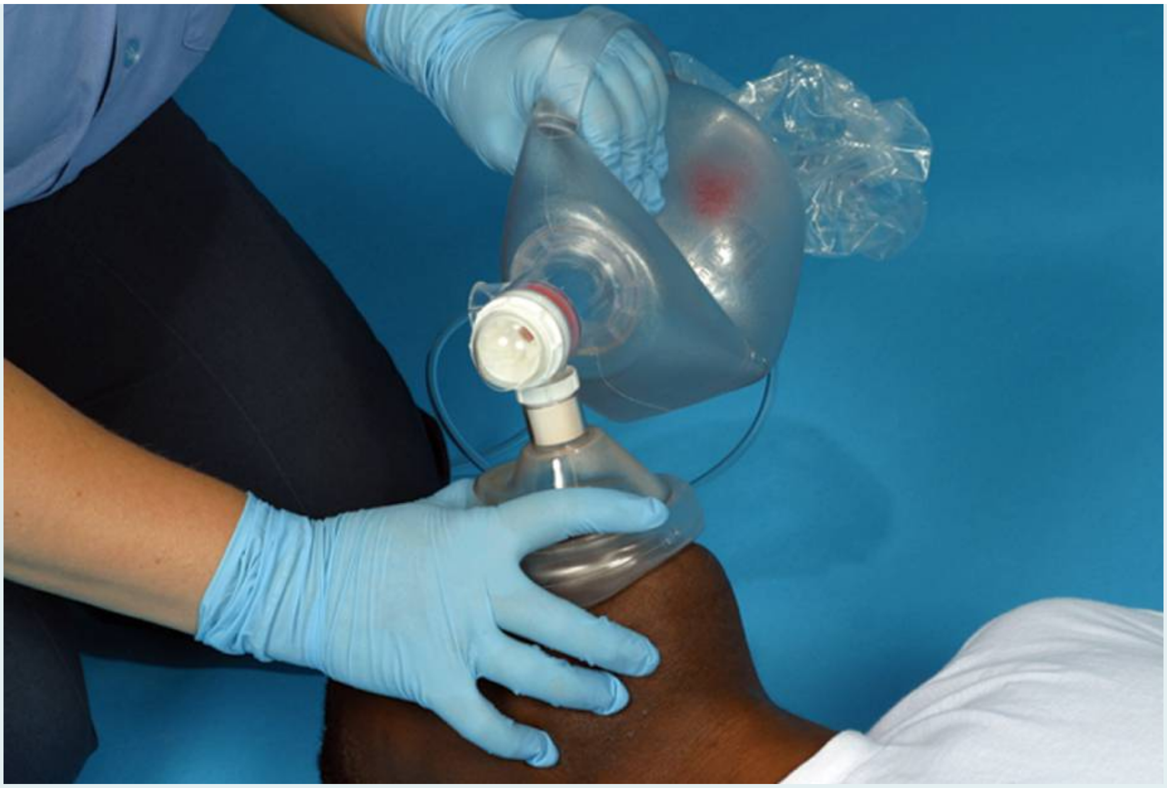
SKILL DRILL 6-4 LMA Insertion



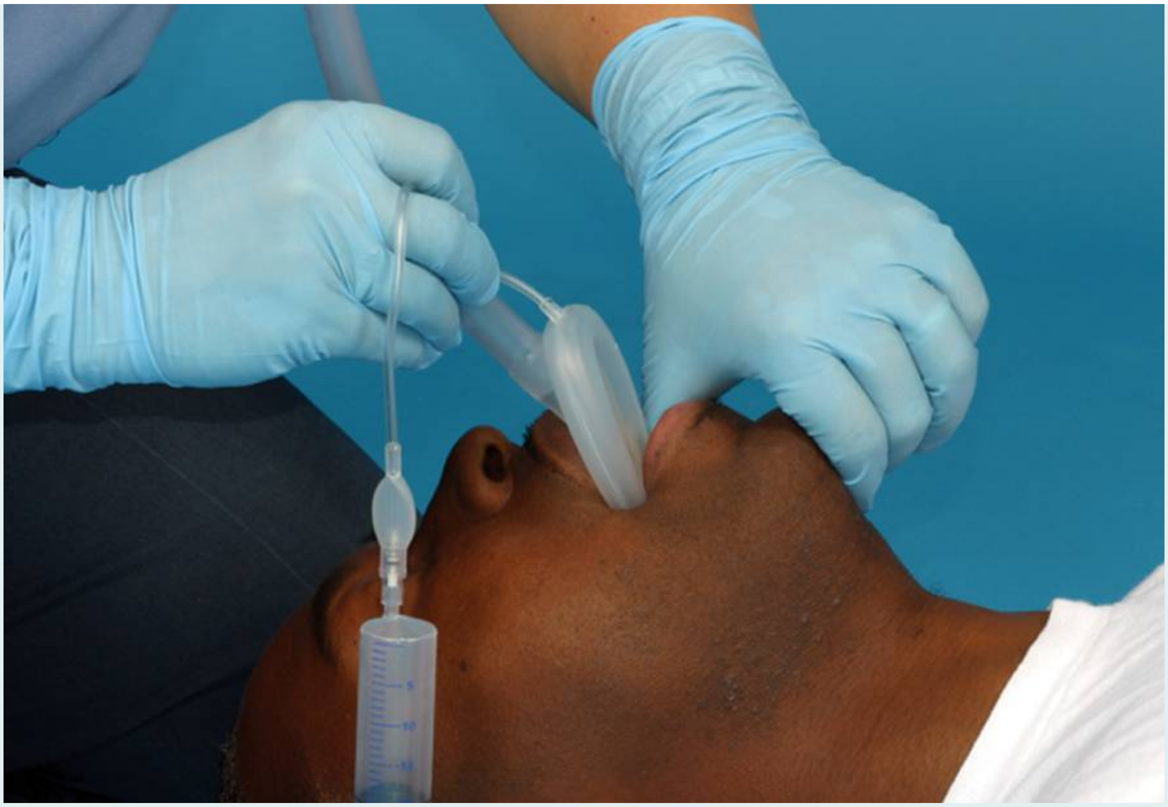
Step 1
Check the cuff of the LMA by inflating it with 50% more air than is required for that size of airway. Then deflate the cuff completely.



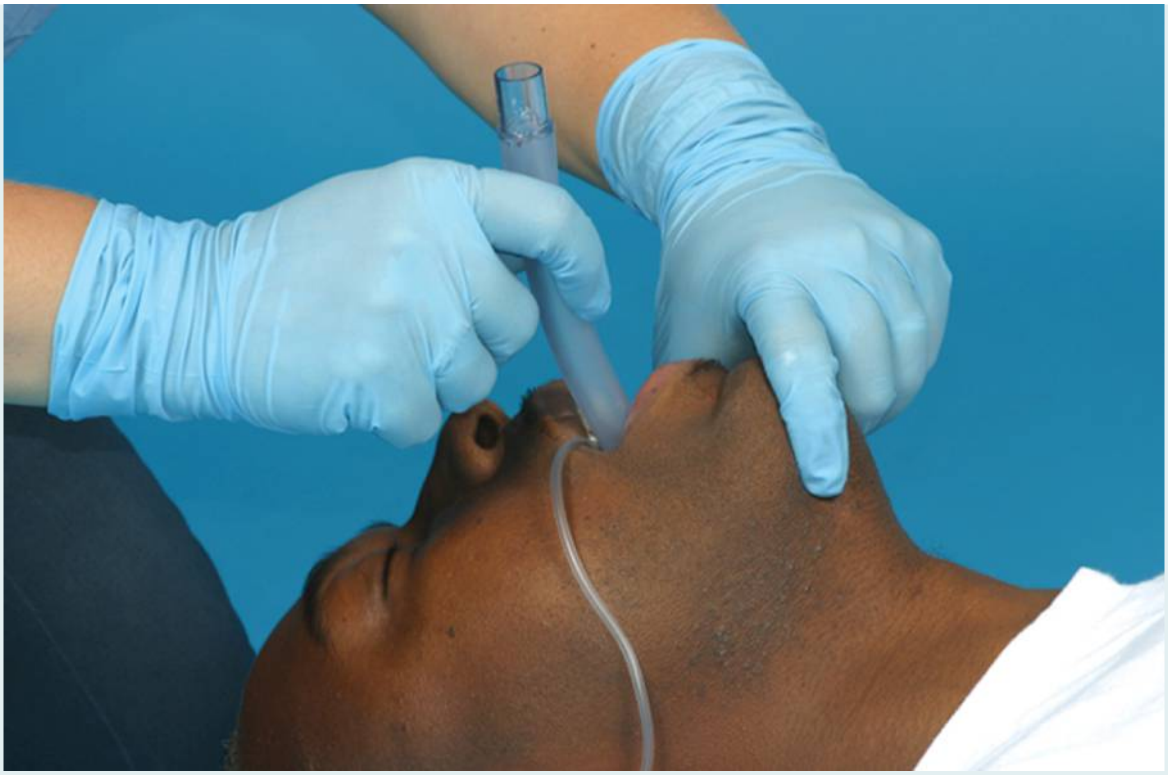
Step 2
Apply a water-soluble lubricant to the base of the device.



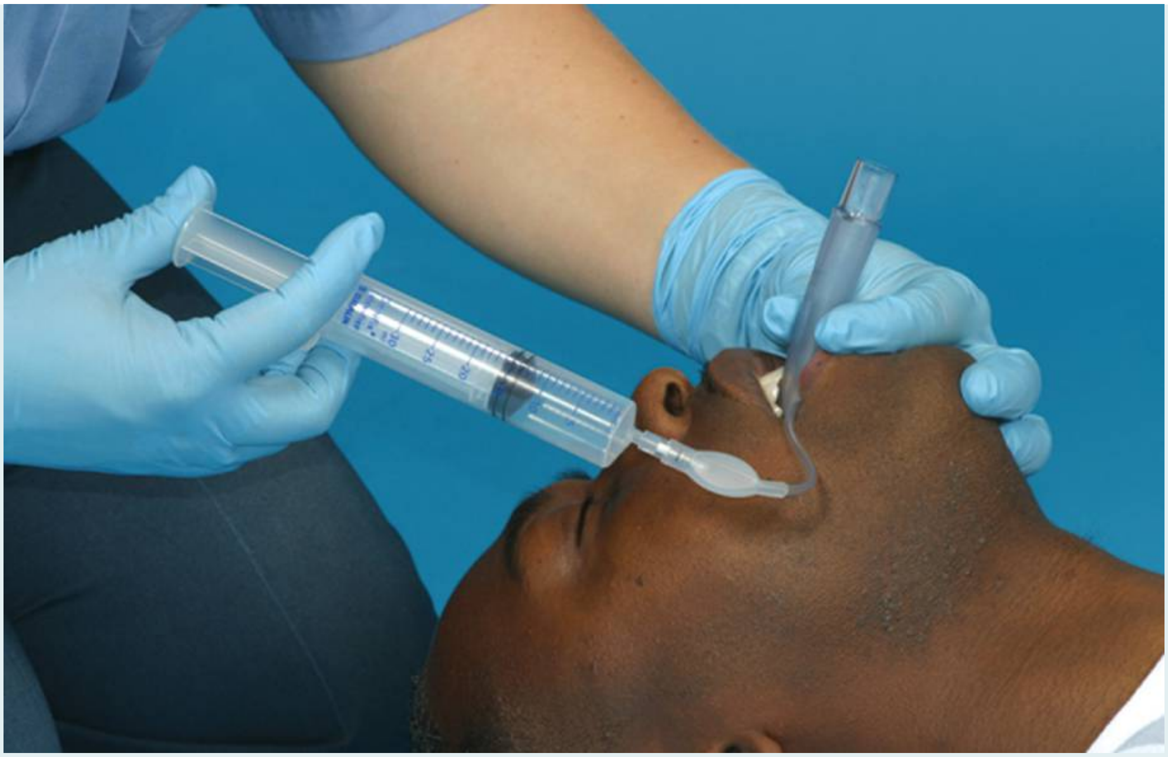
Step 3
Preoxygenate the patient. Ventilation should not be interrupted for more than 30 seconds to accomplish LMA placement.



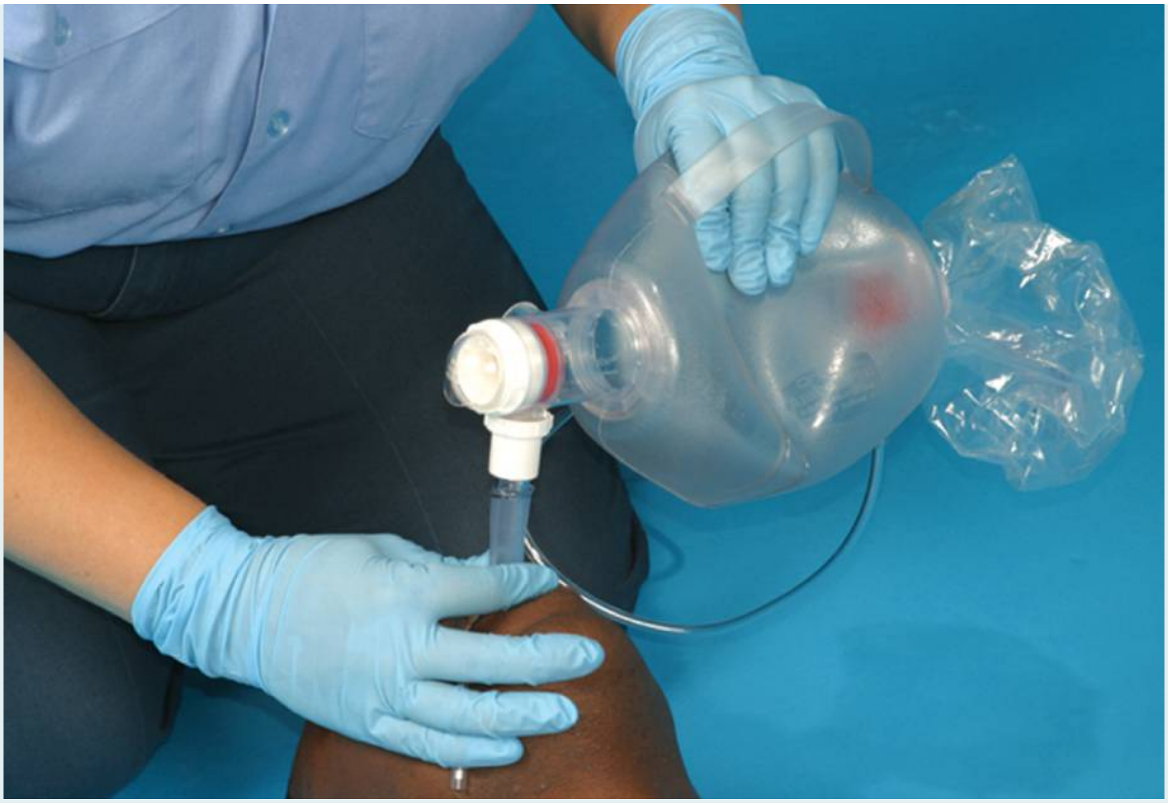
Step 4
Place the patient's head in the sniffing position. Insert your finger between the cuff and the tube. Place the index finger of your dominant hand in the notch between the tube and the cuff. Open the patient's mouth.



Step 5
Insert the LMA along the roof of the mouth, with the aperture of the mask facing the tongue and the back of the mask against the roof of the mouth.



Step 6
Inflate the cuff with the amount of air indicated for that size of airway.



Step 7
Attach the bag-mask device and begin to ventilate the patient. Check for chest rise and lung or epigastrium sounds.

© Jones & Bartlett Learning.

1. Check the cuff of the LMA by inflating it with 50% more air than is required for that size of airway. Then deflate the cuff completely **STEP 1**.
2. Apply a water-soluble lubricant to the base of the device **STEP 2**.
3. Preoxygenate the patient with a bag-mask device and 100% oxygen. Ventilation should not be interrupted for more than 30 seconds to accomplish LMA placement **STEP 3**.
4. Assemble and check the equipment.
5. Place the patient’s head in the sniffing position. Insert your finger between the cuff and the tube. Place the index finger of your

dominant hand in the notch between the tube and the cuff. Open the patient's mouth **STEP 4**.

6. Insert the LMA along the roof of the mouth, with the aperture of the mask facing the tongue and the back of the mask against the roof of the mouth **STEP 5**. Use your finger to push the airway against the hard palate.
7. Blindly push until resistance is felt.
8. Ensure that the black line on the tube shaft is opposite the upper lip.
9. Inflate the cuff rim of the mask with the amount of air indicated for that size of airway **STEP 6**. Remove the syringe.
10. Attach the bag-mask device and begin to ventilate the patient. Check for chest rise and lung or epigastrium sounds **STEP 7**. Continuously monitor the patient.

King LT Airway

The King LT airway is a single-lumen SGA that may be placed blindly **FIGURE 6-42**. Placement occurs mostly within the esophagus. The King LT airway has not been proven to protect the airway from the effects of regurgitation and aspiration; thus, the risk of regurgitation and aspiration must be weighed against the potential benefit of establishing an airway.

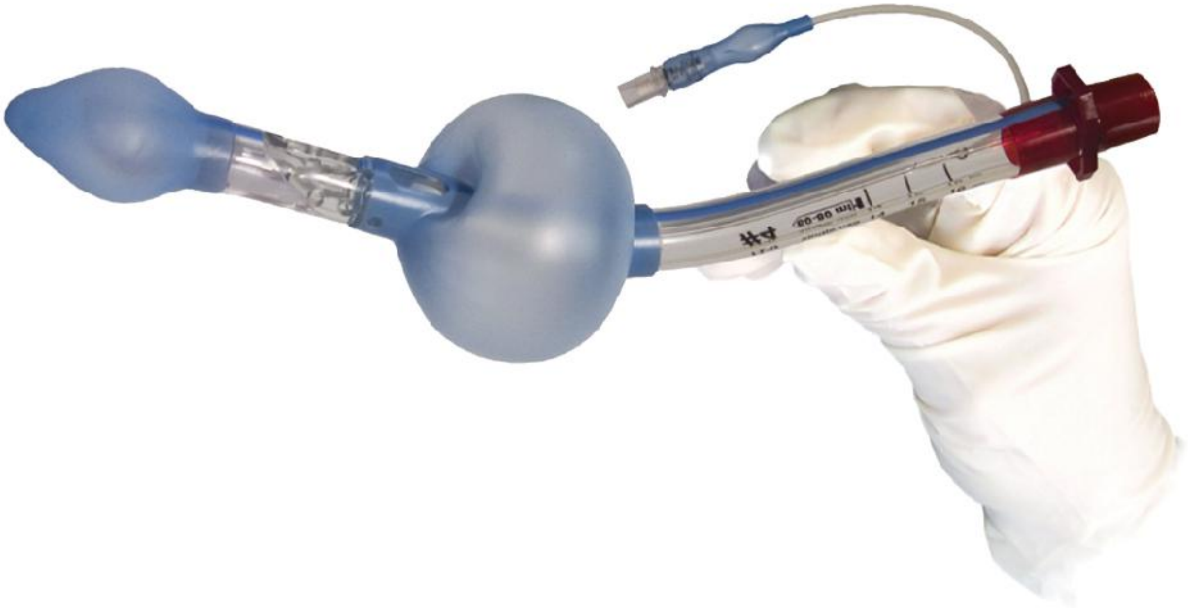


FIGURE 6-42 King LT airway.

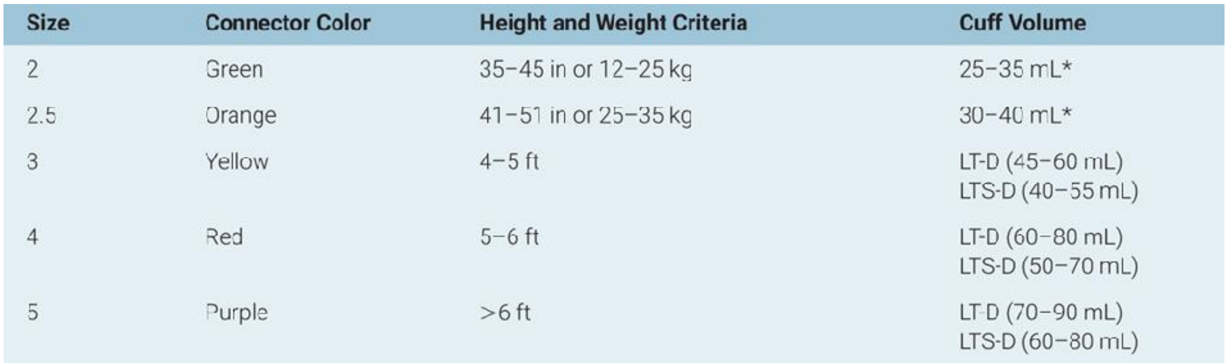
Courtesy of Ambu and King Systems.

Two types of King LT airway are available: the King LT-D and the King LTS-D. The King LT-D can be used in adults and children in the prehospital setting, whereas the King LTS-D is used only in adults. Five sizes of each type are available, with sizes based on the patient's height and/or weight. Each size has a different color of proximal connector and requires different cuff inflation pressures **TABLE 6-4**.

TABLE 6-4 | **King LT-D and LTS-D Sizes, Patient Criteria, and Cuff Volumes**



Size	Connector Color	Height and Weight Criteria	Cuff Volume
2	Green	35–45 in or 12–25 kg	25–35 mL*
2.5	Orange	41–51 in or 25–35 kg	30–40 mL*
3	Yellow	4–5 ft	LT-D (45–60 mL) LTS-D (40–55 mL)
4	Red	5–6 ft	LT-D (60–80 mL) LTS-D (50–70 mL)
5	Purple	>6 ft	LT-D (70–90 mL) LTS-D (60–80 mL)

*Sizes 2 and 2.5 are available only in the King LT-D.
Data from Ambu.

Description

Indications for use of the King LT airway are:

- Inability to perform ET intubation (including lack of equipment).
- Rescue airway in failed intubation, especially in the setting of failed RSI. If the King LT airway is used as a rescue airway after RSI, remember that the patient must be kept sedated and paralyzed once proper placement has been verified.
- Deep coma, cardiac arrest, or respiratory arrest.
- To reduce the risk of gastric distention.

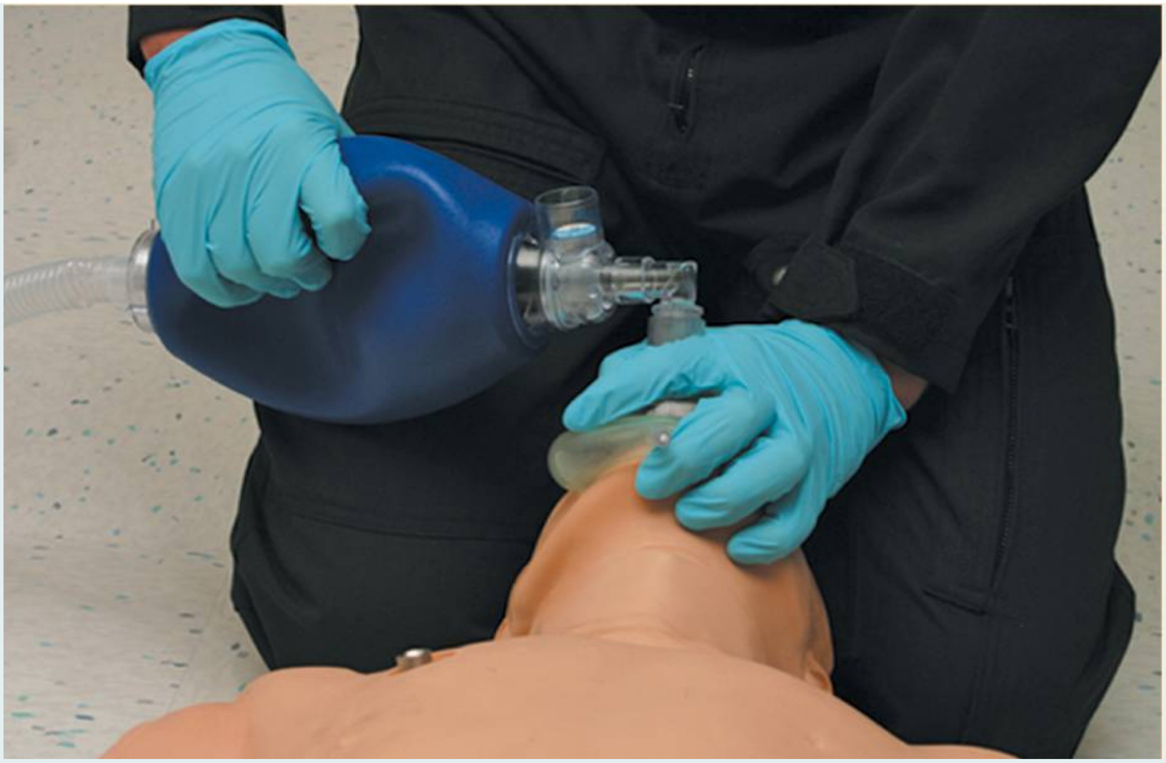
Contraindications are:

- Responsive patient with an intact gag reflex
- Upper airway obstruction
- Patient with known esophageal disease
- Patient who has ingested caustic substances

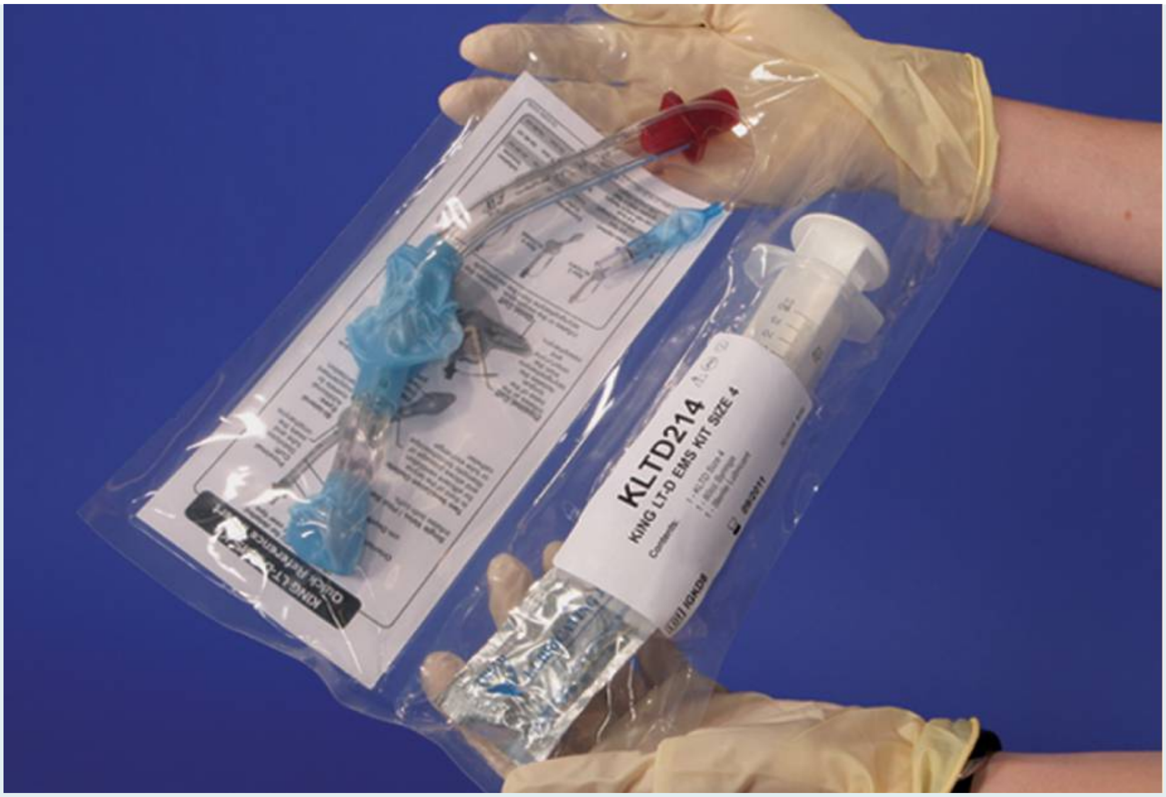
It is recommended that the patient be at least 35 inches (89 cm) tall or weigh at least 26 pounds (12 kg).
Skill Drill 6-5 shows the steps for placement of the King LT airway, which are described here:

SKILL DRILL 6-5 King LT Airway Insertion

Step 1
Take standard precautions (gloves and face shield).

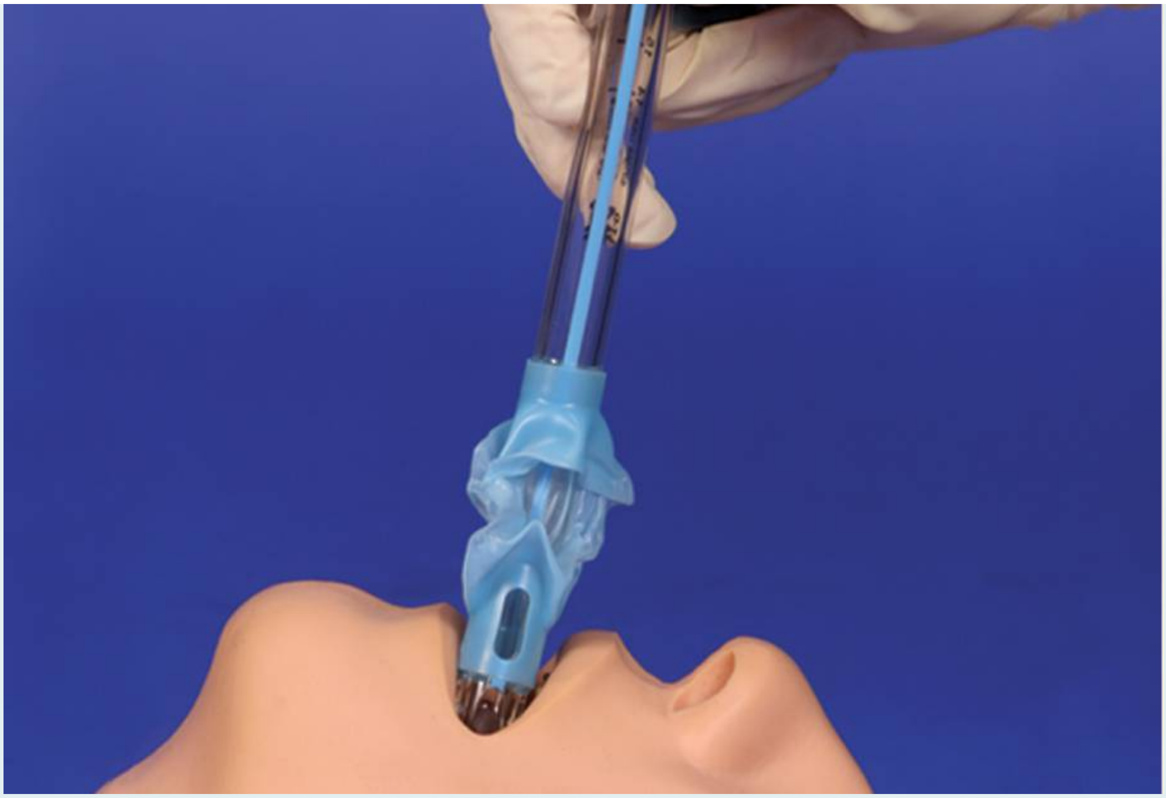


Step 2
Preoxygenate the patient with a bag-mask device and 100% oxygen.

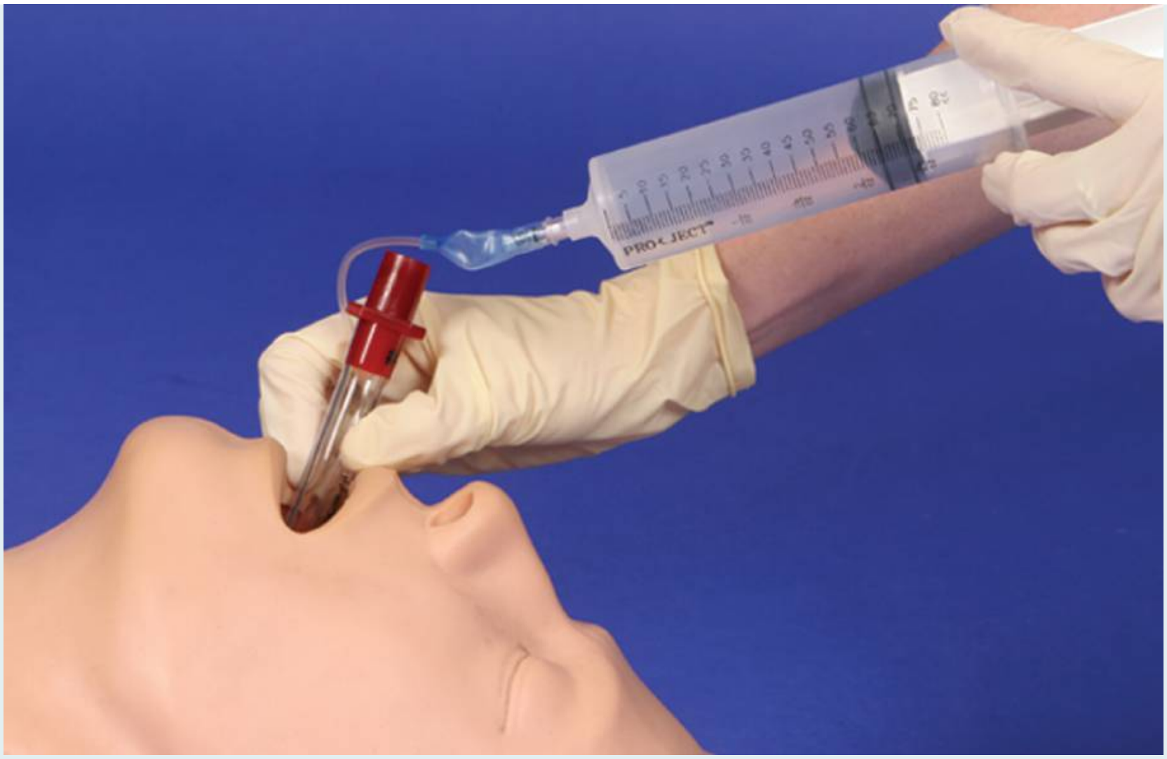


KLTD214
KING LT-D EMS KIT SIZE 4

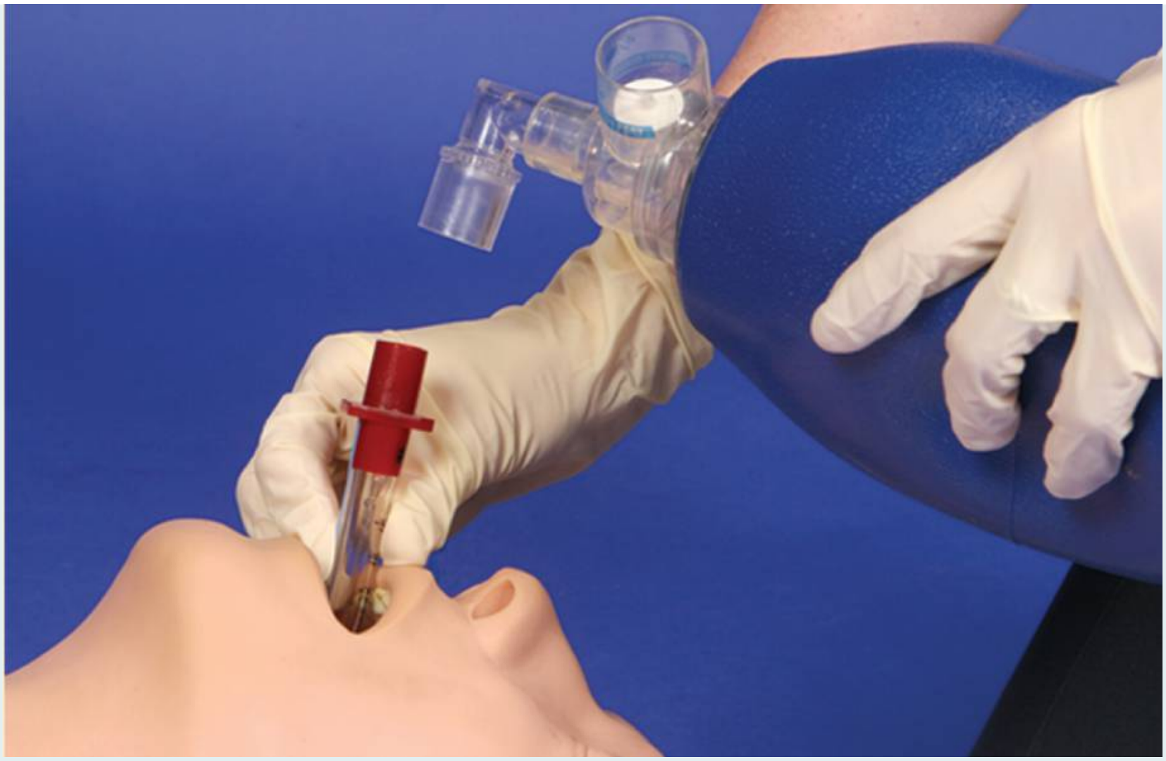
Step 3
Gather your equipment.



Step 4
Place the patient’s head in a neutral position unless contraindicated. Open the patient’s mouth and insert the King LT airway in the corner of the mouth.



Step 5
Advance the tip behind the base of the tongue while rotating the tube back to midline so the blue line on the device faces the patient’s chin. Gently advance the device until the base of the connector is aligned with the teeth or gums. Do not use excessive force. Inflate the cuffs with the recommended amount of air or enough to just seal the device.



Step 6
Attach the tube to the bag-mask device and confirm tube placement by auscultating the lungs and epigastrium and attaching waveform capnography. While ventilating, gently withdraw the tube until ventilation becomes easy and free flowing (ie, good tidal volume with minimal resistance). Adjust the cuff inflation, if necessary, to maximize the airway seal.

© Jones & Bartlett Learning.

1. Take standard precautions (glove and face shield) **STEP 1**.
2. Preoxygenate the patient with a bag-mask device and 100% oxygen **STEP 2**.
3. Gather your equipment **STEP 3**.
4. Choose the proper size of King LT airway for the patient. Test the cuff inflation system for leaks. Ensure that all air is removed from the cuffs before inserting the airway. Lubricate the tip of the device with a water-soluble lubricant for ease of insertion and to minimize risk of airway damage.

5. Place the patient’s head in a neutral position, unless contraindicated (use the jaw-thrust maneuver if trauma is suspected). In your dominant hand, hold the King LT at the connector. With your other hand, hold the patient’s mouth open while positioning the head **STEP 4**.
6. Insert the tip of the device into the corner of the mouth and continue to advance it behind the base of the tongue while rotating the device. When the rotation is complete, the blue line on the device should face the patient’s chin.
7. Continue to gently advance the device until the base of the connector is aligned with the patient’s teeth or gums. Do not use excessive force.
8. Inflate the cuffs with the recommended amount of air or enough to just seal the device **STEP 5**.
9. Attach the tube to the bag-mask device and confirm tube placement by auscultating the lungs and epigastrium and attaching waveform capnography **STEP 6**. While ventilating, gently withdraw the tube until ventilation becomes easy and free flowing (ie, good tidal volume with minimal resistance). Adjust the cuff inflation, if necessary, to maximize the airway seal.
10. Perform standard reassessment of lung sounds while continuing ventilation. Ensure appropriate capnography waveform is present, and consider securing the tube with tape or a commercial tube holder.

i-gel

The i-gel is an SGA that may be placed blindly. In contrast to other SGAs, this device does not require the use of an inflatable cuff or balloon. The i-gel has not been proven to protect the airway from the effects of regurgitation and aspiration; thus, these risks must be weighed against the potential benefits of establishing an airway. The i-gel is constructed of a medical-grade thermoplastic elastomer and is designed to create an anatomic seal of the pharyngeal, laryngeal, and perilaryngeal structures while avoiding compression forces. It includes an integral bite block and gastric channel and is available in both adult and pediatric sizes.

Indications for use of the i-gel airway are:

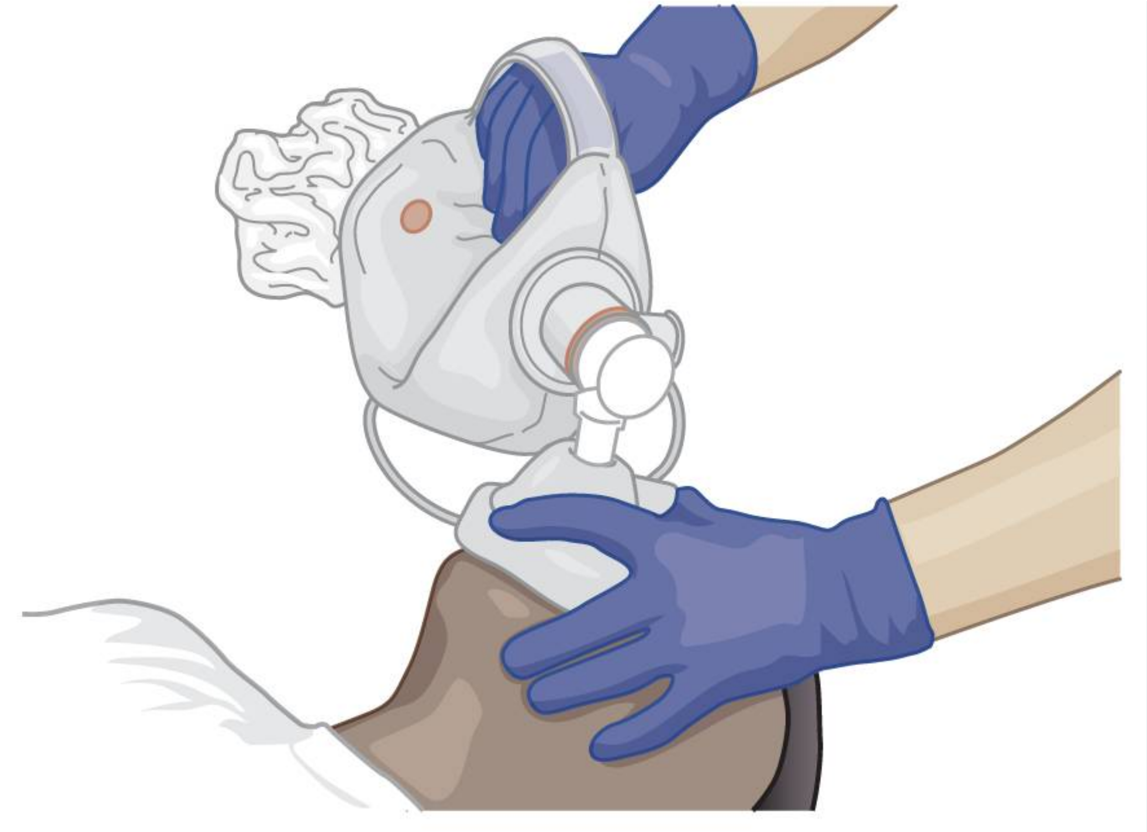
- Inability to perform ET intubation (including lack of equipment).
- Rescue airway in failed intubation, especially in the setting of failed RSI. If the i-gel airway is used for this purpose, remember that the patient must be kept sedated and paralyzed once proper placement has been verified.
- Deep coma, cardiac arrest, and/or respiratory arrest.
- To reduce the risk of gastric distention during bag-mask device ventilations prior to ET intubation.

Contraindications are:

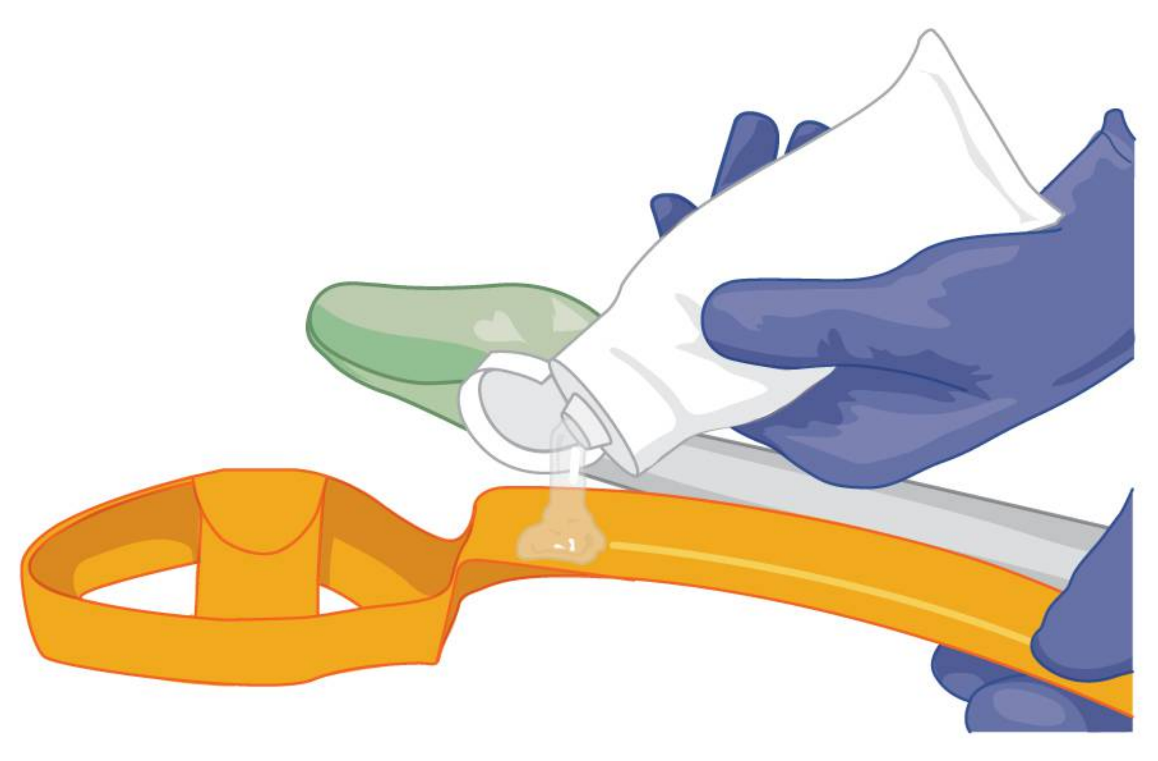
- Responsive patients with an intact gag reflex
- Upper airway obstruction
- Patients with known esophageal disease
- Patients who have ingested caustic substances
- Obstructive lesions below the glottis
- Trismus, limited mouth opening, pharyngo-perilaryngeal abscess, trauma, or mass
- Conscious or semiconscious patients with an intact gag reflex

Skill Drill 6-6 shows the steps for placement of the i-gel airway, which are described here:

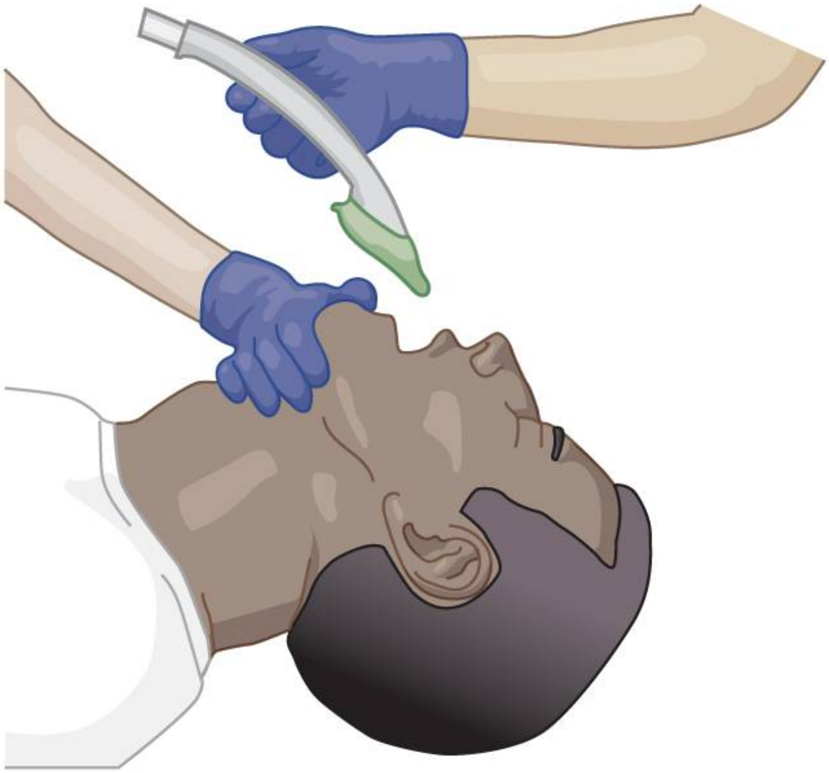
SKILL DRILL 6-6 i-gel Airway Insertion



Step 1
Take standard precautions (gloves and face shield). Preoxygenate the patient with a bag-mask device and 100% oxygen.

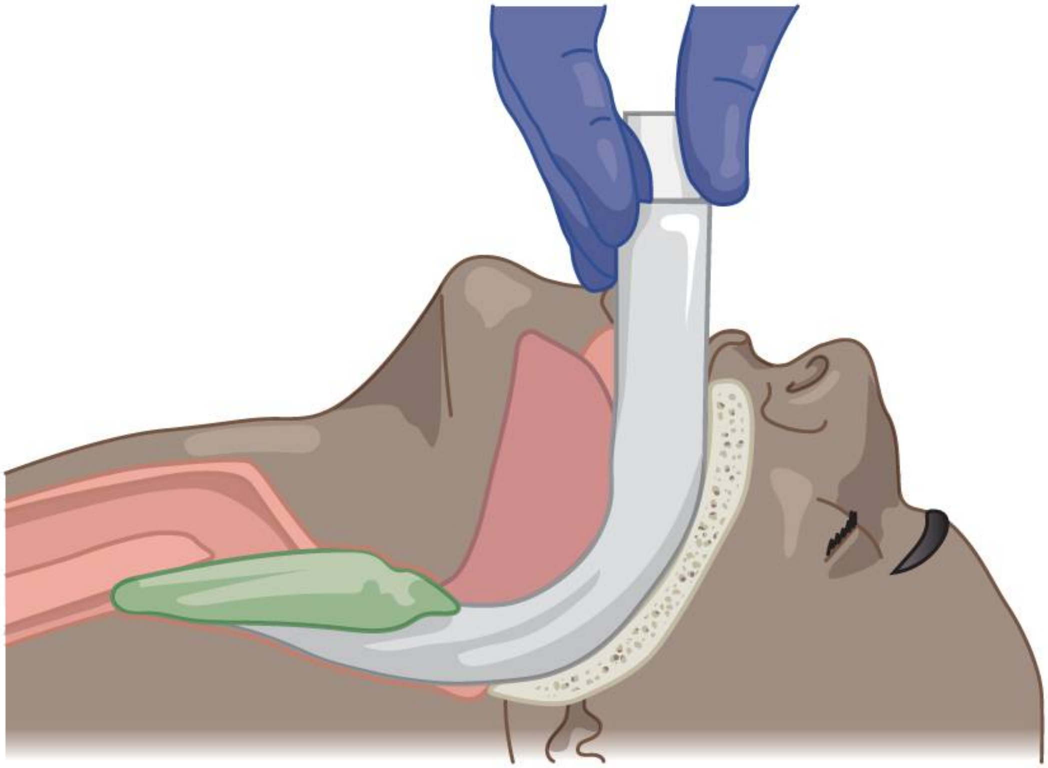


Step 2
Gather your equipment and choose the proper size of i-gel airway. Lubricate the back, sides, and front of the cuff with a water-soluble lubricant applied initially to the protective cradle.



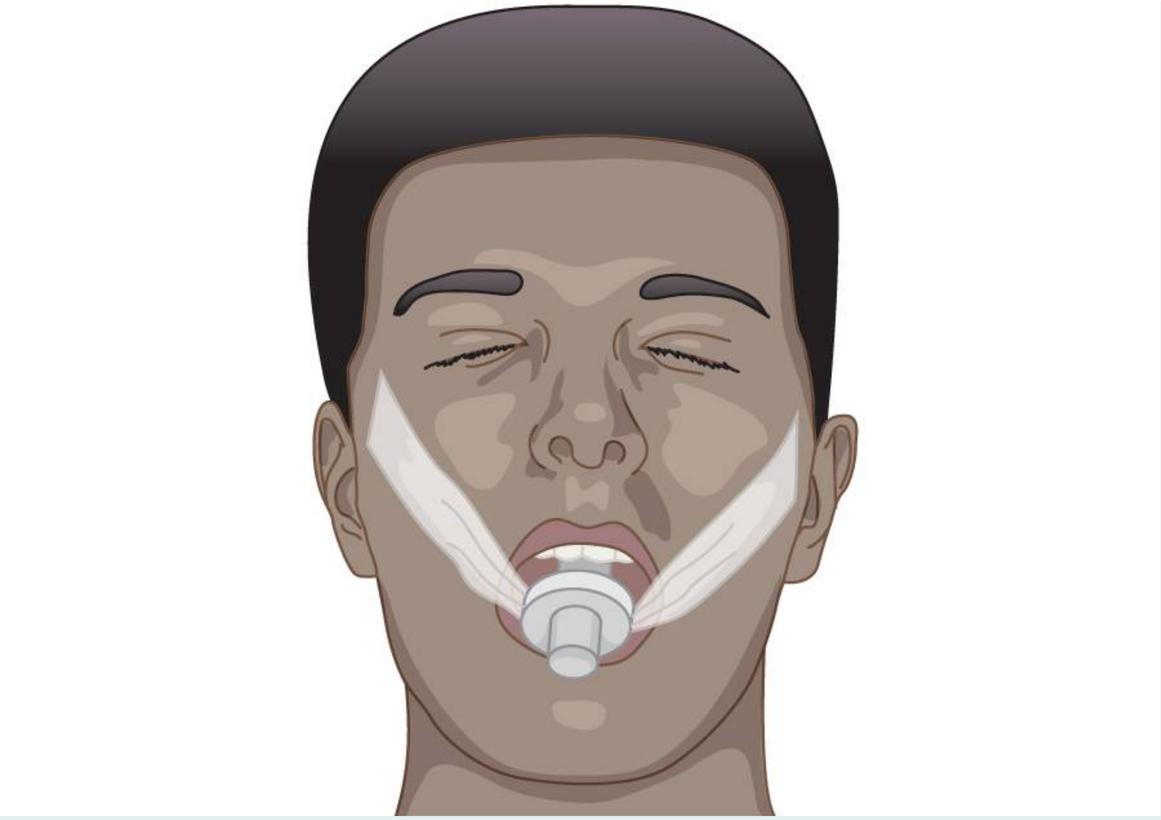
Step 3

Place the patient’s head in a sniffing position, unless contraindicated. Use the jaw-thrust maneuver if trauma is suspected.



Step 4

Introduce the leading soft tip into the patient’s mouth, directed toward the hard palate. Glide the device downward and backward along the hard palate with a continuous but gentle push until a definitive resistance is felt.



Step 5
Secure the i-gel. Attach the bag-mask device and ventilate.

© Jones & Bartlett Learning.

1. Take standard precautions (glove and face shield).
2. Preoxygenate the patient with a bag-mask device and 100% oxygen **STEP 1**.
3. Gather your equipment and choose the proper size of i-gel airway for the patient.
4. Open the i-gel package and, on a flat surface, take out the protective cradle containing the device.
5. Lubricate the back, sides, and front of the cuff with a water-soluble lubricant for ease of insertion and to minimize the risk of airway damage **STEP 2**.
6. Place the patient’s head in a sniffing position, unless contraindicated **STEP 3**. Use the jaw-thrust maneuver if trauma is

suspected.

7. Grasp the lubricated i-gel firmly along the integral bite block. Position the device so that the i-gel cuff outlet is facing toward the patient’s chin.
8. Gently press down the patient’s chin to open the mouth.
9. Introduce the leading soft tip into the patient’s mouth, directed toward the hard palate.
10. Glide the device downward and backward along the hard palate with a continuous but gentle push until a definitive resistance is felt **STEP 4**. The tip of the airway should be located in the upper esophageal opening and the cuff should be located against the laryngeal framework. The incisors should be resting on the integral bite block. If early resistance is encountered during insertion, a jaw thrust or insertion with deep rotation is recommended.
11. Tape down the i-gel from “maxilla to maxilla” **STEP 5**.

Surgical Airways

In case of a failed airway, meaning the patient cannot be oxygenated or ventilated despite maximization of the bag-mask device or advanced airways, placement of an airway by other means becomes necessary. This frequently means some type of surgical airway must be established. Before undertaking this procedure, you must have an adequate understanding of the anatomy of the anterior part of the neck.

The most prominent structure in the anterior part of the neck is the thyroid cartilage (Adam’s apple). It is more easily palpable in males than in females. Directly inferior to the thyroid cartilage is the cricoid cartilage. The cricothyroid membrane lies between these two structures. A thin membrane covered only by skin, the cricothyroid membrane is an important landmark to identify in the setting of a surgical airway.

Equipment

The equipment needed to perform a surgical airway depends on the method used. This equipment may include:

- ET tube or tracheostomy tube (various sizes)
- Scalpel
- Bougie
- Curved hemostats
- Suction equipment
- 14-gauge or larger over-the-needle catheter
- ¼-inch tape
- 10-mL syringe
- Three-way stopcock
- Two pieces of standard oxygen tubing, 4 to 5 feet (1 to 2 m) each
- Y-connector
- Oxygen cylinder (coupled with a 50-psi step-down regulator and a needle flowmeter)
- Povidone-iodine swabs
- PPE, including sterile gloves
- Sterile fenestrated drape (hole in center)
- 4 × 4–inch gauze pads
- Bag-mask device
- Guide wire (28 inches [70 cm])
- Cotton tie or commercial tracheostomy tube holder

Needle Cricothyrotomy

A surgical airway is used to provide temporary oxygenation when intubation by other means is not possible. This type of airway may be needed in the unusual situation in which the patient cannot be intubated or ventilated. Needle cricothyrotomy may be performed in any patient but is the surgical airway of choice in the emergent setting for children younger than 10 to 12 years. In these patients, anatomic differences create a higher potential for damage to the larynx and surrounding structures when a formal cricothyrotomy is performed.

In a needle cricothyrotomy, a large-bore angiocatheter (14 to 16 gauge) is placed through the cricothyroid membrane into the trachea. A transtracheal jet ventilator may be used to provide temporary oxygenation through this catheter. Exhalation is passive and requires SGA patency.

Needle cricothyrotomy does not allow optimal ventilation—only oxygenation—so hypercarbia is an expected complication. It also does not protect the airway or allow suctioning. Instead, this surgical airway is simply a temporary measure intended to oxygenate the patient until a more definitive airway can be placed.

Indications for needle cricothyrotomy include:

- Intubation is not feasible.
- Intubation does not relieve obstruction.
- A field procedure is necessary to establish a temporary airway.

Contraindications to needle cricothyrotomy include severe airway obstruction below the site of the catheter insertion.

Complications of needle cricothyrotomy are:

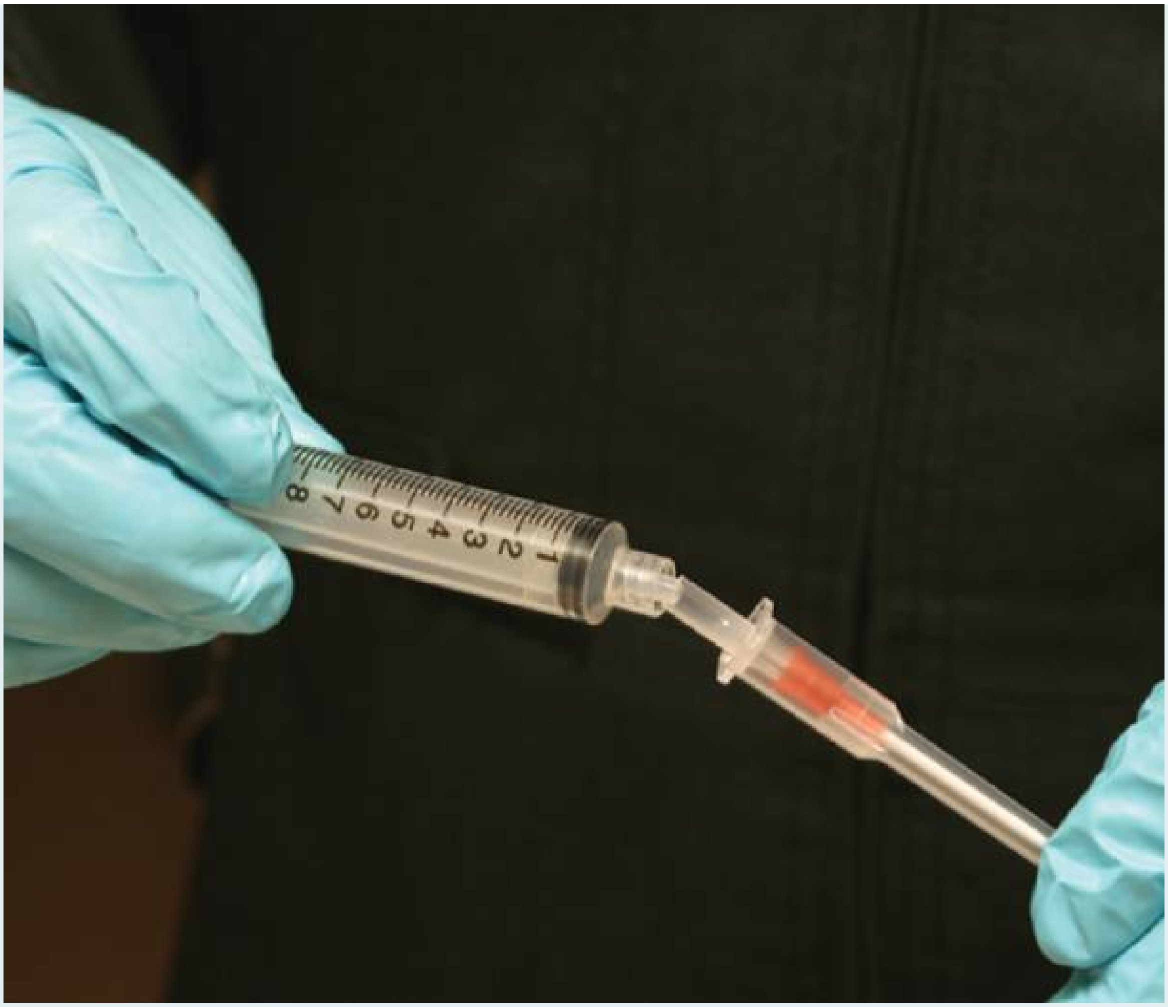
- Hemorrhage
- Subcutaneous emphysema
- Infection
- Misplacement of the cannula
- Accidental removal
- Subglottic stenosis
- Mediastinal emphysema
- Tracheal and esophageal laceration
- **Barotrauma**

Skill Drill 6-7 shows the steps for needle cricothyrotomy, which are described here:

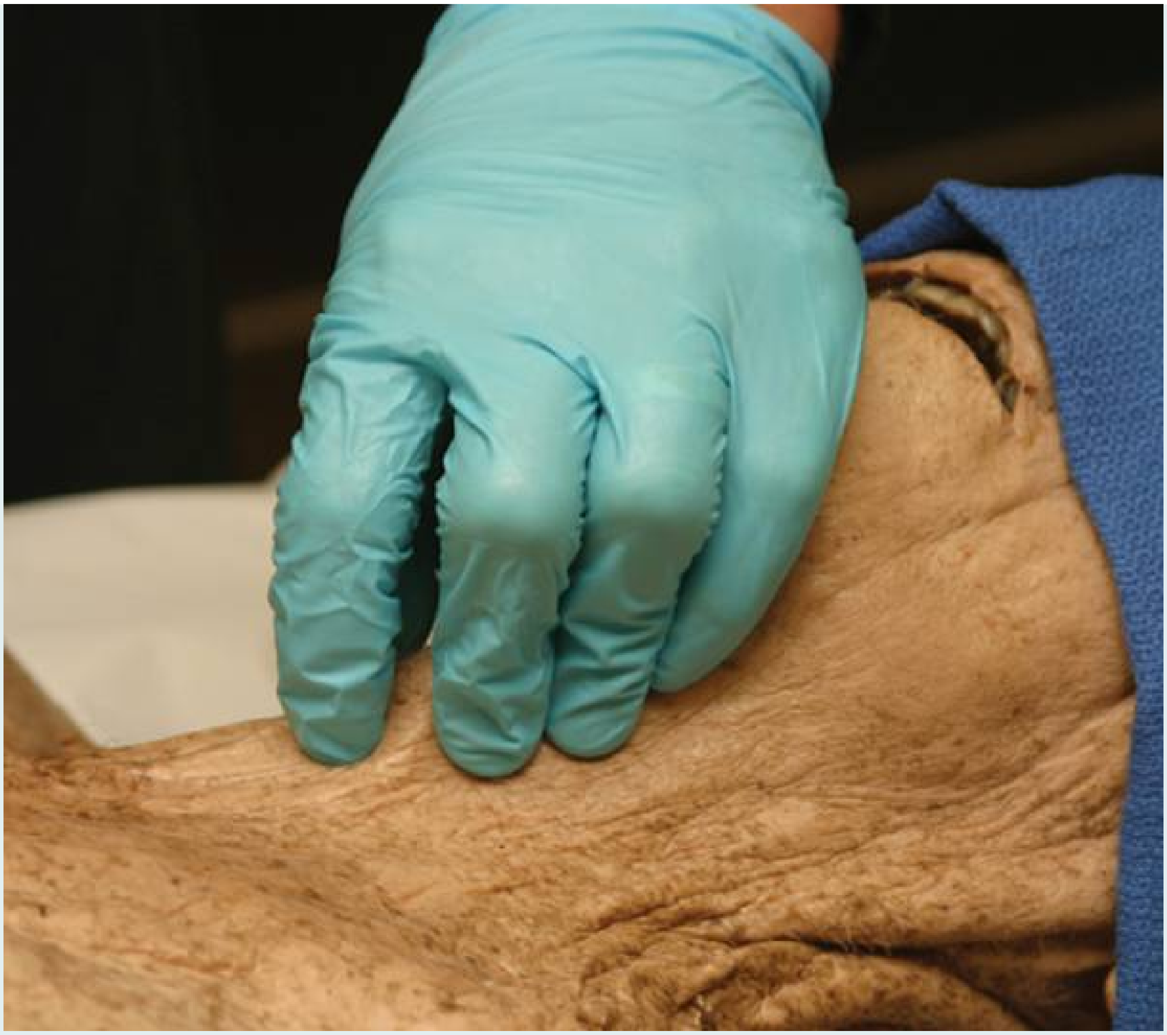
SKILL DRILL 6-7 Performing Needle Cricothyrotomy

Johns Hopkins
STAT Medivac

Step 1
Follow standard precautions (gloves and face shield).

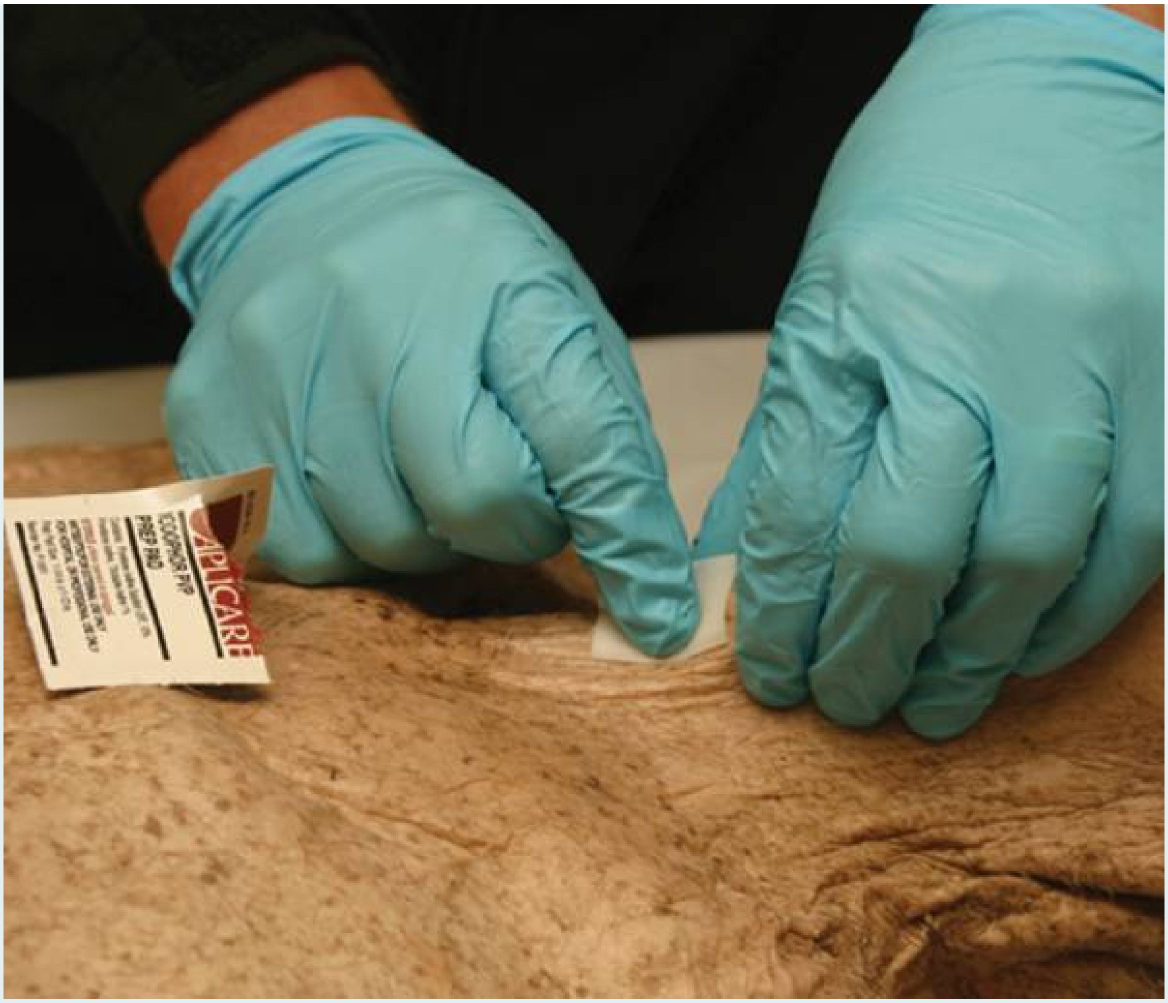


Step 2
Attach a 14- to 16-gauge IV catheter to a 10-mL syringe containing approximately 3 mL of sterile saline or water.



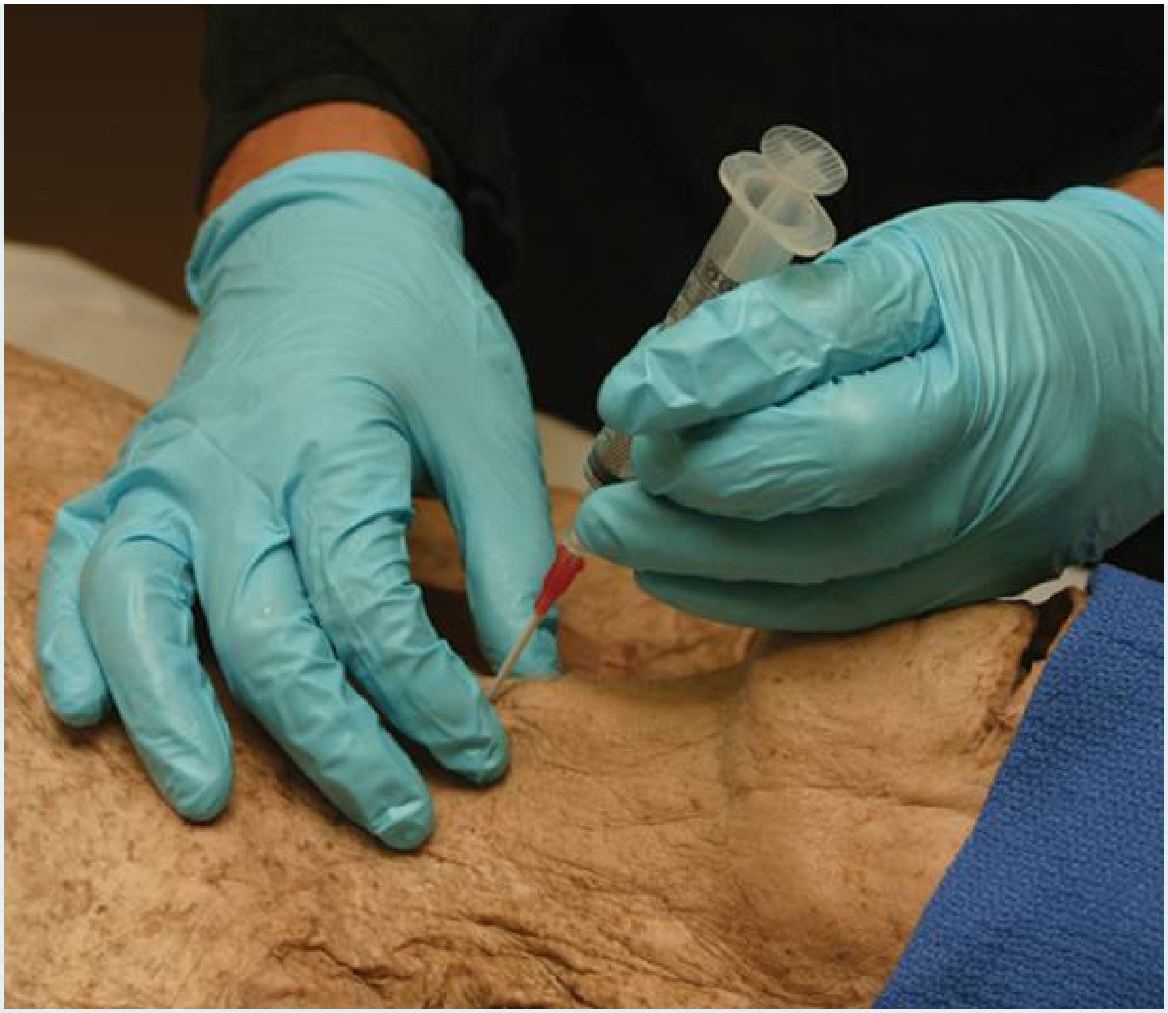
Step 3

With the patient’s head in a neutral position, palpate for and locate the thyroid cartilage, cricothyroid membrane, and suprasternal notch.

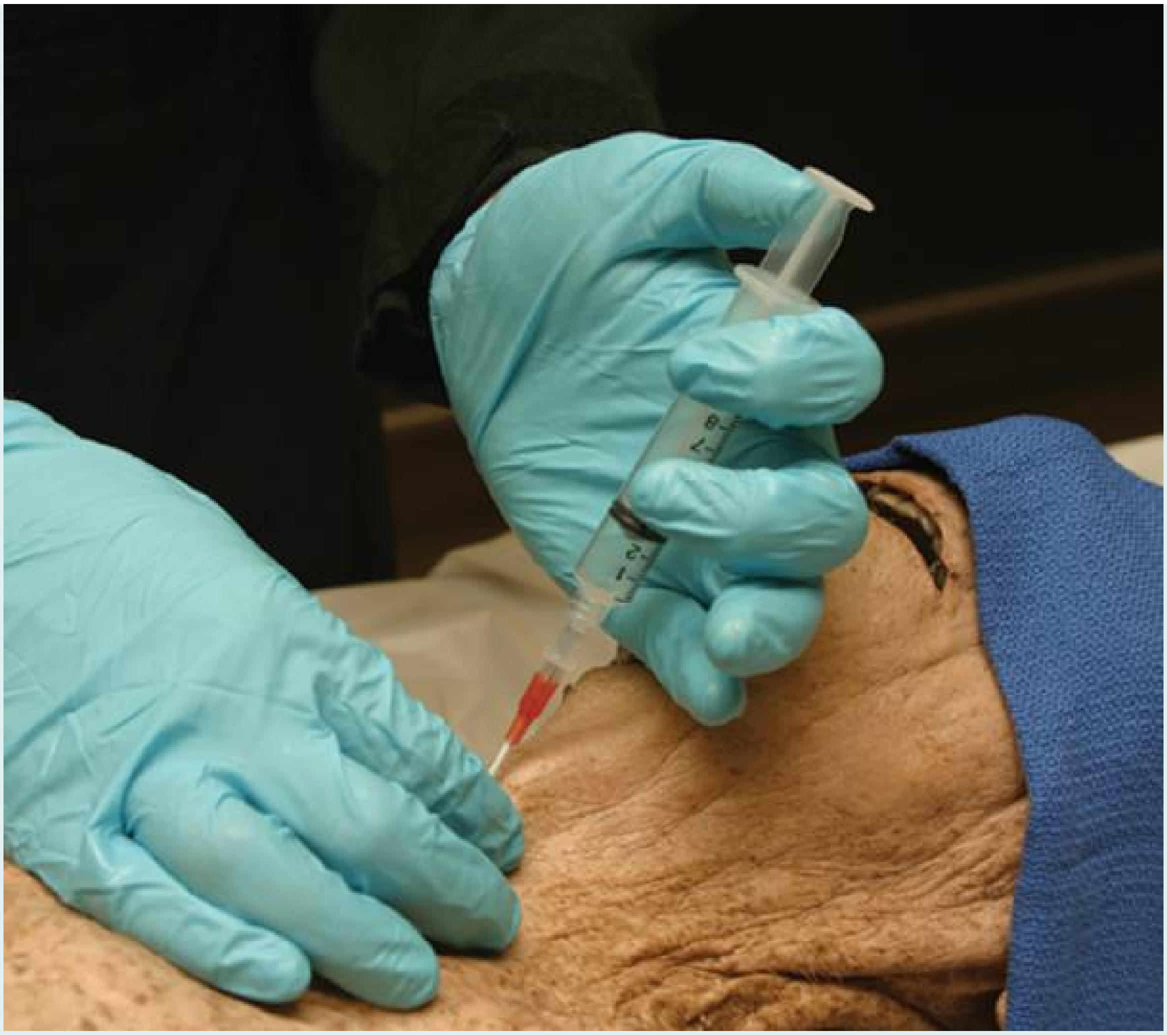


APLICARE
IODOPHOR PVP
PREP PAD

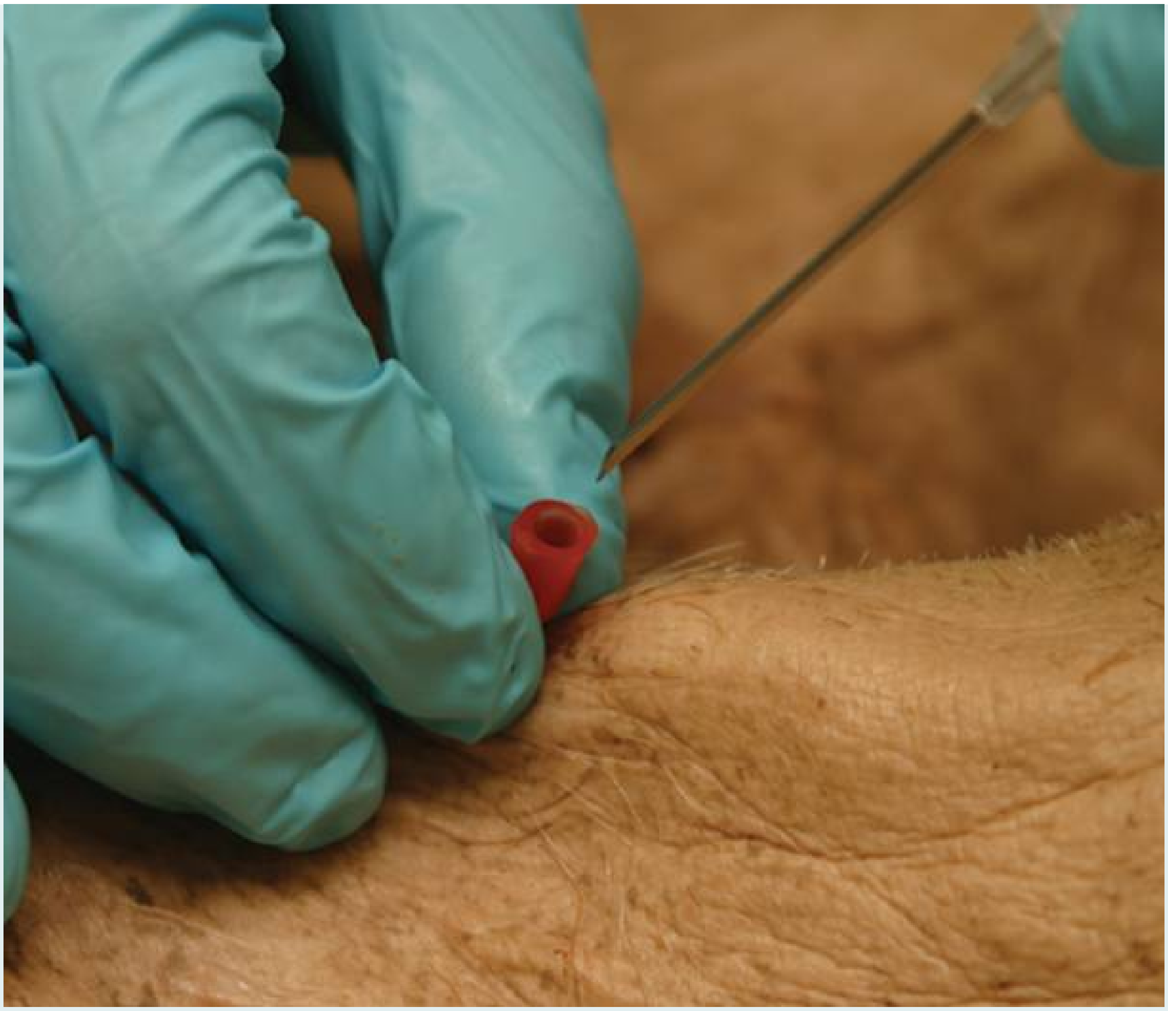
Step 4
Cleanse the area with an iodine-containing solution.



Step 5
Attach the syringe (if preferred) to the needle. Stabilize the patient’s larynx, and insert the needle into the cricothyroid membrane at a 45° angle toward the feet.

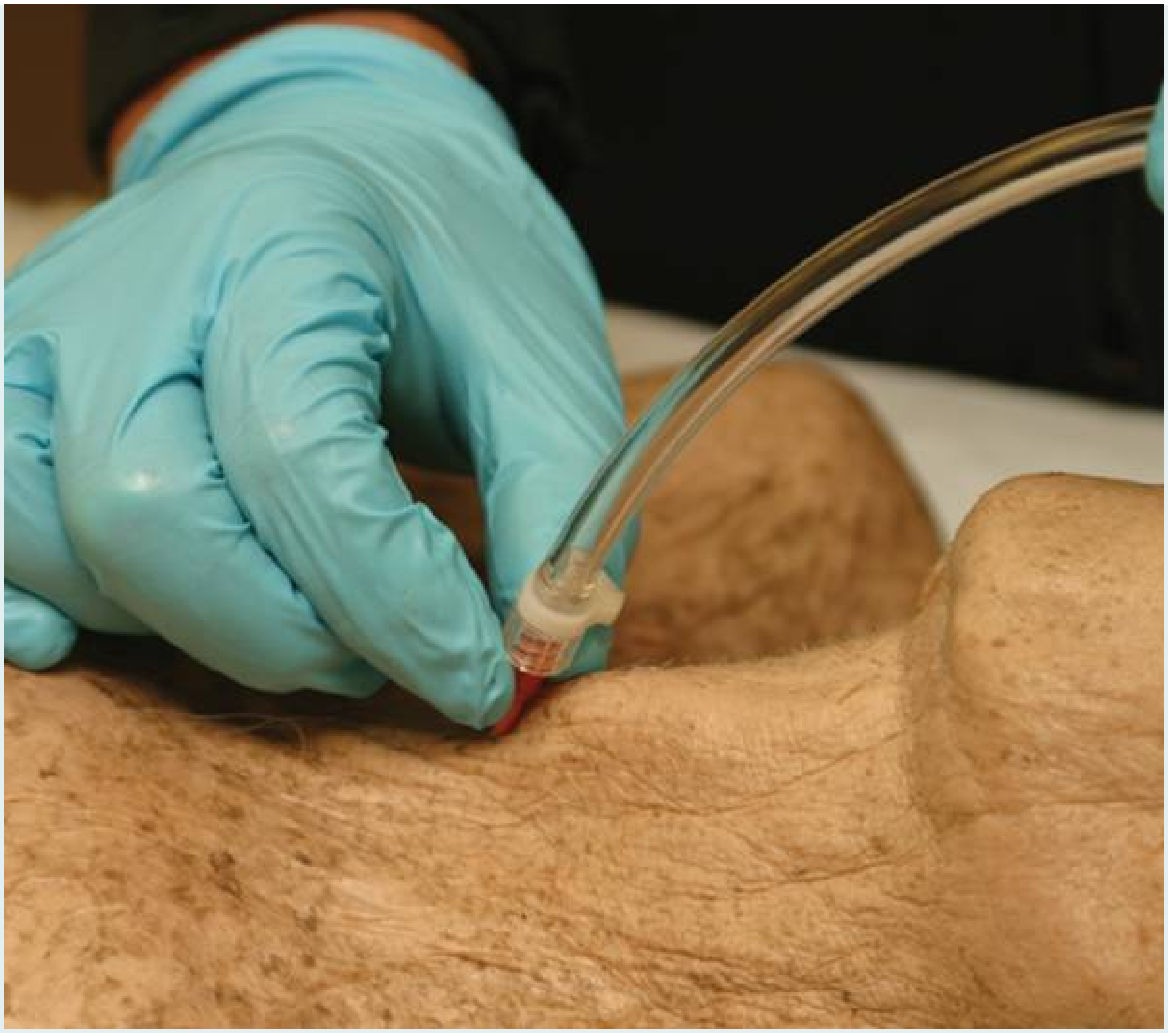


Step 6
Push the needle until it pops into the trachea. Aspirate with the syringe to determine correct catheter placement.

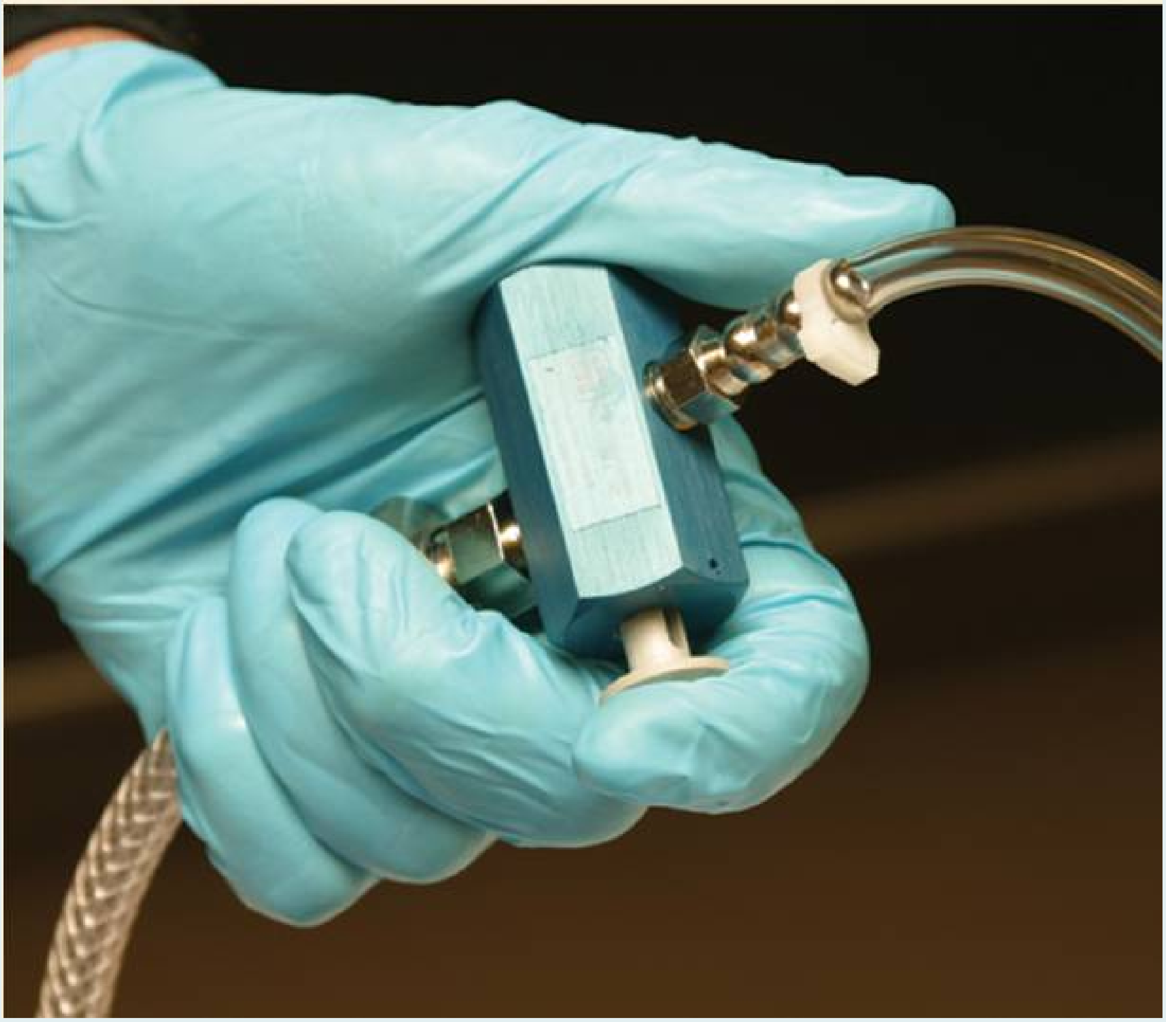


Step 7
While holding the catheter, slide the catheter off the needle until the hub of the catheter is flush with the patient’s skin.

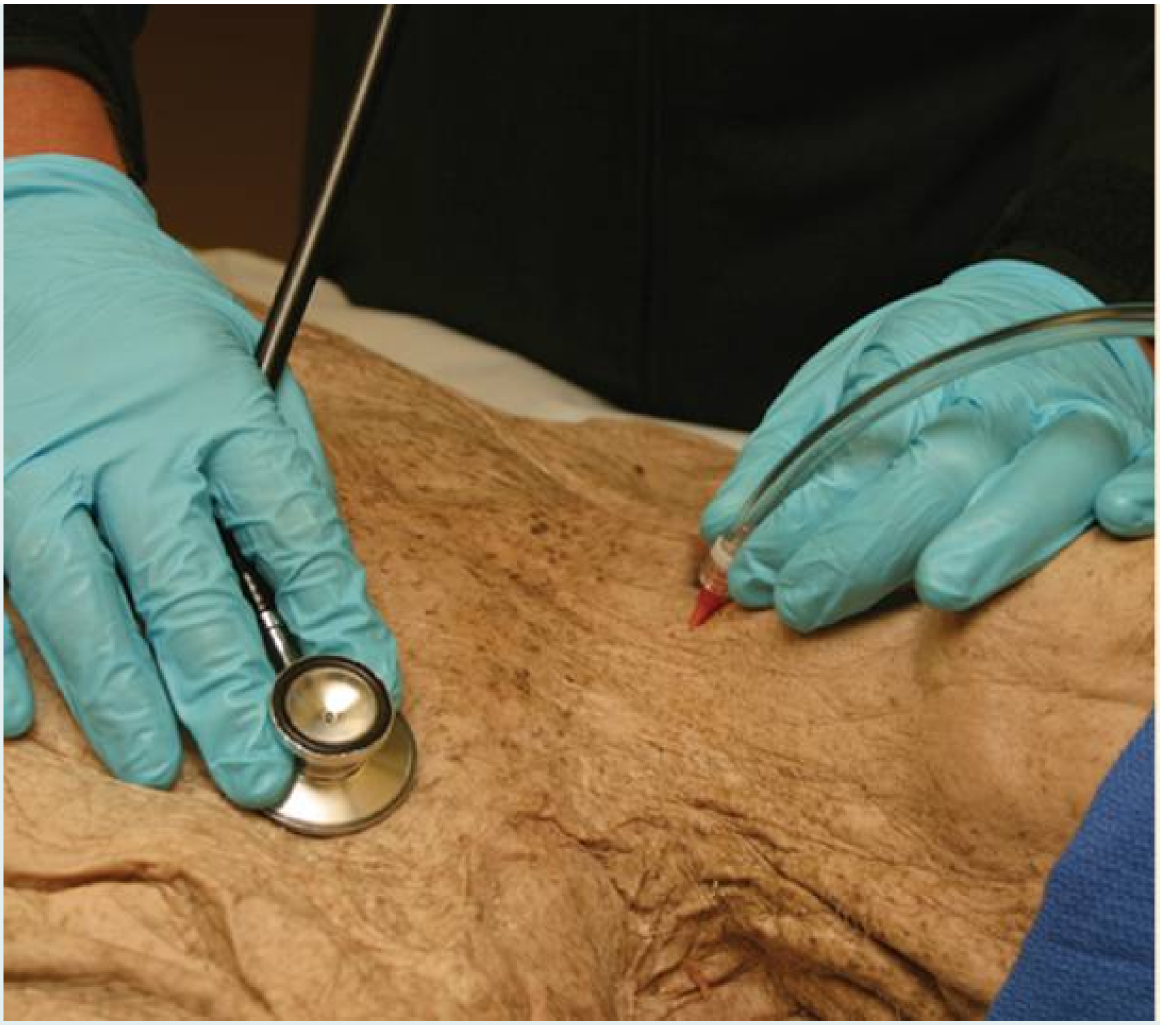
Step 8
Place the syringe and needle in a puncture-proof container.



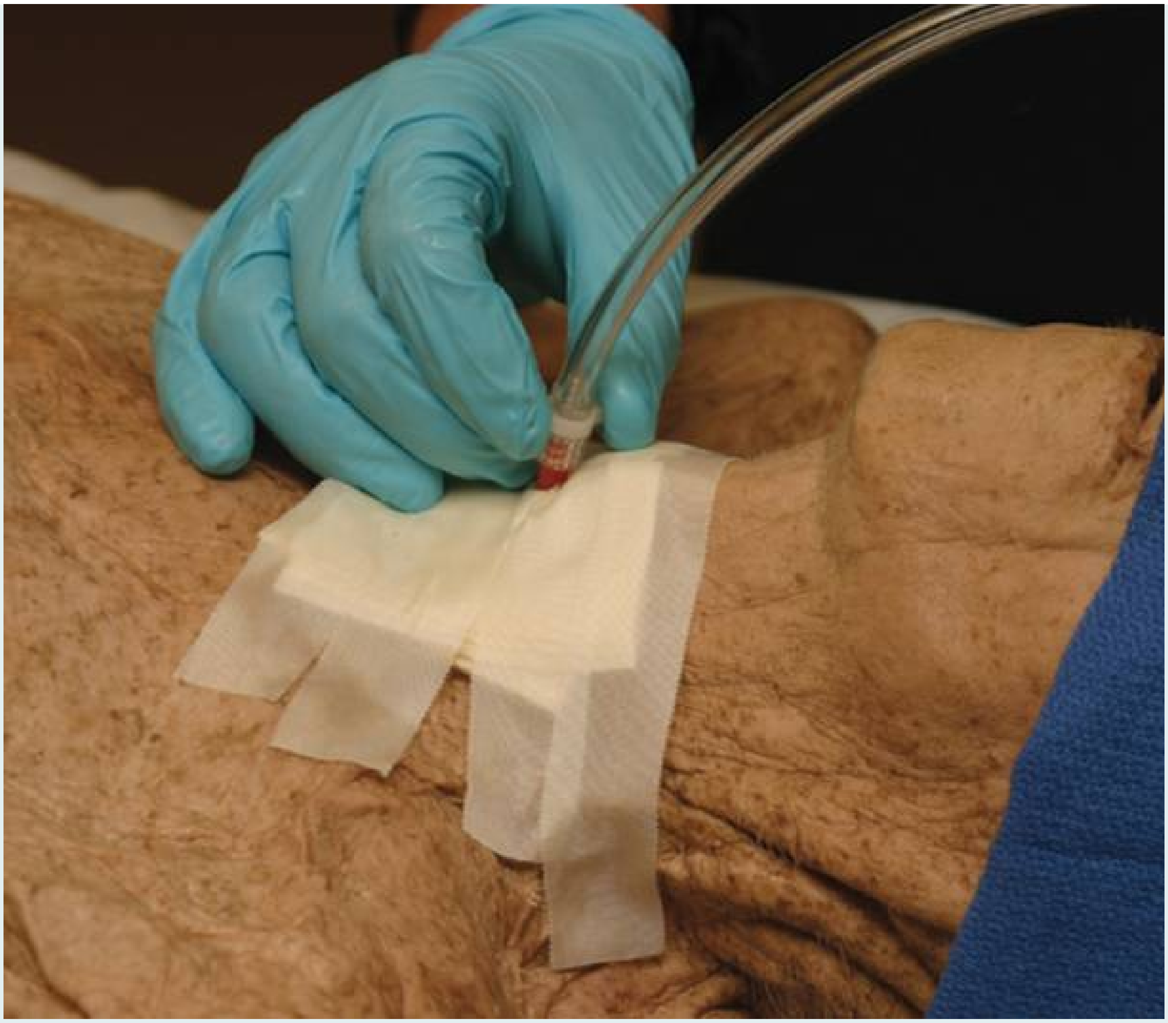
Step 9
Connect one end of the oxygen tubing to the catheter and the other end to the jet ventilator.



Step 10
Open the release valve on the jet ventilator and adjust the pressure to provide adequate chest rise.



Step 11
Auscultate the apices and bases of both lungs and over the epigastrium to confirm correct catheter placement.



Step 12
Secure the catheter with a 4 × 4–inch gauze pad and tape. Continue ventilations while frequently reassessing for adequate ventilations and any potential complications.

All images © Jones & Bartlett Learning.

1. Follow standard precautions (gloves and face shield) **STEP 1**.
2. Attach a 14- to 16-gauge IV catheter to a 10-mL syringe containing approximately 3 mL of sterile saline or water **STEP 2**.
3. With the patient's head in a neutral position, palpate for and locate the thyroid cartilage, cricothyroid membrane, and suprasternal notch **STEP 3**.
4. Cleanse the area with an iodine-containing solution **STEP 4**.

5. Attach the syringe (if preferred) to the needle.
6. Stabilize the patient’s larynx, and insert the needle into the cricothyroid membrane at a 45° angle toward the feet **STEP 5**.
7. Push the needle until it “pops” into the trachea. Aspirate with the syringe to determine correct catheter placement **STEP 6**.
8. Confirm correct tracheal placement by noting movement of air.
9. Advance the catheter over the needle until the hub rests against the skin **STEP 7**.
10. Place the syringe and needle in a puncture-proof container **STEP 8**.
11. Connect one end of the oxygen tubing to the catheter and the other end to the jet ventilator **STEP 9**.
12. Open the release valve on the jet ventilator, and adjust the pressure to provide adequate chest rise **STEP 10**. If a jet ventilator is unavailable, temporary ventilation can be provided with a bag-mask device by attaching a 15-mm bag-mask device adapter from a 3-0 ET tube to the catheter, or by attaching a 3-mL syringe with the plunger removed and an adapter from a 7-0 tube.
13. Auscultate the apices and bases of both lungs and over the epigastrium to confirm correct catheter placement **STEP 11**.
14. Secure the catheter with a 4 × 4–inch gauze pad and tape. Continue ventilations while frequently reassessing for adequate ventilations and any potential complications **STEP 12**.

Surgical Cricothyrotomy

Many techniques for performing a surgical cricothyrotomy have been developed, ranging from a fully open technique using only a scalpel, bougie, and 6.0 ET tube (scalpel–finger–bougie technique) to modified techniques using various premanufactured kits. The advantages of an open cricothyrotomy are the greater speed of insertion compared with formal tracheostomy and the improved oxygenation and ventilation compared with needle cricothyrotomy.

Indications for surgical cricothyrotomy include:

- Intubation is not feasible, in that the patient is unable to be ventilated and/or oxygenated.
- Intubation does not relieve the airway obstruction.
- A field procedure is necessary to establish a temporary airway.

Contraindications to surgical cricothyrotomy are as follows:

- Inability to identify anatomic landmarks, usually secondary to trauma.
- Pediatric patients younger than 10 years. Children younger than this age have a smaller cricothyroid membrane that generally cannot accept a larger-bore tube, making needle cricothyrotomy the preferred procedure in such patients.

Complications to surgical cricothyrotomy include the following conditions:

- Hemorrhage
- Infection
- Misplacement of the cannula/tube
- Accidental removal
- Subglottic stenosis
- Mediastinal emphysema
- Tracheal and esophageal laceration

Open cricothyrotomy involves incising the patient’s skin and cricothyroid membrane with a scalpel and placing an ET tube or tracheostomy tube. Several commercial kits containing the equipment needed to perform a modified cricothyrotomy are available, many of which rely on a variant of the **Seldinger technique** to place the airway **FIGURE 6-43**. The Seldinger technique uses a needle and guide wire/guide catheter or tube placement in blood vessels or other hollow organs. Other devices for performing cricothyrotomy, such as the Nu-Trake and Pertrach, are commercially manufactured airway placement devices that may be used in the prehospital environment **FIGURE 6-44**. These devices do not use the Seldinger technique, but rather rely on a device that functions as both an introducer and an airway.

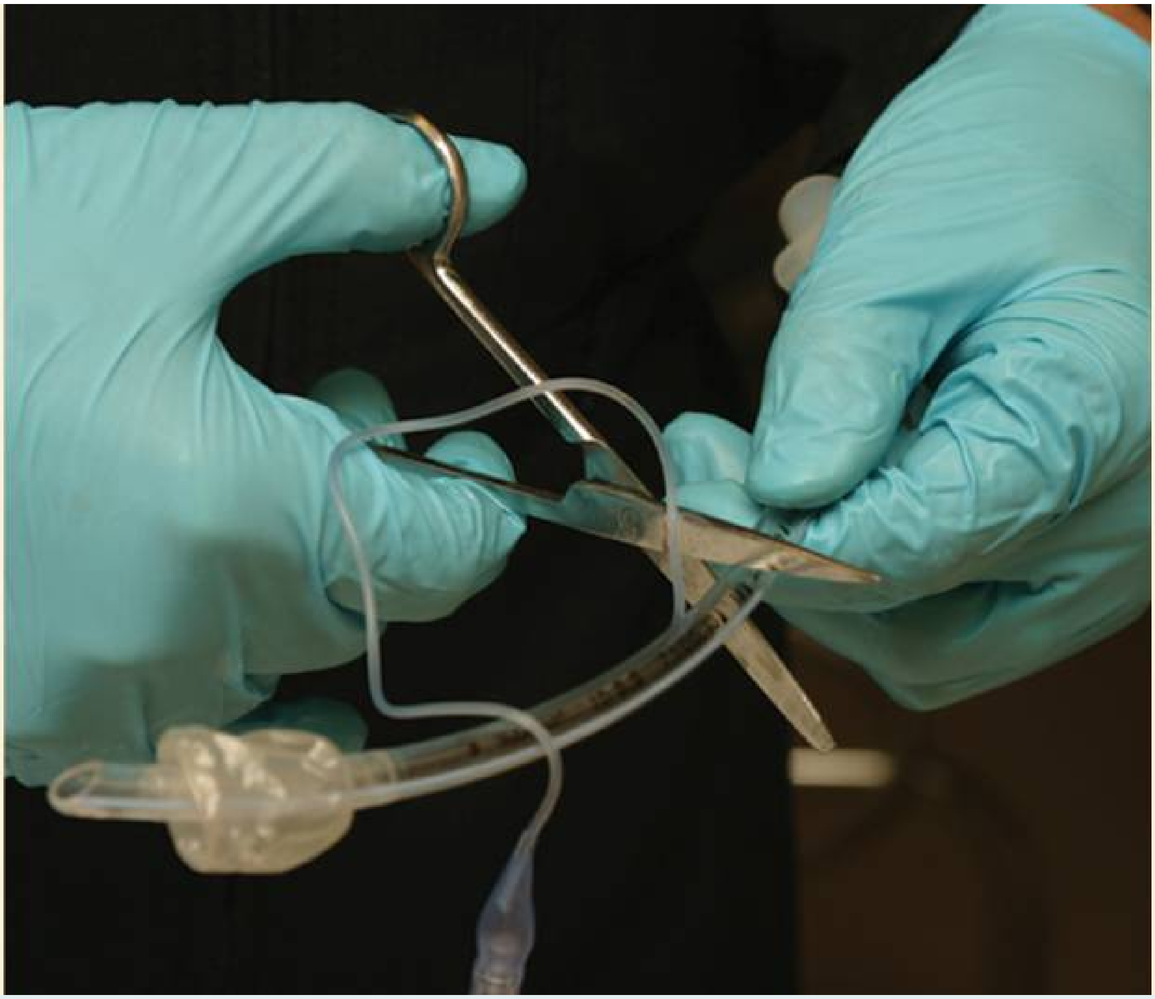
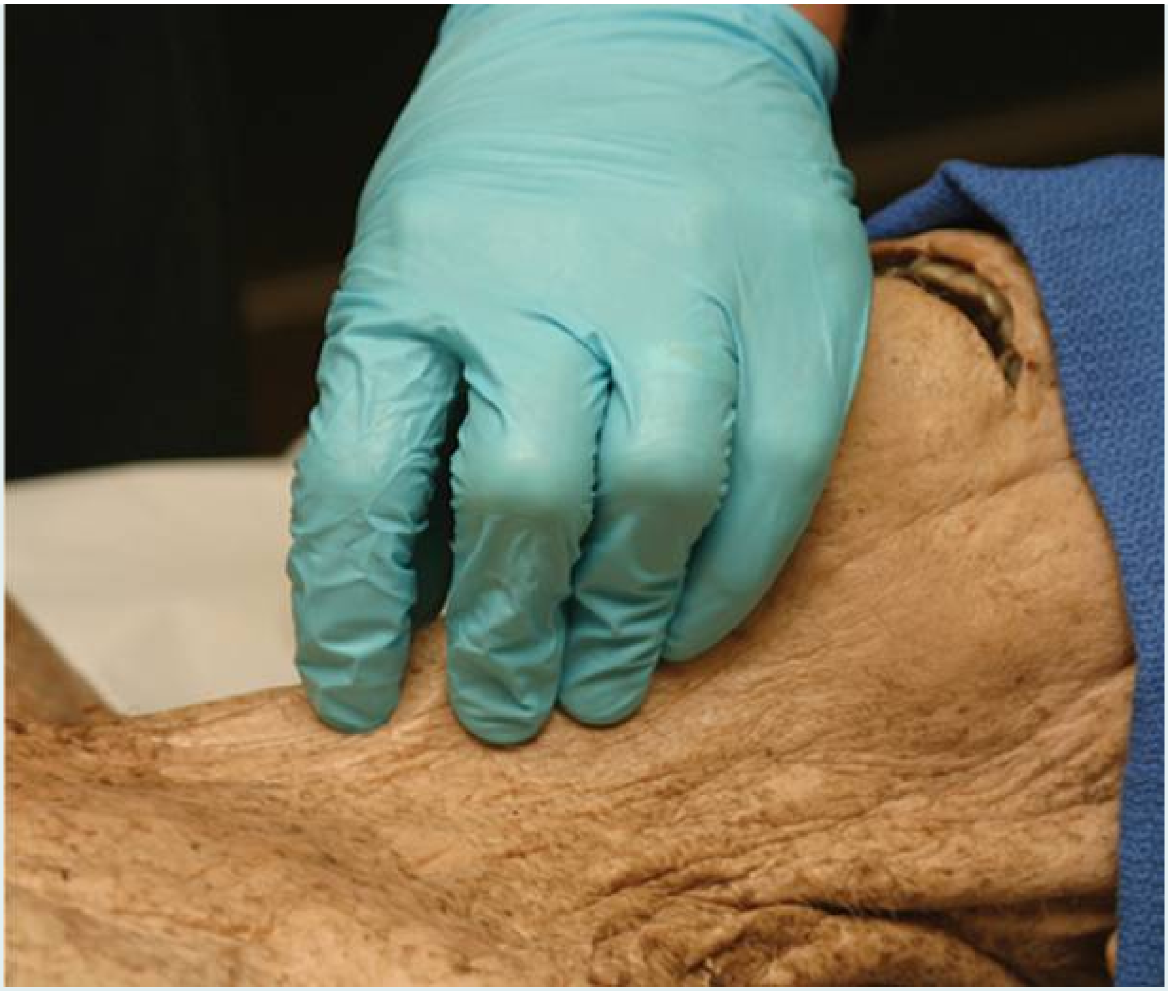
Skill Drill 6-8 shows the steps for one surgical cricothyrotomy technique, which are described here:

SKILL DRILL 6-8 Performing Surgical Cricothyrotomy

Step 1
Follow standard precautions, including use of gloves and a face shield.

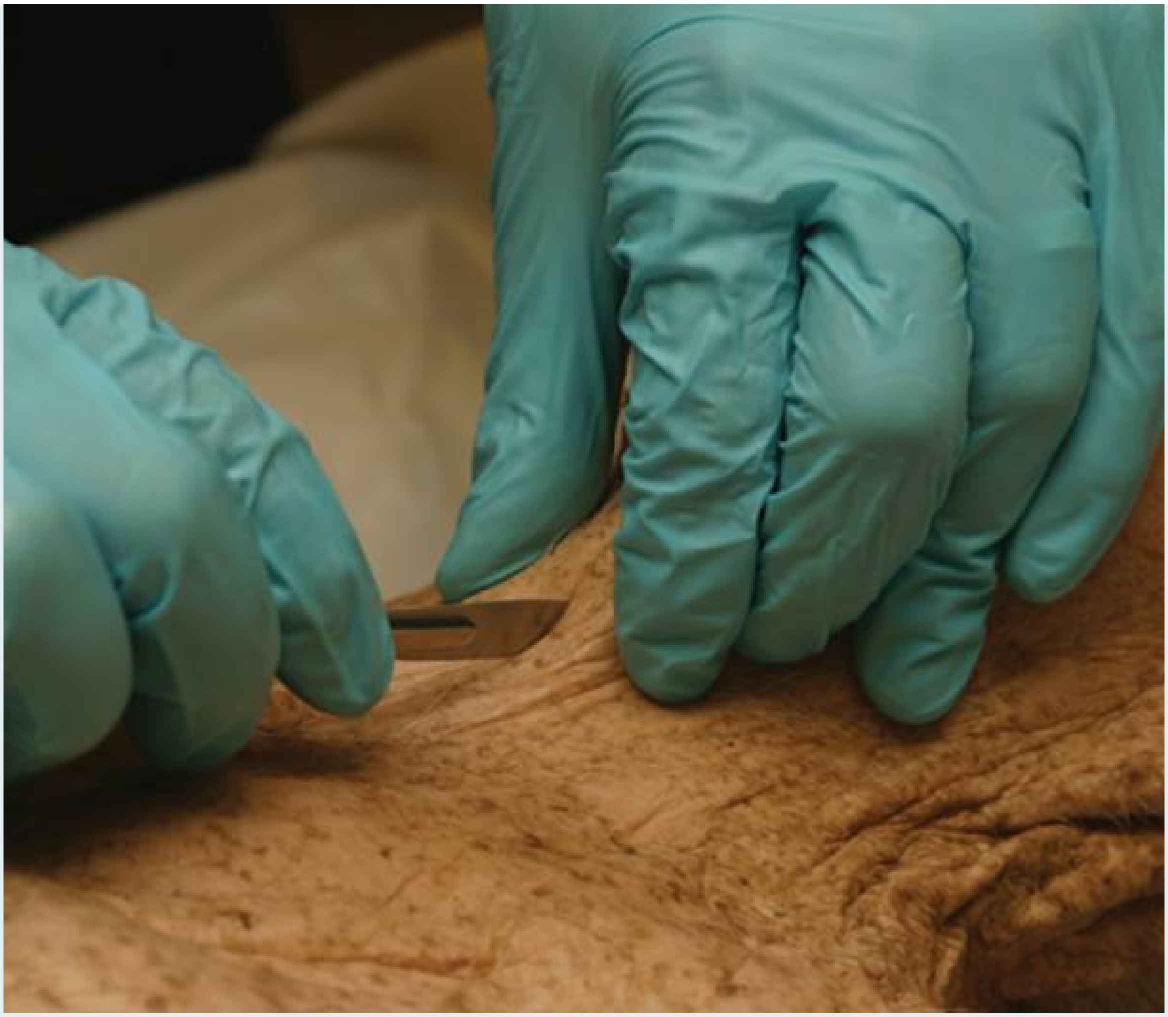


Step 2
Check, assemble, and prepare the equipment.

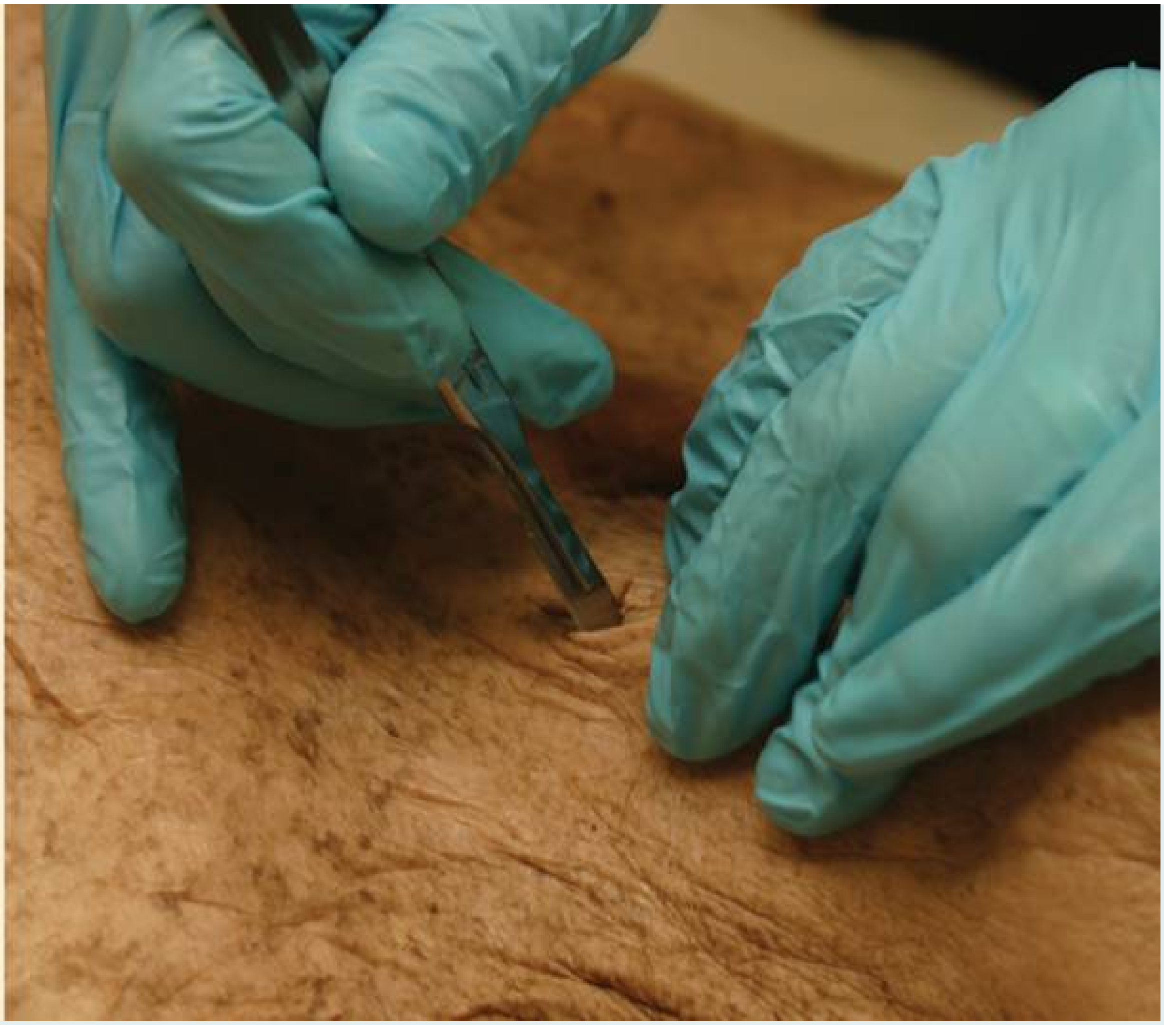


Step 3
Approach the patient from the left side of the neck. With the patient’s head in a neutral position, palpate for and locate the cricothyroid membrane.

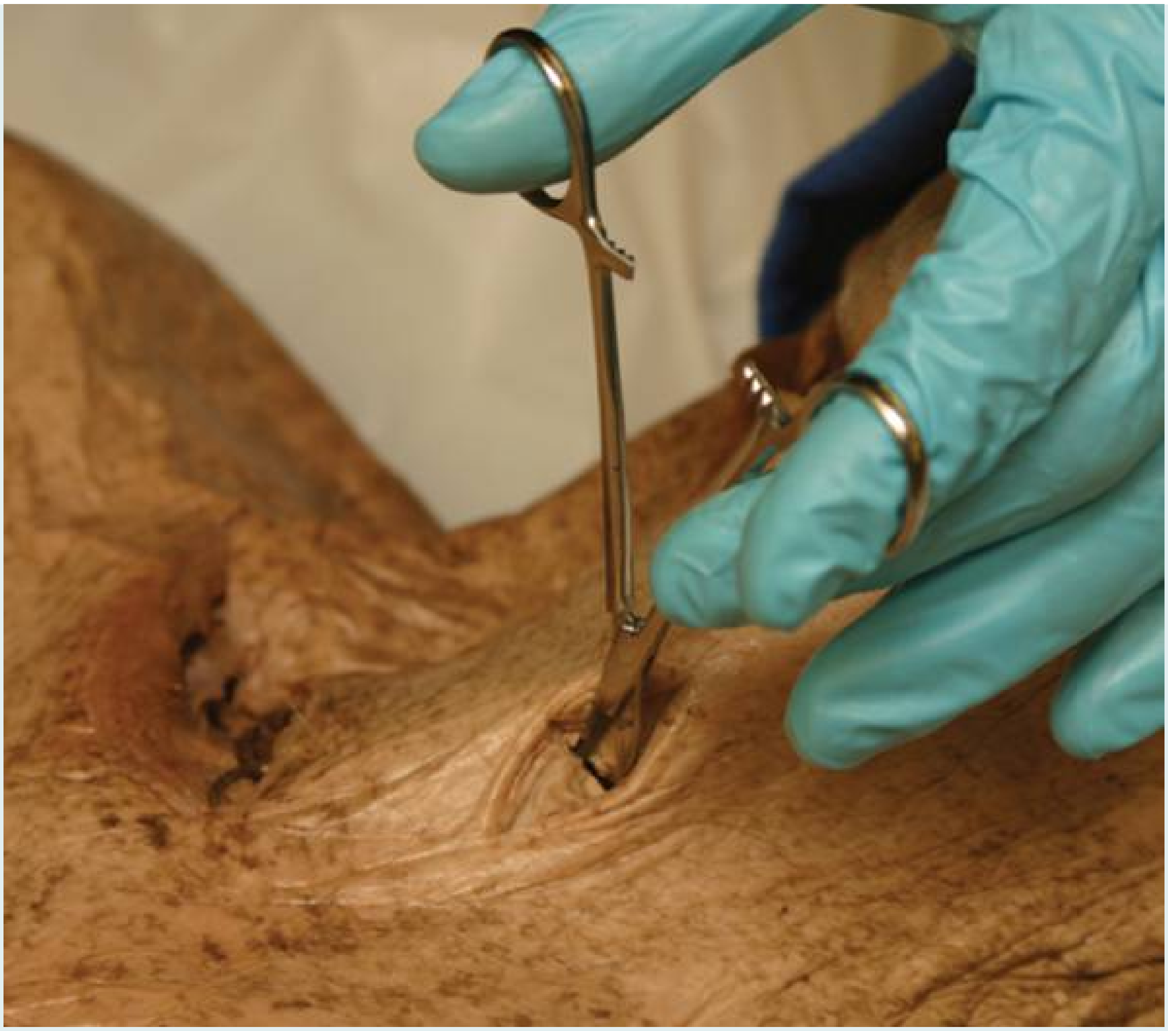
Step 4
Cleanse the anterior part of the neck from the laryngeal prominence to just below the cricoid ring and position a fenestrated drape.



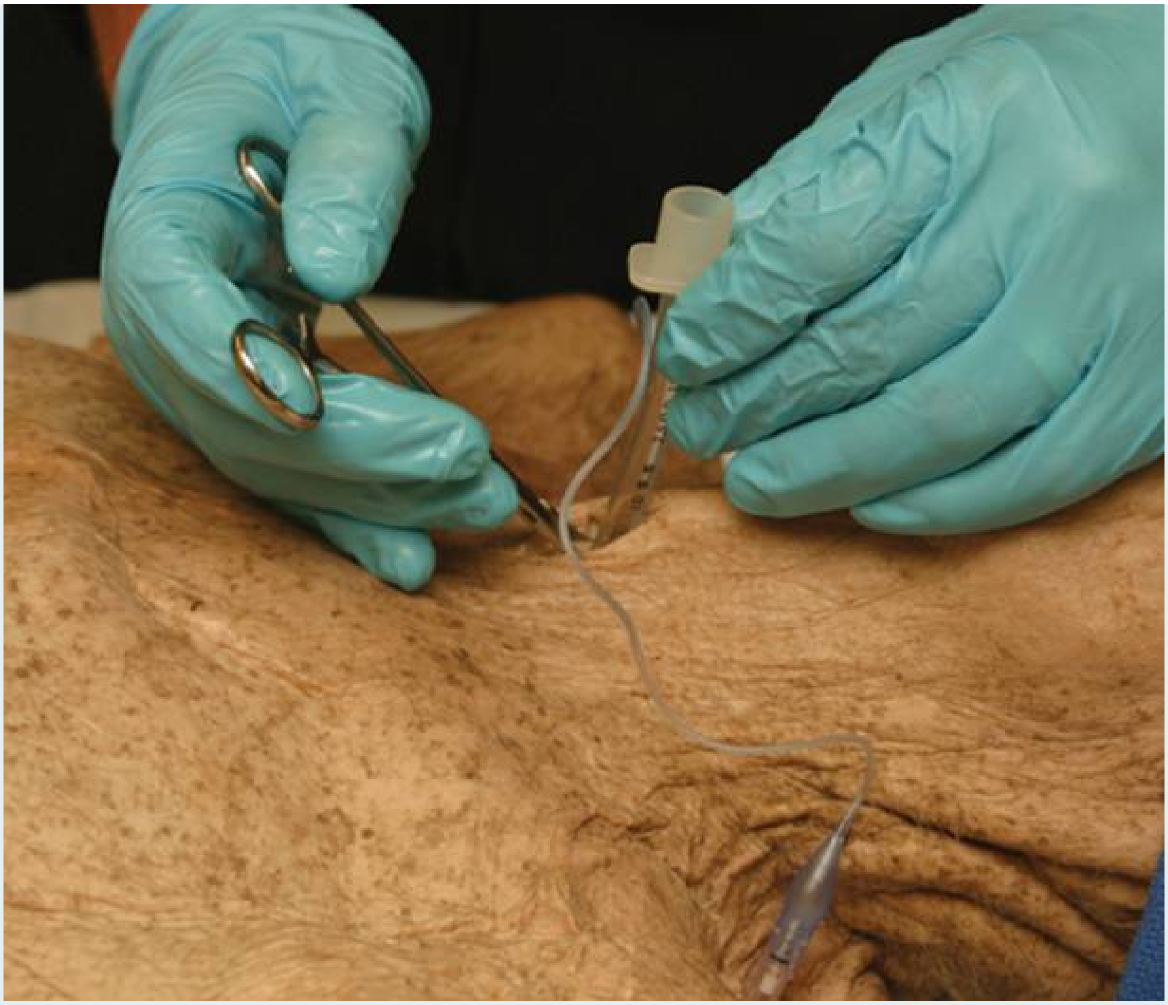
Step 5
With the scalpel in your dominant hand, make a 1- to 2-cm vertical skin incision over the cricothyroid membrane.



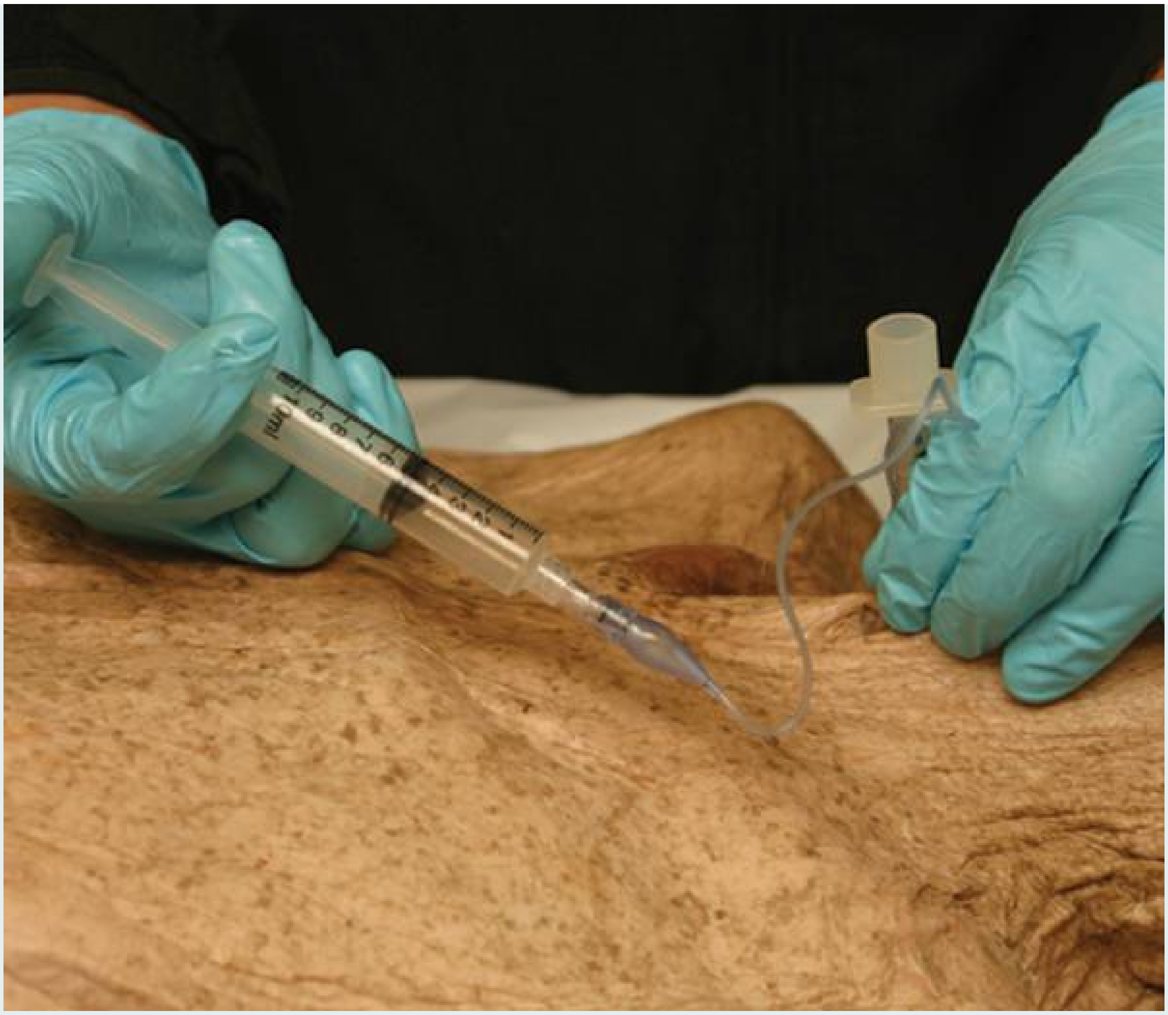
Step 6
Puncture the cricothyroid membrane and make a horizontal incision 1 cm in each direction from the midline (a shallow incision, so that the posterior tracheal wall is not injured).



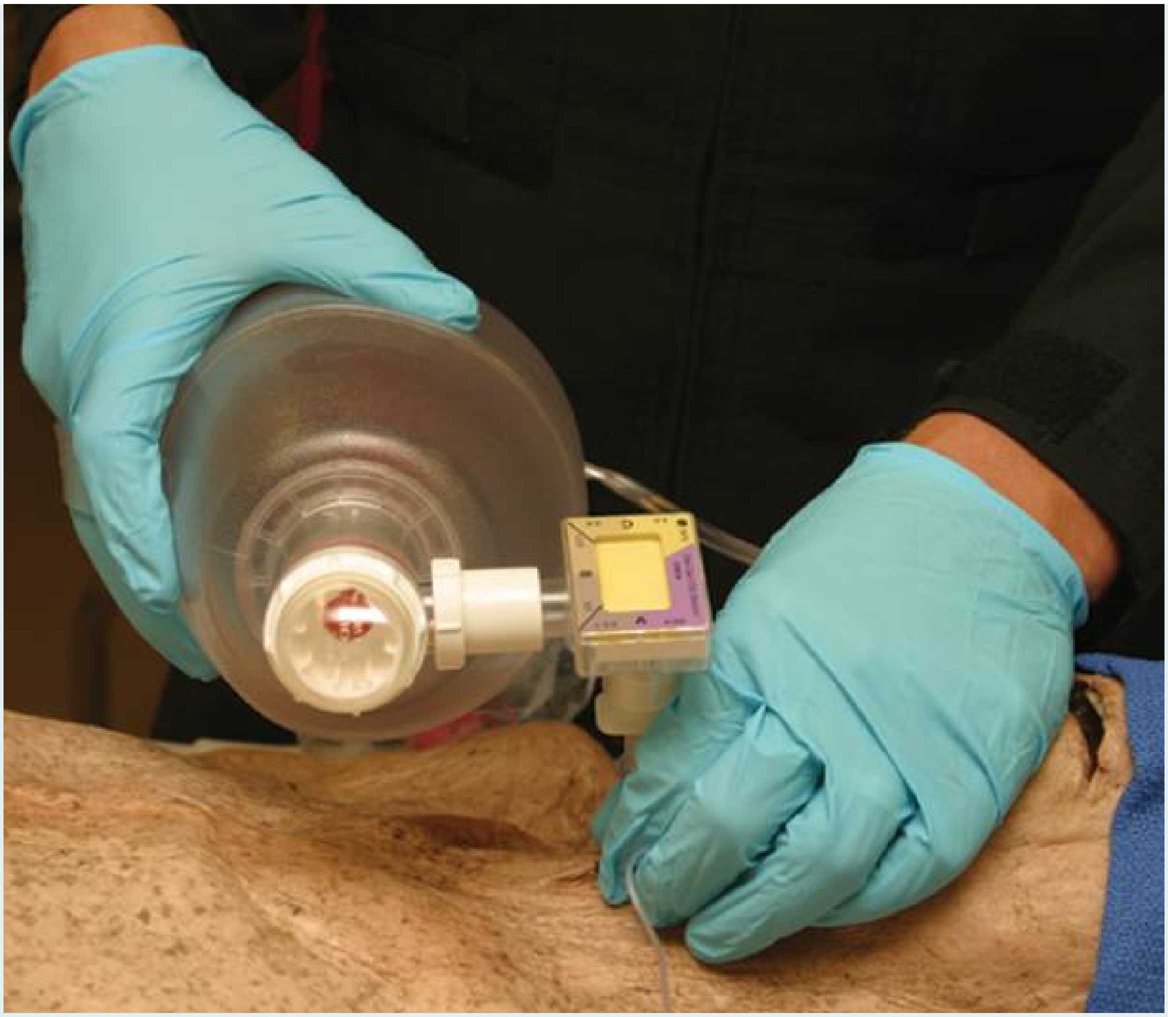
Step 7
Place a curved hemostat (pictured) or a tracheal hook through the incision before removing the scalpel. Open the hemostats, ensuring that the tips are well within the trachea.



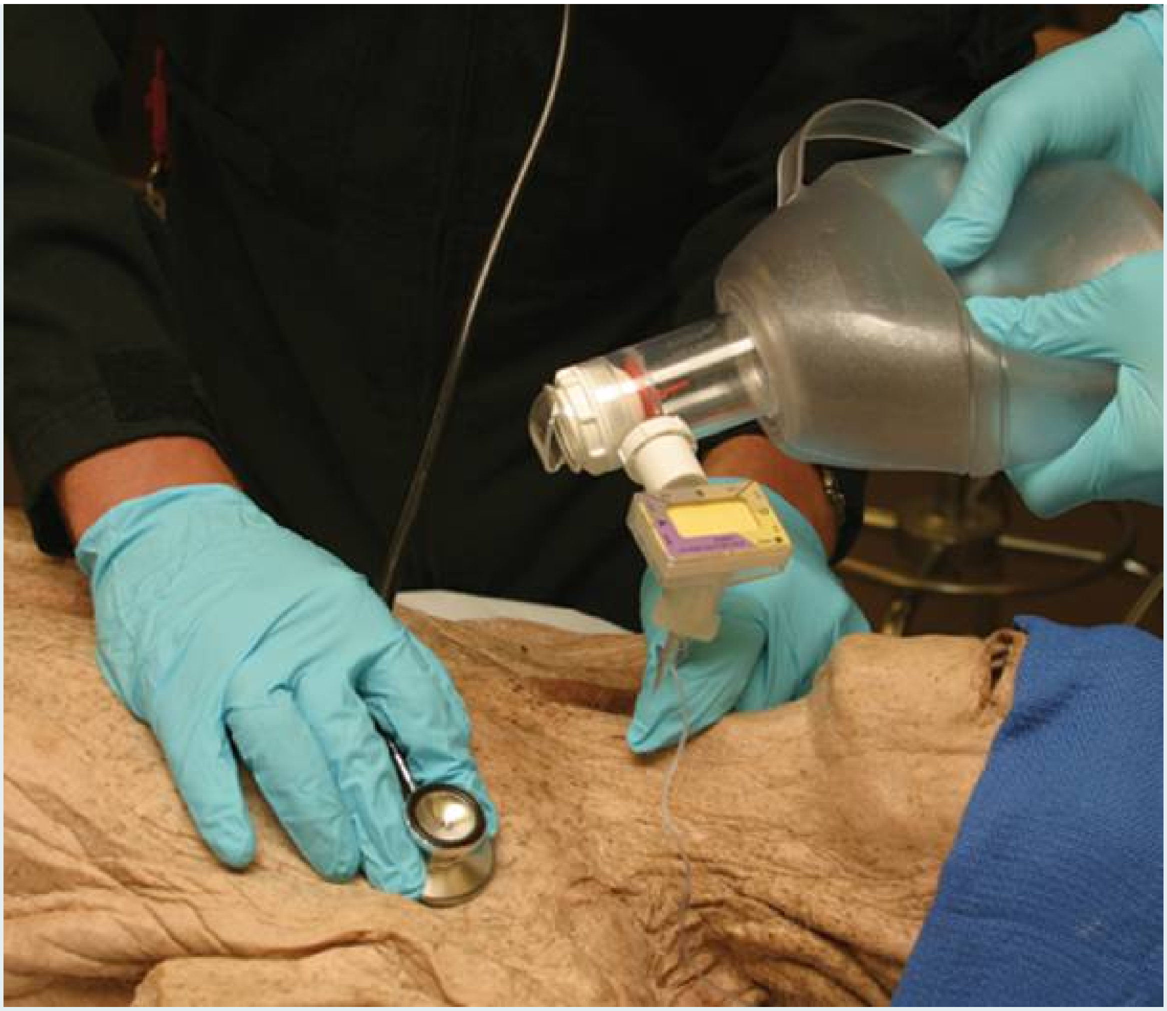
Step 8
With your free hand, insert the ET tube between the tips of the open hemostats, advancing the balloon about 1.0 to 1.5 cm below the lower margin of the incision.



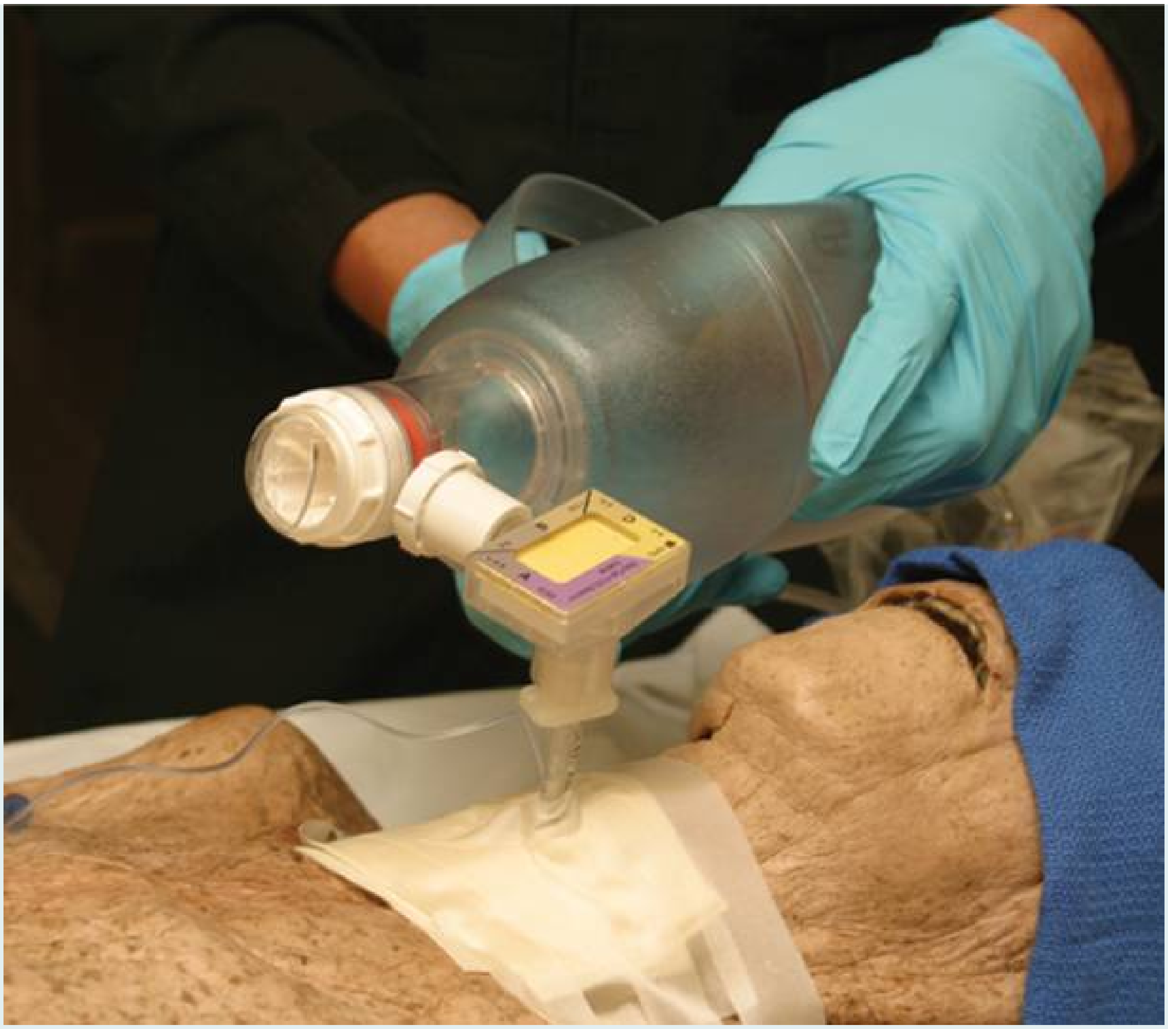
Step 9
Inflate the cuff on the tube with 8 to 10 mL of air and remove the syringe.



Step 10
Attach an ETCO$_2$ detector between the tube and the bag-mask device.



Step 11
Ventilate the patient and auscultate the chest bilaterally and over the epigastrium.



Step 12
Secure the tube to the neck and reconfirm correct tube placement. Continue to ventilate the patient.

All images © Jones & Bartlett Learning.

1. Follow standard precautions, including use of gloves and a face shield **STEP 1**.
2. Place the patient supine. Ventilate the patient.
3. Check, assemble, and prepare the equipment **STEP 2**.
4. Approach the patient from the left side of the neck. With the patient’s head in a neutral position, palpate for and locate the cricothyroid membrane **STEP 3**.

5. Cleanse the anterior part of the neck from the laryngeal prominence to just below the cricoid ring and position a fenestrated drape **STEP 4**.
6. Palpate the cricothyroid membrane.
7. Stabilize the thyroid cartilage with your nondominant hand.
8. With the scalpel in your dominant hand, make a 1- to 2-cm vertical skin incision over the cricothyroid membrane **STEP 5**.
9. Puncture the cricothyroid membrane and make a horizontal incision 1 cm in each direction from the midline (a shallow incision, so that the posterior tracheal wall is not injured) **STEP 6**.
10. Place a curved hemostat through the incision *before* removing the scalpel. Open the hemostats, ensuring that the tips are well within the trachea **STEP 7**.
11. Remove the scalpel.
12. With your free hand, insert the ET tube between the tips of the open hemostats, advancing the balloon about 1.0 to 1.5 cm below the lower margin of the incision **STEP 8**.
13. Remove the hemostats.
14. Inflate the cuff on the tube with 8 to 10 mL of air and remove the syringe **STEP 9**.
15. Attach an $ETCO_2$ detector between the tube and the bag-mask device **STEP 10**.
16. Ventilate the patient and verify correct tube position by auscultating the chest bilaterally and over the epigastrium **STEP 11**.
17. Secure the tube to the neck and reconfirm correct tube placement. Continue to ventilate the patient **STEP 12**.

An alternative technique, commonly referred to as the scalpel–finger–bougie method, replaces the use of hemostats with the insertion of a fingertip into the incision to palpate the tracheal lumen. A bougie is then passed alongside the finger, and (generally) a 6.0 ET tube is subsequently passed over the bougie until the balloon is no longer visible, then inflated.

Rapid Sequence Intubation

Rapid sequence intubation (RSI) involves the rapid administration of sedative induction and neuromuscular blocking agents to produce a state of unconsciousness and paralysis in the patient and allow for tracheal intubation. RSI was originally developed to facilitate airway management in obstetric patients requiring intubation with a presumed full stomach.

The 7 Ps of RSI

1. Prepare
2. Preoxygenation
3. Preintubation optimization
4. Paralysis with induction
5. Positioning
6. Placement with proof
7. Postintubation management

The indications for performing RSI include many of the same indications for ET intubation, with one notable exception: Patients in cardiac arrest should not undergo medication-facilitated intubation. Remember, sedatives may eliminate the patient's ability to protect their airway and cause hemodynamic effects if the patient is catecholamine dependent. Paralytic agents will cause respiratory arrest, and the CCTP must be prepared to ventilate a patient who begins to desaturate. When these medications are administered, the CCTP *must* be able to successfully establish an airway on the first pass without inducing hypoxia or hypotension in the patient. RSI also assumes that patients have eaten prior to needing emergent intubation. When medications are administered during RSI to sedate and paralyze patients, the risks of regurgitation and aspiration are minimized but not eliminated.

The usual contraindications and complications for standard intubation also apply to RSI. Airway assessment and planning are essential. The most crucial contraindication is predicted inability to intubate. In this case, RSI should not be attempted; other airway management strategies, such as using an SGA or performing a cricothyrotomy, should be considered. The most devastating complication of RSI is not being able to oxygenate or ventilate the patient. This scenario will almost invariably result in a catastrophic patient outcome. Thus, the use of RSI requires careful assessment, planning, and preparation.

RSI consists of a series of steps to facilitate ET intubation following preoxygenation and patient optimization. It begins with preparation. All equipment necessary for intubation, rescue ventilation, and placement of a surgical airway must be available, checked, and working prior to use. At least one working intravenous (IV) or intraosseous (IO) access must be available—and preferably two, because one IV/IO line may infiltrate, fall out, or be pulled out inadvertently—for the administration of the appropriate medications.

The next step is preoxygenation. All patients undergoing RSI should be given oxygen prior to the CCTP beginning the procedure. In the patient who is breathing spontaneously with adequate tidal volumes, applying high-flow oxygen via a nonrebreathing mask *and* a nasal cannula running at the maximum flow rate is sufficient. The nasal cannula remains in place during laryngoscopy, allowing for passive apneic oxygenation and subsequent oxygen diffusion. (This process is now called apneic oxygenation, but has been described in the past as mass flow ventilation, diffusion respiration, or apneic diffusion oxygenation.) Once spontaneous breathing ceases, the nonrebreathing mask is removed to provide access for the intubation. Positioning of the patient before and during the apneic period should focus on maximizing upper airway patency. Bag-mask device ventilation with RSI prior to intubation should be used only when absolutely necessary, with attention paid to avoiding gastric insufflation and possible regurgitation.

The goals of preoxygenation are twofold: (1) to maximize the patient's oxygenation reserve and (2) to remove nitrogen from the lungs to prolong the safe apneic time. Preoxygenation with high-flow oxygen saturates the air remaining in the lungs after normal expiration (functional residual capacity, approximately 30 mL/kg) with 100% oxygen. Many RSI protocols recommend administering high-flow oxygen for at least 3 minutes, if possible. This will allow for a prolonged period of apnea without significant desaturation in most patients. Children and patients who are obese or pregnant tend to desaturate much more rapidly than do typical adults.

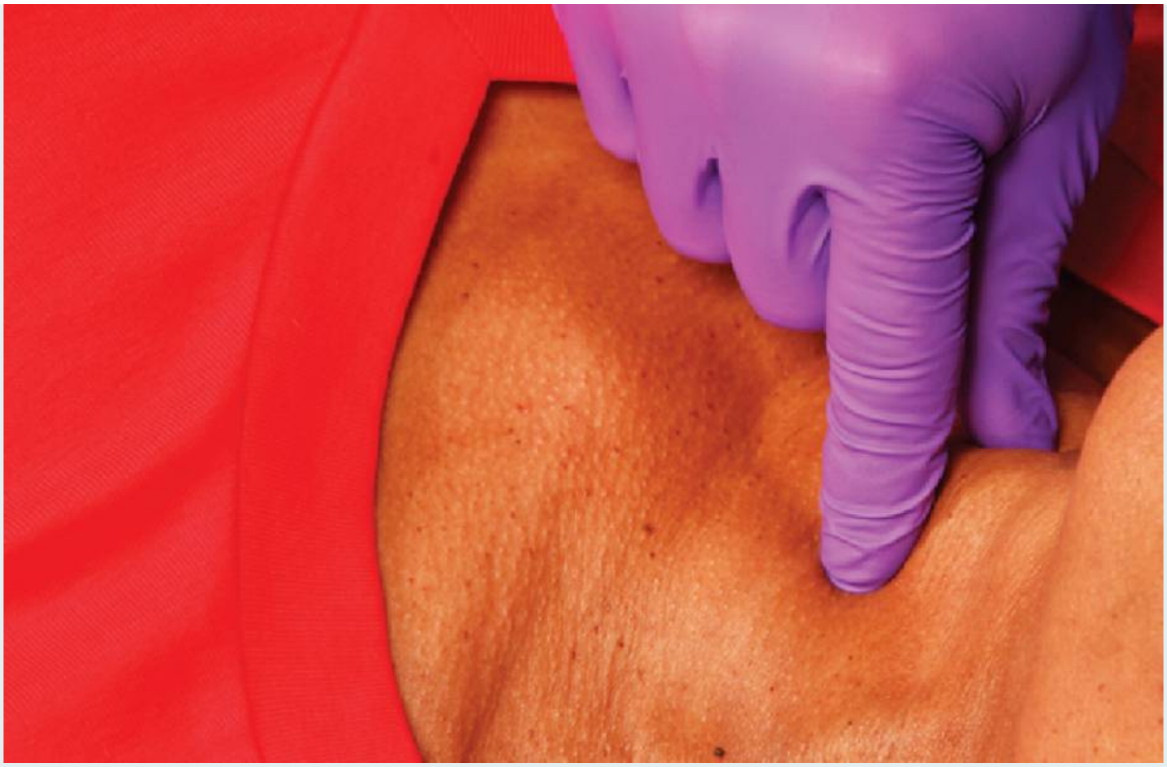
To reduce the changes of hypoxic injury or peri-intubation cardiovascular collapse, the CCTP must consider preintubation optimization to assess for potential hemodynamic stressors and take corrective actions to mitigate them. In the critical care transport setting, a patient requiring RSI often exhibits hypotension and respiratory failure, requiring positive-pressure ventilation to remedy these conditions. The confluence of these conditions coupled with the administration of induction agents with vasodilatory and cardiac depression effects may be a precursor to peri-arrest. In such a case, the CCTP should consider "resuscitation sequence intubation" and the physiologic *HOp* killers: *H*ypotension, *O*xygenation (hypoxemia), and *p*H and ventilation (metabolic acidosis). Mass hemorrhage, tension pneumothorax, cardiac tamponade, hypotension, and hypoxia should be corrected before RSI begins.

The medications used in RSI are classified into two broad categories: (1) sedative induction agents to induce unconsciousness and (2) neuromuscular blocking agents to induce paralysis. The combination of both types of medications is essential to successful RSI and intubation. For both types of medications, the ideal agent would have a rapid onset, a short duration of action, a stable hemodynamic profile, and few, if any, adverse side effects. Unfortunately, no such agent meets all of these criteria. Also, the use of these agents as single therapies may result in adverse outcomes. That is, the use of sedative/induction agents alone frequently does not result in successful intubation secondary to intact airway reflexes. Conversely, the use of neuromuscular blocking agents alone may result in a paralyzed, yet awake, patient. The combination of both sedation/induction and neuromuscular blockade results in significantly greater intubation success with fewer complications.

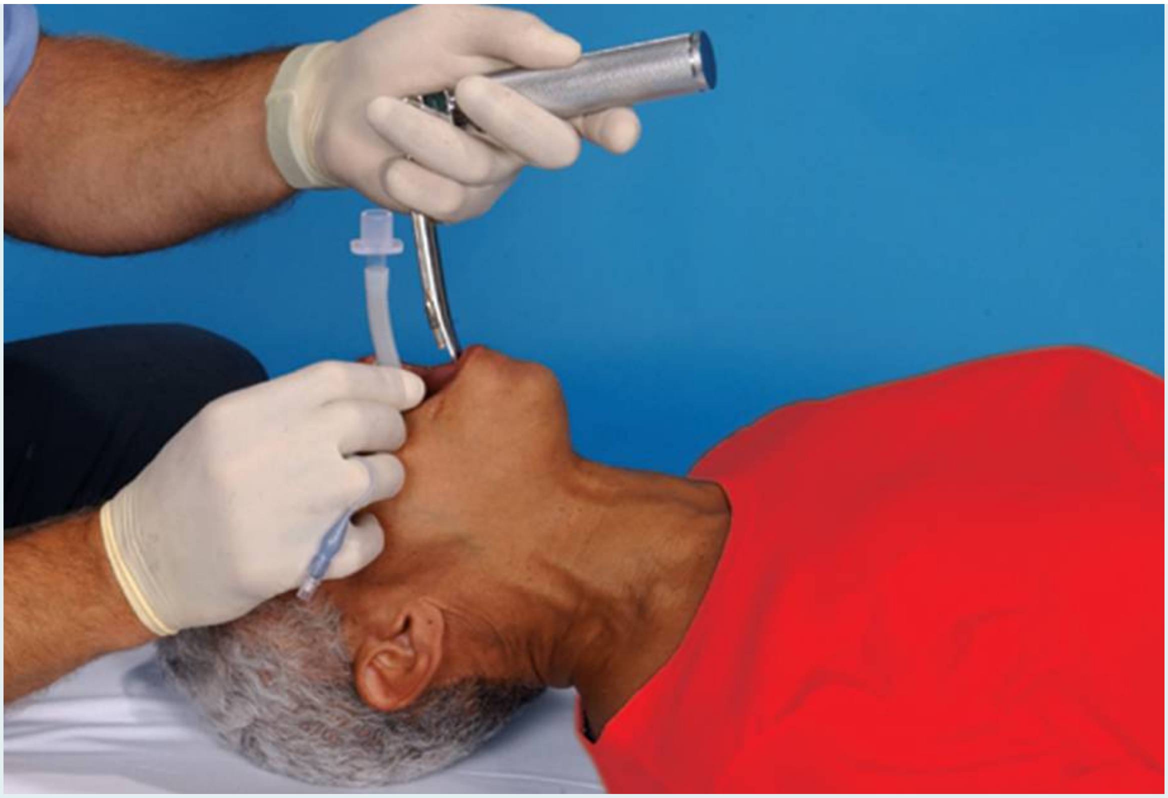
Skill Drill 6-9 shows the steps for performing RSI, which are described here:

SKILL DRILL 6-9 Performing Rapid Sequence Intubation

Step 1
Prepare and assemble the equipment. Preoxygenate the patient. Administer medications to premedicate, sedate, and paralyze the patient.



Step 2
Apply posterior cricoid pressure.



Step 3
Intubate the patient. Confirm correct ET tube placement. Release cricoid pressure.

All images © Jones & Bartlett Learning.

1. Prepare and assemble the equipment.
2. Preoxygenate with 100% oxygen **STEP 1**.
3. Administer medications to premedicate, sedate, and paralyze the patient. When premedicating:
   a. If your medical director or protocol recommends it, consider a defasciculating dose of a nondepolarizing neuromuscular blocking agent.
   b. Consider opiates to decrease the cardiovascular effects and elevations of intracranial pressure associated with upper airway stimulation.
   c. Consider atropine in pediatric patients to decrease the bradycardia associated with the administration of succinylcholine.

4. When sedating the patient, use an agent that induces sedation and amnesia, provided the patient is hemodynamically stable (systolic blood pressure >90 mm Hg).
5. Paralyze the patient using an appropriate agent.
6. Apply posterior cricoid pressure **STEP 2**.
7. Intubate the patient **STEP 3**.
8. Confirm correct ET tube placement.
9. Release the cricoid pressure.
10. Maintain paralysis and sedation.

As with non–medication-facilitated intubation, ET tube confirmation is crucial in RSI. Continuous waveform end-tidal capnography is considered the gold standard for confirming proper ET tube location. Pulse oximetry and a chest radiograph, if available, can also aid in confirmation. The ET tube should be secured in place. Subsequent placement of an orogastric tube to decompress the stomach should be considered as well. A ventilator should be attached with the proper settings, as described in Chapter 7, *Ventilation*.

Following RSI, postintubation sedation and analgesia should be ensured. If a long-acting paralytic such as rocuronium is administered, it is crucial that appropriate sedation and analgesia be automatically provided to prevent the patient from having awareness during paralysis. Because the paralyzed patient will likely not exhibit signs of pain, strict attention to ongoing pharmacologic interventions is necessary.

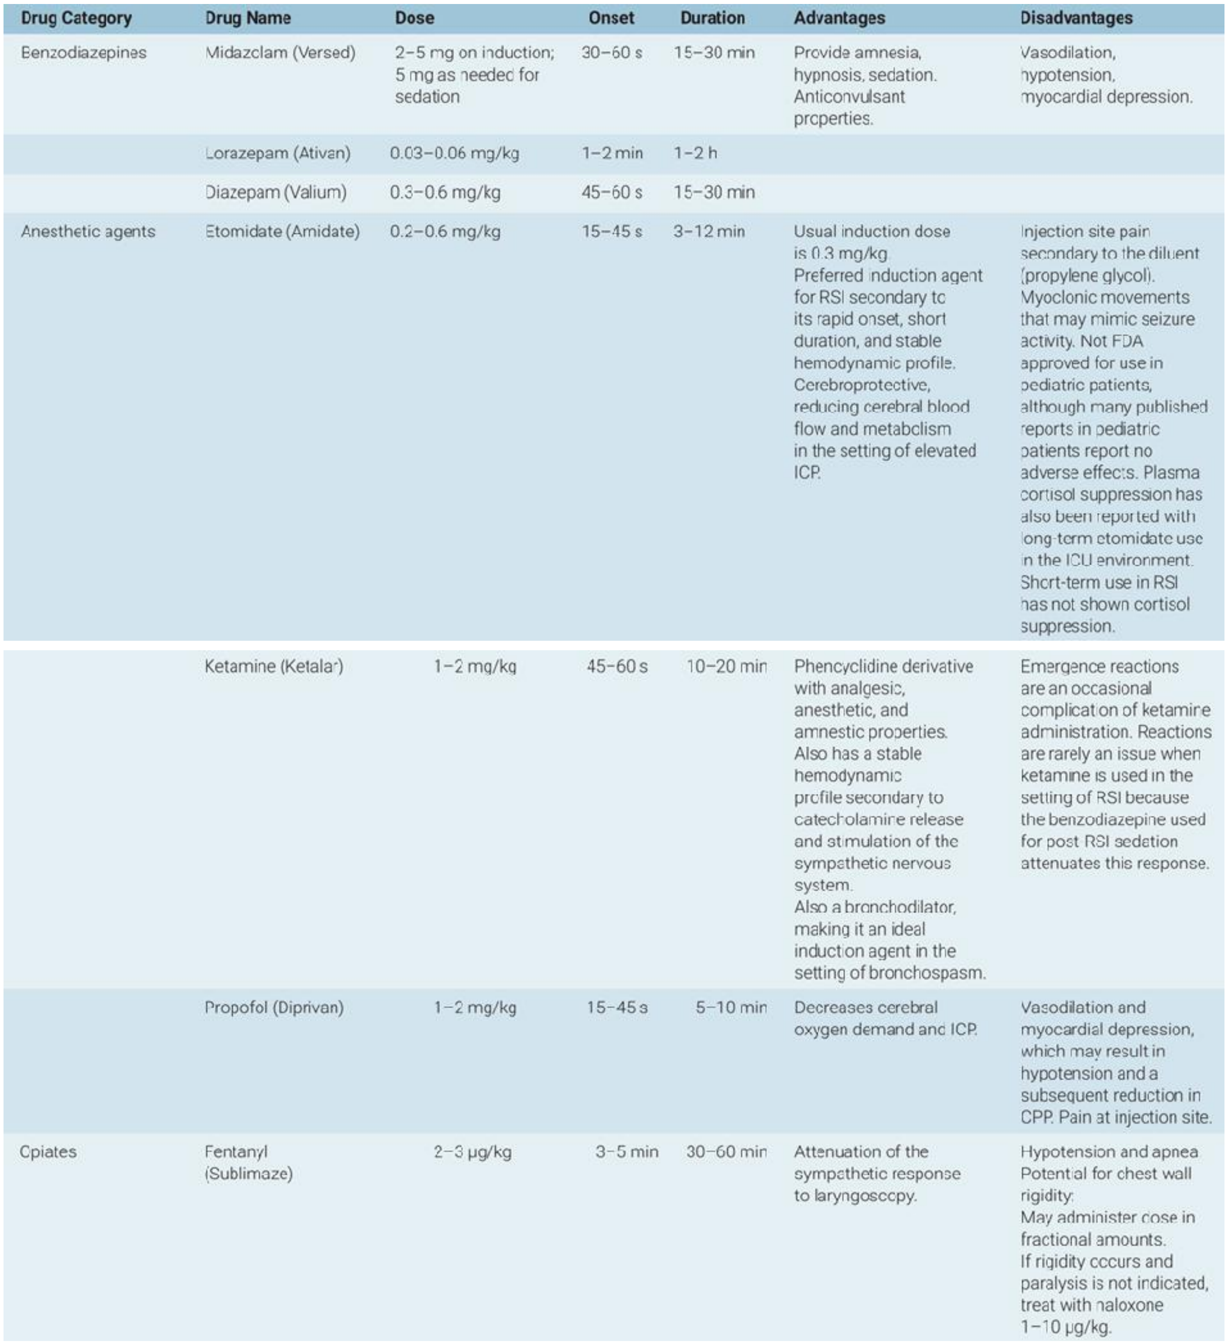
Special Populations

Children and patients who are obese or pregnant desaturate much more rapidly than the typical adult patient.

Pharmacologic Agents Used in RSI

Sedative/Induction Agents. TABLE 6-5 lists sedative/induction agents that may be used in RSI, and their doses, onsets, durations, advantages, and disadvantages. The induction agent chosen for use in RSI must be appropriate for the individual patient, preexisting comorbidities, acute clinical condition, and expected clinical course, including the anticipated success of the RSI.

TABLE 6-5 Sedative/Induction Agents



Drug Category	Drug Name	Dose	Onset	Duration	Advantages	Disadvantages
Benzodiazepines	Midazolam (Versed)	2–5 mg on induction; 5 mg as needed for sedation	30–60 s	15–30 min	Provide amnesia, hypnosis, sedation. Anticonvulsant properties.	Vasodilation, hypotension, myocardial depression.
	Lorazepam (Ativan)	0.03–0.06 mg/kg	1–2 min	1–2 h		
	Diazepam (Valium)	0.3–0.6 mg/kg	45–60 s	15–30 min		
Anesthetic agents	Etomidate (Amidate)	0.2–0.6 mg/kg	15–45 s	3–12 min	Usual induction dose is 0.3 mg/kg. Preferred induction agent for RSI secondary to its rapid onset, short duration, and stable hemodynamic profile. Cerebroprotective, reducing cerebral blood flow and metabolism in the setting of elevated ICP.	Injection site pain secondary to the diluent (propylene glycol). Myoclonic movements that may mimic seizure activity. Not FDA approved for use in pediatric patients, although many published reports in pediatric patients report no adverse effects. Plasma cortisol suppression has also been reported with long-term etomidate use in the ICU environment. Short-term use in RSI has not shown cortisol suppression.
	Ketamine (Ketalar)	1–2 mg/kg	45–60 s	10–20 min	Phencyclidine derivative with analgesic, anesthetic, and amnestic properties. Also has a stable hemodynamic profile secondary to catecholamine release and stimulation of the sympathetic nervous system. Also a bronchodilator, making it an ideal induction agent in the setting of bronchospasm.	Emergence reactions are an occasional complication of ketamine administration. Reactions are rarely an issue when ketamine is used in the setting of RSI because the benzodiazepine used for post RSI sedation attenuates this response.
	Propofol (Diprivan)	1–2 mg/kg	15–45 s	5–10 min	Decreases cerebral oxygen demand and ICP.	Vasodilation and myocardial depression, which may result in hypotension and a subsequent reduction in CPP. Pain at injection site.
Opiates	Fentanyl (Sublimaze)	2–3 μg/kg	3–5 min	30–60 min	Attenuation of the sympathetic response to laryngoscopy.	Hypotension and apnea Potential for chest wall rigidity. May administer dose in fractional amounts. If rigidity occurs and paralysis is not indicated, treat with naloxone 1–10 μg/kg.

Abbreviations: CPP, cerebral perfusion pressure; FDA, Food and Drug Administration; ICP, intracranial pressure; ICU, intensive care unit; RSI, rapid sequence intubation
© Jones & Bartlett Learning.

Description

Etomidate is a hypnotic with no analgesic properties. Due to its hemodynamic stability and cerebroprotective action, this agent is widely used in RSI. Etomidate's onset of action is 15 to 45 seconds, and patients have a rapid recovery. The induction dose should be reduced in hemodynamically compromised patients. Patients may exhibit myoclonic movement (which is not seizure activity) following administration of etomidate, though this movement should end with neuromuscular blockade.

The benzodiazepines midazolam, lorazepam, and diazepam have a slightly longer onset of action and a significantly longer duration of action, especially as compared to etomidate, which makes them less attractive as induction agents. They also have the ability to cause hypotension secondary to vasodilation. However, they are frequently used for sedation after intubation in hemodynamically stable patients.

Ketamine is a dissociative anesthetic agent with analgesic properties. Its onset of action is 45 to 60 seconds when given intravenously. It has minimal impact on respiratory drive, and its bronchodilatory properties make it an attractive induction agent in patients with reactive airway disease. Ketamine is also used for awake intubation and is increasingly being used in patients with head injury, despite previously noted concerns that it might increase intracranial pressure. Ketamine may increase secretions and can cause laryngospasm in rare cases.

Propofol is commonly used for induction in surgical cases, as well as for sedation of ventilated patients and for short painful procedures in the emergency department. However, its use as an induction agent in emergent situations is often limited by its tendency to produce vasodilation and hypotension.

Special Populations

Heightened vagal stimulation in pediatric patients can result in significant bradycardia. It is a good idea to administer atropine to children younger than 1 year who will be receiving succinylcholine and to have it available for children between 1 and 10 years old.

Neuromuscular Blocking Agents. Two types of neuromuscular blocking agents are distinguished: depolarizing and nondepolarizing. The depolarizing agents act by rapidly depolarizing the neuromuscular end plate, causing resistance to further stimulation. The nondepolarizing agents block the binding of acetylcholine to its receptors in the neuromuscular end plate. Both types of drugs result in paralysis. The only depolarizing neuromuscular blocking agent in use in the United States is succinylcholine.

Succinylcholine has a rapid onset of action and a short duration, which has made it a commonly selected paralytic agent for RSI in the EMS setting. However, this medication has several important absolute contraindications for its use. It should not be used in patients who have suspected or confirmed hyperkalemia, burns greater than 5 days old, denervation injury (stroke, spinal cord injury) greater than 5 days old until 6 months post injury, crush injuries, a history of malignant hyperthermia, or neuromuscular diseases (eg, amyotrophic lateral sclerosis [ALS], muscular dystrophy).

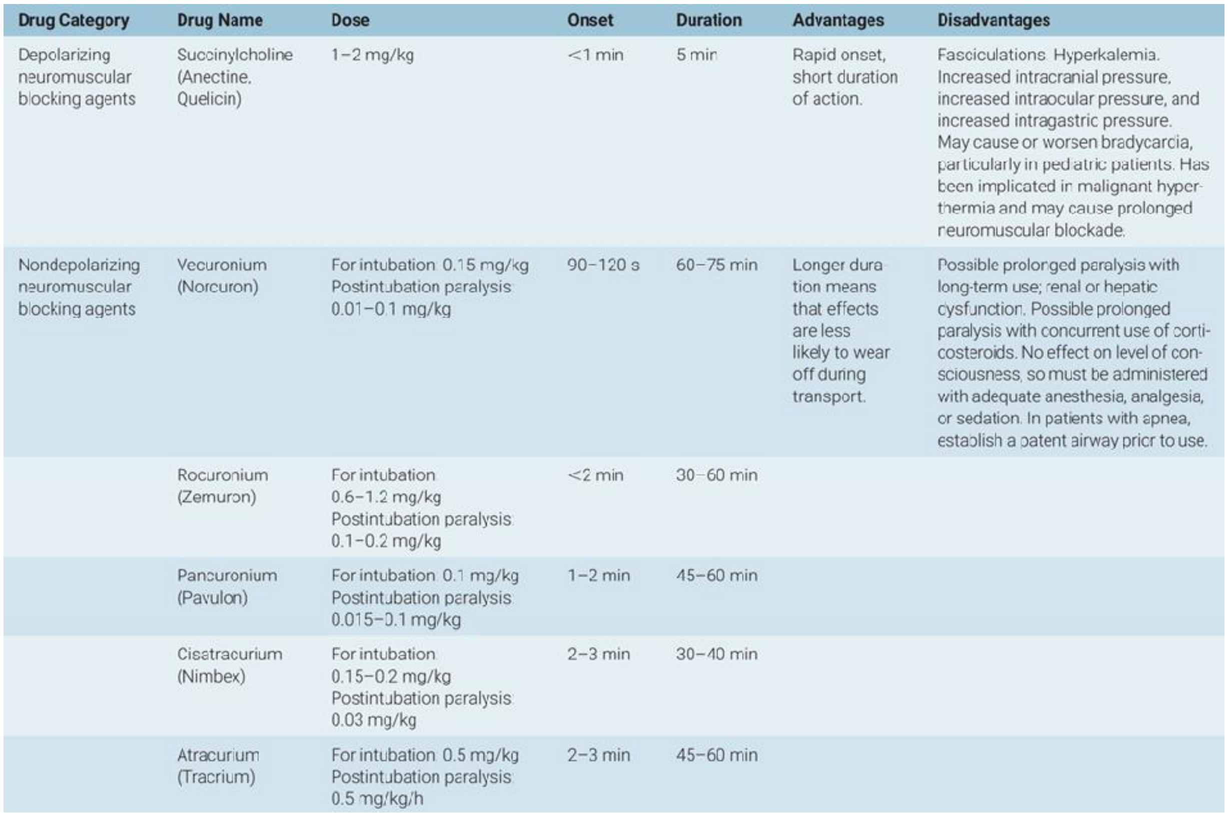
Several nondepolarizing neuromuscular blocking agents are used in RSI: vecuronium, pancuronium, rocuronium, atracurium, and cisatracurium. These agents primarily serve three purposes as a part of the RSI sequence:

- They may be used as pretreatment agents to prevent the fasciculations encountered with succinylcholine. The defasciculating dose range is 10% to 20% of the intubating dose. For vecuronium and pancuronium, the range is 0.01 to 0.02 mg/kg; for rocuronium, the dose is 0.06 mg/kg. The use of defasciculating doses is rare in the prehospital setting, however.
- They may be used as the primary paralytic agent in the face of contraindications to succinylcholine (hyperkalemia).
- They are used to maintain postintubation paralysis.

Recently, a reversal agent for rocuronium and vecuronium has been introduced into clinical practice. Sugammadex selectively binds to these neuromuscular agents in the blood plasma, thereby reducing the amount of paralytic molecules available to bind to receptors at the neuromuscular junction. Following administration of sugammadex, rocuronium and vecuronium cannot be readministered for 24 hours.

Neuromuscular blocking agents are summarized in **TABLE 6-6**.

TABLE 6-6 Neuromuscular Blocking Agents



Drug Category	Drug Name	Dose	Onset	Duration	Advantages	Disadvantages
Depolarizing neuromuscular blocking agents	Succinylcholine (Anectine, Quelicin)	1–2 mg/kg	<1 min	5 min	Rapid onset, short duration of action.	Fasciculations. Hyperkalemia. Increased intracranial pressure, increased intraocular pressure, and increased intragastric pressure. May cause or worsen bradycardia, particularly in pediatric patients. Has been implicated in malignant hyperthermia and may cause prolonged neuromuscular blockade.
Nondepolarizing neuromuscular blocking agents	Vecuronium (Norcuron)	For intubation: 0.15 mg/kg Postintubation paralysis: 0.01–0.1 mg/kg	90–120 s	60–75 min	Longer duration means that effects are less likely to wear off during transport.	Possible prolonged paralysis with long-term use; renal or hepatic dysfunction. Possible prolonged paralysis with concurrent use of corticosteroids. No effect on level of consciousness, so must be administered with adequate anesthesia, analgesia, or sedation. In patients with apnea, establish a patent airway prior to use.
	Rocuronium (Zemuron)	For intubation: 0.6–1.2 mg/kg Postintubation paralysis: 0.1–0.2 mg/kg	<2 min	30–60 min		
	Pancuronium (Pavulon)	For intubation: 0.1 mg/kg Postintubation paralysis: 0.015–0.1 mg/kg	1–2 min	45–60 min		
	Cisatracurium (Nimbex)	For intubation: 0.15–0.2 mg/kg Postintubation paralysis: 0.03 mg/kg	2–3 min	30–40 min		
	Atracurium (Tracrium)	For intubation: 0.5 mg/kg Postintubation paralysis: 0.5 mg/kg/h	2–3 min	45–60 min		

© Jones & Bartlett Learning.

Description

Tracheostomy Management

Patients receiving interfacility transport may already have a tracheostomy in place for a variety of reasons:

- Facial trauma
- Significant tracheal trauma
- Head injury
- Most commonly, failure to wean/long-term ventilator support

Contraindications to a tracheostomy include coagulopathy, neck tumor, and infection. These are relative contraindications, however, because the alternative is death.

Complications of a tracheostomy include:

- Accidental removal, particularly of a “fresh” or nonmature tracheostomy
- False passage or false tract
- Infection
- Hemorrhage
- Aspiration
- Mediastinal emphysema
- Tracheoesophageal fistula
- Tracheal stenosis
- Tracheomalacia
- Tracheoarterial fistula (frequently from a “low-lying” tracheostomy that erodes into the innominate artery)

Tracheostomy placement does not occur in the field, so it is usually not in the skill set of the prehospital provider. This procedure takes longer to perform than other surgical airways and requires equipment not typically found in the prehospital environment.

In general, patients with long-term tracheostomy devices can easily remove and replace them. In the acute setting, it is common hospital policy to have a spare tracheostomy at the bedside. For the CCTP, it is recommended to carry that spare tracheostomy during the transport. If necessary, ET tubes can be placed into a tracheotomy stoma if a device cannot be replaced or is malfunctioning. In addition, if a patient with a tracheostomy goes into acute respiratory failure, deep suctioning, such as with a red rubber suction catheter, should be performed immediately, as tracheostomies can be susceptible to formation of mucus plugs.

A false passage may occur when moving a patient on transport. Signs of this event include the patient appearing air hungry, the vent alarm signaling high or low pressure, subcutaneous emphysema, or crepitus in the upper chest and neck area. Measures to prevent dislodgement include keeping the tracheostomy securing devices tight and midline while monitoring frequently. In a patient who needs positive-pressure ventilation, the cuff on a tracheostomy device should be inflated or replaced with a cuffed ET tube if ventilation is inadequate.

Summary

Assessing the respiratory system of a critical care transport patient involves a thorough physical assessment and a review of the patient's history and care chart. Obtaining a thorough report from the transferring personnel will help establish the clinical picture before the transport begins.

Establishing a baseline assessment and being able to differentiate normal and abnormal findings in the respiratory system are paramount to comprehensive respiratory care during transport. Essential skills include auscultating breath sounds, evaluating oxygenation and ventilatory adequacy, and setting up and troubleshooting the ventilator.

Concepts such as tidal volume, minute volume, and anatomic dead space are crucial to understanding respiratory function and monitoring the patient's condition, as are a variety of devices and laboratory studies. ABG values, if available, will reveal the acid–base balance and blood levels of oxygen and CO_2. Pulse oximetry, capnography, and $ETCO_2$ detection offer a continuous, noninvasive means of measuring these gases during transport.

CCTPs must have a comprehensive understanding of airway assessment and management strategies. The use of video laryngoscopy is expanding as technologic advances have reduced the cost and enhanced the effectiveness of these devices. CCTPs should develop expertise in the specific video laryngoscopy device available to them, and consider transitioning to it as a primary instrument for most intubations.

CASE STUDY

Your team is dispatched to a rural hospital 75 miles (121 km) away for a 23-year-old, 154-pound (70-kg) woman in status asthmaticus. She was brought to the emergency department 2 hours ago by local EMS for difficulty breathing. She presented to the emergency department in acute respiratory distress, with audible inspiratory and expiratory wheezes, intercostal and supraclavicular retractions, and tripod positioning. Her initial vital signs included the following: respiratory rate, 32 breaths/min and labored; heart rate, 126 beats/min; blood pressure, 126/84 mm Hg; and SpO_2, 92% on an 8-L nebulizer.

Brush fires in the area have placed the county under an air quality warning. The patient's attack occurred after she had taken her dog for a walk. Her medical history includes asthma, which is controlled with daily use of an Advair inhaler. She has been hospitalized three times for asthma-related conditions prior to this episode. One of these admissions resulted in a stay in the intensive care unit for respiratory failure requiring intubation.

A radiograph of the patient's lungs obtained on her arrival at the emergency department demonstrated hyperinflation. The initial ABG reading while the patient was receiving a nebulizer treatment using 8 L of oxygen was pH 7.52, $PaCO_2$ 27 mm Hg, and PaO_2 88 mm Hg. A subsequent ABG reading 45 minutes later with the patient on a nonrebreathing mask at 15 L/min was pH 7.46, $PaCO_2$ 33 mm Hg, and PaO_2 79 mm Hg. All other chemistry and blood values were within normal limits.

You and your team arrive at the emergency department 4 hours after the patient's arrival. While your partner obtains her paperwork and speaks with the nurse caring for her, you assess the patient. You observe a young woman who is minimally responsive to verbal stimuli. She exhibits poor air exchange with shallow respirations accompanied by severe intercostal and supraclavicular retractions and minimal air exchange on auscultation. Current vital signs include the following: pulse rate, 87 beats/min; respiratory rate, 18 breaths/min, labored and shallow; blood pressure, 112/78 mm Hg; and SpO_2, 86% on a nonrebreathing mask with oxygen administered at 15 L/min. As you are completing your assessment of the patient, the nurse brings you the most recent ABG results drawn with the patient on the nonrebreathing mask, showing pH 7.25, $PaCO_2$ 62 mm Hg, and PaO_2 65 mm Hg.

1. Does this patient meet the criteria for intubation?
2. Which factors should be considered when assessing the patient for a difficult airway?
3. Which medications are used during rapid sequence intubation?

Per your protocol, you and your partner prepare for rapid sequence intubation. Using the LEMONS mnemonic, you determine that the patient should not be a difficult intubation. While your partner provides oxygen to the patient using a bag-mask device attached to 100% oxygen and a 15-L nasal cannula, you prepare the following medications for administration: etomidate, 21 mg for sedation; vecuronium, 0.7 mg as a defasciculating agent prior to paralysis; and succinylcholine, 140 mg for paralysis. Your partner administers the etomidate and succinylcholine while you are ventilating the patient and waiting for muscle relaxation. After 90 seconds, you notice that the patient still does not feel completely relaxed and presents with an intact gag reflex. You follow your protocol and administer a second dose of succinylcholine through another IV line. You are able to intubate the patient without difficulty, and confirm correct tube placement by auscultation, visualization, and use of capnography. The patient is placed on the transport ventilator and prepared for the trip back to your facility. Prior to leaving the hospital, you administer an additional 7 mg of vecuronium and 2 mg of lorazepam for continued paralysis and sedation during transport. Additional treatment includes a continuous albuterol nebulizer at 10 mg/h, 125 mg of methylprednisolone sodium succinate, and a normal saline drip at 150 mL/h.

Once you have the patient loaded in the back of your helicopter, you notice that the patient's $ETCO_2$ is rising and her SpO_2 is dropping. Reassessment of the ET tube indicates that the tube has become dislodged and is now ventilating the stomach. You and partner decide to pull the tube and reattempt intubation. After two unsuccessful attempts, you give your partner a chance; your partner is unable to visualize the vocal cords. Your King LT airway is retrieved and inserted without difficulty. After confirming placement of this airway, you secure the tube with a commercial tube holder, place the patient back on the ventilator, and continue your transport.

You arrive at the receiving hospital approximately 90 minutes later following an uncomplicated trip. A detailed patient report is given to the awaiting staff on your arrival, which includes a list of all the medications given, along with the reason for the insertion of the King LT airway.

1. Was it an acceptable practice to administer a second dose of succinylcholine? What are some possible causes for having to repeat the dose?
2. What is a King LT airway, and why could you insert it without difficulty when the ET tube could not be inserted?
3. Was there ever a point in this patient's care when noninvasive positive-pressure ventilation would be considered appropriate?

Analysis

This patient was a candidate for ET intubation due to her decreased mental status and respiratory failure, as shown by ineffective respirations, minimal air movement, and ABG results. Initially, the patient arrived at the emergency department awake and alert in respiratory distress. The first ABG results showed respiratory alkalosis, a common finding in the early stages of an acute asthma attack. The second blood gas analysis came back with close to normal values, with the exception of oxygenation. This finding should be a warning sign and should prompt you to reassess the patient to determine whether her condition is improving or whether she is getting tired and bears close watching. Do not let the numbers trick you!

Patient history and assessment play an important role in the preparation for intubation. Questions that can be answered by a review of patient history include the presence of congenital anomalies, recent surgery, trauma, infection, or cancer. Pertinent assessment findings include patients with short necks, those who are obese, and those with dental abnormalities such as an overbite. Two assessment tools can be used to guide your decision: the Mallampati method and the 3-3-2 rule.

The Mallampati method ranks the difficulty of intubation (class I is the easiest and class IV is the most difficult) based on how well the oropharyngeal structures can be visualized in a patient who is seated in an upright position with a fully open mouth. A class I airway is one in which all oropharyngeal structures can be visualized. With a class II airway, the glottis is only partially visible. With a class III airway, the glottis cannot be exposed, but the corniculate cartilages can be seen. Finally, the class IV airway prevents the visualization of any oropharyngeal structures.

The 3-3-2 rule refers to three easy anatomic methods of assessing candidates for intubation. For the first 3, have the patient open their mouth as wide as possible. This opening should allow for a minimum of three fingerbreadths (approximately 5 cm); an opening of less than three fingerbreadths may be an indicator of a difficult airway. The second 3 is a measurement of the length of the mandible, from the tip of the chin to the hyoid bone. Again, an optimal measurement is the width of at least three fingers. The final measurement, 2, refers to the distance from the hyoid bone to the thyroid notch. An ideal airway would have a distance of at least two fingerbreadths.

Medications administered during rapid sequence intubation are given to premedicate, sedate, and paralyze the patient. Medications given to premedicate the patient include a smaller dose (also known as a defasciculating dose) of a nondepolarizing neuromuscular blocking agent, such as vecuronium; atropine in the pediatric population, to decrease the bradycardic effects associated with succinylcholine; and a sedative, or induction agent (eg, etomidate), to provide sedation and amnesia.

The succinylcholine dose can be repeated if needed using the same dosing regimen. The most likely reason that the succinylcholine did not work in this patient is an infiltrated intravenous line. Alternatively, because succinylcholine is temperature sensitive, that particular vial of medication might have been exposed to extreme temperatures for a prolonged period of time, which in turn contributed to the ineffectiveness of the medication.

The King LT airway is a supraglottic airway that does not require the direct visualization of the vocal cords during its placement. This device is actually inserted into the esophagus, after which a distal and proximal balloon is inflated and the patient’s lungs ventilated through fenestrations located between the two balloons. Even though it is a supraglottic device, the patient can be mechanically ventilated without difficulty.

A trial of noninvasive positive-pressure ventilation might have been attempted after the second ABG results were obtained.

PREP KIT

Ready for Review

- The goal of the CCTP is to ensure the adequacy of ventilation and oxygenation of the critically ill patient during transport. To do so, the CCTP must have a good understanding of respiratory function and assessment.
- An understanding of airway anatomy and physiology, including the structures of the nose, mouth, pharynx, larynx, and trachea, is essential to successful airway management.
- The airway anatomy of pediatric patients is different from the anatomy of adults. The small size of the cricothyroid membrane in children younger than 4 years may make needle and surgical cricothyrotomy difficult or impossible. Children also have significantly higher oxygen consumption rates compared to adults.
- The respiratory system is divided into the conducting zone and the respiratory zone, with the conducting zone further divided into the upper airway and lower airway. The pulmonary circulatory system is a low-pressure system.
- An adult lung contains approximately 300 million alveoli, each of which is in contact with a pulmonary capillary. The interface between an alveolus and a pulmonary capillary is called the alveolar-capillary membrane. For gas exchange to occur, blood flow must be in contact with the alveoli.
- Gas exchange occurs as a result of pressure gradient changes across the alveolar-capillary membrane. Through diffusion, molecules of oxygen move out of the alveoli and into the blood because there are fewer oxygen molecules in the blood, and molecules of CO_2 move out of the blood and into the alveoli because there are fewer CO_2 molecules in the alveoli.
- Ventilation-perfusion mismatch factors—due to inadequate ventilation, perfusion, or both—can affect the diffusion of gases

across the alveolar-capillary membrane. The mechanics and dynamics of breathing involve the concepts of elastance, compliance, resistance, and pressure gradients.

- The total lung capacity of a healthy male adult ranges between 5 and 6 L of gas, which can be further divided into different lung volumes and capacities.
- Diseases that result in difficulty moving air out of the lungs are classified as obstructive diseases. They include asthma, chronic obstructive pulmonary disease, cystic fibrosis, and bronchiectasis, and involve an increase in airway resistance.
- Diseases that result in difficulty moving air into the lungs are classified as restrictive diseases. These diseases, which result from loss of chest or lung compliance, either individually or together, include occupational lung diseases (the pneumoconioses) and idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and the neuromuscular diseases that affect breathing.
- Assessment of a patient’s respiratory system includes visually inspecting the patient with a focus on the chest, using auscultation sites to check breath sounds, assessing respiratory patterns and breathing rate, and using palpation to check the status of the lungs, skin, subcutaneous tissues, and chest expansion. Prior to transport, the CCTP needs to review the patient care report carefully, noting any medications, underlying disease, or trauma that might compromise ventilation.
- The functioning of the respiratory system is measured using ABG levels, in which blood is obtained from a superficial artery and then analyzed for pH, Pa_{CO_2} (partial pressure of CO_2 in arterial blood), Pa_{O_2} (partial pressure of oxygen in arterial blood), HCO_3^- (concentration of bicarbonate ion), base excess, and Sp_{O_2} (oxygen saturation of the hemoglobin molecule).
- Respiratory insufficiency is the inability of the respiratory system to keep up with the metabolic demands of the body; it can lead to respiratory depression. Respiratory failure—either oxygenation

failure or ventilatory failure—occurs when the respiratory system is unable to meet the body’s metabolic needs.

- Basic airway skills are the starting point in the CCTP’s initial assessment and treatment of the patient with a respiratory disorder. They include positioning the nontrauma victim in the recovery position; using the head tilt–chin lift, tongue-jaw lift, or jaw-thrust maneuver; or using airway adjuncts such as an oropharyngeal airway or nasopharyngeal airway.
- Suctioning to remove debris (vomit and blood) and turning the patient onto their side while using a large-bore suction device can restore airway patency and minimize the potential for aspiration.
- Patients with respiratory disorders should receive some form of supplemental oxygen based on the provider’s assessment, regardless of documented $\text{Sp}O_2$.
- Oxygen delivery may take many forms, including mouth-to-mouth ventilation, barrier device/resuscitation mask, and bag-mask ventilation.
- Definitive airway management is considered to be the placement of an endotracheal (ET) tube or tracheostomy tube within the trachea.
- In anticipation of a difficult airway, several factors need to be considered, including patient history and patient assessment.
- The 3-3-2 rule should be used as part of the airway assessment. A mouth opening of less than three fingers wide, a mandible length of less than three fingers wide, and a distance from the hyoid bone to the thyroid notch of less than two fingers wide indicate a possibly difficult airway.
- Once the decision to intubate a patient has been made, the CCTP needs to determine how to most effectively accomplish the procedure. The goal is to intubate the patient on the first attempt (first-pass success) without inducing hemodynamic compromise or aspiration.
- Orotracheal intubation can be performed in two ways: direct visualization of the vocal cords by displacement of the tongue with

a laryngoscope blade or indirect visualization of the vocal cords using video laryngoscopy.

- Nasotracheal intubation has been used only infrequently since the advent of rapid sequence intubation (RSI); however, it may still be indicated in the prehospital setting if RSI is inadvisable. Thus, providers should maintain competency in this technique.
- A bougie is an ET tube introducer that allows the CCTP to perform laryngoscopy in difficult airways. It provides a tactile sensation as the bougie slides alongside the tracheal rings.
- Advantages of using the laryngeal mask airway (LMA) include greater ease of insertion and superior oxygenation and ventilation compared with bag-mask ventilation; disadvantages are the risk of aspiration and difficulty with obtaining an adequate seal. Use an LMA if the patient is in a deep coma or cardiac or respiratory arrest, or if ET intubation is not possible. The LMA is contraindicated for use in patients with an intact gag reflex or facial or esophageal trauma, or if an airway obstruction by a foreign body is suspected.
- The King LT airway and the i-gel are supraglottic airways that may be placed blindly; once proper placement is verified, the patient must be kept sedated and paralyzed. This kind of airway is used when ET intubation is not possible, if intubation has failed and the patient is in a deep coma or cardiac or respiratory arrest, or to reduce the risk of gastric distention. Contraindications include an intact gag reflex, an upper airway obstruction or suspected foreign body obstruction, facial or esophageal trauma, known esophageal disease, and possible caustic ingestion.
- When a patient cannot be intubated or ventilated, placement of a surgical airway via needle cricothyrotomy, surgical cricothyrotomy (either open or modified), or RSI is required.
- RSI involves the coadministration of both anesthetic agents and neuromuscular blocking agents to produce a state of unconsciousness and paralysis that allow for tracheal intubation.

- Some pharmacologic agents used in RSI are sedative/induction agents, including benzodiazepines such as lorazepam and diazepam, anesthetic agents such as etomidate and ketamine, opiates such as fentanyl, and atropine for pediatric patients.
- Other pharmacologic agents used in RSI are neuromuscular blocking agents, which are either depolarizing or nondepolarizing. Succinylcholine is the only depolarizing neuromuscular blocking agent used in the United States, but several nondepolarizing neuromuscular blocking agents, including vecuronium, pancuronium, rocuronium, atracurium, and cisatracurium, are also used. The nondepolarizing agents are primarily used as pretreatment agents, as the primary paralytic agent, or more commonly, to maintain postintubation paralysis.

Vital Vocabulary

3-3-2 rule A method used to predict difficult intubation. A mouth opening of less than three fingers wide, a mandible length of less than three fingers wide, and a distance from the hyoid bone to the thyroid notch of less than two fingers wide indicate a possibly difficult airway.

adventitious breath sounds Abnormal breath sounds that are heard in addition to, or in place of, normal sounds.

agonal respirations Slow, shallow, irregular respirations or occasional gasping breaths; result from cerebral anoxia.

alveolar ventilation (V_a) The volume of air that comes into contact with the alveolar-capillary membrane surfaces and participates in the exchange of gases between the lung and blood.

anatomic dead space (V_d) Space in airway structures such as the trachea, bronchi, and bronchioles that does not participate in gas exchange. It is defined physiologically as ventilation without perfusion.

apnea The absence of respiration.

apneustic breathing A condition in which lesions in the respiratory center of the brainstem lead to a breathing pattern characterized by prolonged, gasping inspiration, followed by extremely short, ineffective expiration.

arterial blood gas (ABG) Analysis of the following characteristics of blood: pH, partial pressure of carbon dioxide (in arterial blood), partial pressure of oxygen (in arterial blood), concentration of bicarbonate ion, base excess (indicating whether the patient is acidotic or alkalotic), and oxygen saturation of the hemoglobin molecule.

barotrauma Injury to the chest or lungs as a result of increased intrathoracic pressure.

Biot (ataxic) respiration Breathing characterized by three patterns: (1) slow and deep, (2) rapid and shallow, and (3) apnea. Causes include meningitis, increased intracranial pressure, and central nervous system dysfunction.

bradypnea A respiratory rate that is slower than normal.

bronchovesicular sounds A combination of the tracheal and vesicular breath sounds, heard in places where airways and alveoli are found, including the upper part of the sternum and between the scapulae.

capnography A method for measuring exhaled CO_2, which in most cases correlates with the CO_2 levels in arterial blood. Two different types of devices can be used—an electronic monitor that displays a waveform and a colorimetric device that should turn yellow during exhalation, indicating proper tube placement.

capnometry A method for measuring exhaled CO_2; it is performed the same way as capnography, but provides a light-emitting diode readout of the patient's exhaled CO_2.

central neurogenic hyperventilation A pattern of very deep, rapid respirations at rates of 40 to 60 breaths/min, caused by a midbrain lesion or dysfunction.

Cheyne-Stokes respiration A cyclic pattern of increased respiratory rate and depth with periods of apnea. Causes include increased intracranial pressure, renal failure, meningitis, drug overdose, or hypoxia secondary to congestive heart failure.

cluster breathing An abnormal respiratory pattern in which a cluster of irregular respirations that vary in depth are followed by a period of apnea at irregular intervals.

compliance A change in volume per unit of pressure; $\Delta V/\Delta P$.

crackles A breath sound produced as fluid-filled alveoli pop open under increasing inspiratory pressure; can be fine or coarse.

difficult airway An airway in which the provider anticipates complications in securing an airway.

elastance The tendency to collapse (as in lung tissue).

eupnea Normal breathing at a rate of 12 to 20 breaths/min in the adult patient.

exhalation A passive process in which gas leaves the lungs.

expiratory reserve volume (ERV) The amount of air that can be expelled from the lungs after a normal exhalation.

face-to-face intubation Intubation in which the provider's face is at the same level as the patient's face; used when the standard position is not possible. In this position, the laryngoscope is held in the provider's right hand and the endotracheal tube in the left.

failed airway An unsuccessful intubation attempt in a patient for whom oxygenation cannot be adequately maintained with bag-mask ventilation; three unsuccessful intubation attempts by an experienced operator but with adequate oxygenation; and failed intubation using one best attempt in the "forced to act" situation.

fraction of inspired oxygen (FIO_2) Percentage of inhaled oxygen expressed as a decimal. For example, 40% oxygen = FIO_2 of 0.40.

functional residual capacity (FRC) The amount of air remaining in the lungs after normal expiration; the sum of the residual volume and the expiratory reserve volume.

hyperangulated blade A video laryngoscope blade with a high degree of curvature to get around anatomic structures.

hyperpnea A breath that is deeper than normal; it can lead to low levels of CO_2.

hypopnea A shallow breath; it can lead to increased CO_2 levels and decreased oxygen levels.

hypoxemia An abnormally low oxygen level.

I:E ratio An expression for comparing the length of expiration to the length of inspiration. The normal ratio is 1:2, which means that expiration is twice as long as inspiration. This ratio is not measured in seconds.

inspiration An active process in which gas is taken into the lungs.

inspiratory capacity (IC) The maximum amount of air that can be inspired; the sum of the inspiratory reserve volume and the tidal volume.

inspiratory reserve volume (IRV) The amount of air that can be inhaled after a tidal volume is inhaled.

Kussmaul respiration A fast and deep respiratory pattern without any periods of apnea. The rate and depth are greater than the normal rate expected; breathing is labored, with periods of deep breaths punctuated by sighs.

laryngeal mask airway (LMA) A rescue airway with a basic design similar to an endotracheal tube at the proximal end, in that a standard adapter is present to allow ventilation. The distal end is equipped with an elliptical cuff, which, when inflated, covers the supraglottic area and allows ventilation.

Mallampati classification A system for predicting the relative difficulty of intubation based on the amount of oropharyngeal structures visible in an upright, seated patient who is fully able to open their mouth.

minute volume Total volume of air breathed in and out in 1 minute. It is calculated by multiplying the respiratory rate per minute by the tidal volume.

obstructive diseases Diseases that result in difficulty with moving air out of the lungs, such as asthma, chronic obstructive pulmonary disease, cystic fibrosis, and bronchiectasis.

pleural friction rub The result of an inflammation that causes the pleura to thicken, decreasing the pleural space and allowing the surfaces of the pleura to rub together.

positive end-expiratory pressure (PEEP) The amount of pressure above ambient pressure present in the airway at the end of the respiratory cycle.

pressure gradients Differences in pressure, which allow for movement of gas into and out of the lung.

pulse oximetry Measurement of arterial oxygen saturation and the pulse.

rapid sequence intubation (RSI) The coadministration of both anesthetic agents and neuromuscular blocking agents to produce a state of unconsciousness and paralysis, which in turn allows for tracheal intubation.

residual volume (RV) The amount of air remaining in the lungs after the expiratory reserve volume is exhaled.

resistance The amount of force needed to move a gas or fluid through a single capillary tube.

respiratory depression A low respiratory rate (<2 breaths/min in adults) for a prolonged period of time; also called hypoventilation.

respiratory failure A situation in which the respiratory system fails to meet the body's metabolic needs. If not reversed, it may lead to respiratory or cardiopulmonary arrest.

respiratory insufficiency The inability of the respiratory system to keep up with the metabolic demands of the body.

restrictive diseases Diseases that result in difficulty moving air into the lungs, such as occupational lung diseases, idiopathic pulmonary fibrosis, pneumonia, atelectasis, chest wall deformities and injuries, and neuromuscular diseases that affect breathing.

rhonchi Rattling vibrations produced as air flows through mucus or around obstruction in the larger airways.

rigid stylet A hyperangulated intubation stylet used to facilitate endotracheal tube passage when using an hyperangulated blade.

Seldinger technique A technique for obtaining vascular or other hollow organ access that uses a hollow-bore needle inserted percutaneously, followed by placement of a soft-tipped guide wire. The needle is removed and a dilator is temporarily placed. The dilator is removed, the desired catheter is placed over the guide wire, and the guide wire is removed. The catheter is then secured.

shunt Perfusion without ventilation.

SpO_2 The noninvasive pulse oximetry measurement of oxyhemoglobin saturation by means of a beam of light applied to a superficial capillary bed such as the digits or ear lobe.

standard geometry blade A device used during indirect (video) laryngoscopy that allows the CCTP to visualize the oral cavity on a monitor.

stridor High-pitched sound representing air moving past fluid or mechanical obstruction within or immediately above the glottic opening.

tachypnea An abnormally fast respiratory rate.

tidal volume (V_t) The volume of air moved into and out of the lungs with each respiratory cycle.

total lung capacity (TLC) The maximal amount of air that can fill the lungs; the sum of tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume.

tracheal breath sounds Breath sounds heard by placing the stethoscope diaphragm over the trachea or over the sternum; also called bronchial breath sounds.

ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch A state of inadequate ventilation, perfusion, or both, in which there is inadequate gas exchange.

vesicular breath sounds Softer, muffled sounds in which the expiratory phase is barely audible.

video laryngoscopy An orotracheal intubation technique that involves indirect visualization of the vocal cords via a video camera at the distal end of a blade that provides a video feed to a screen.

vital capacity (V_c) The maximal amount of air that can be exhaled following a maximal inspiration; the sum of tidal volume, inspiratory reserve volume, and expiratory reserve volume; approximately 80% total lung capacity.

$\dot{V}/\dot{Q}$ ratio The relationship between alveolar ventilation and alveolar capillary perfusion. The normal value is 0.8.

wheezes A high-pitched musical sound caused by airflow through a narrowed or constricted airway.

CHAPTER 7

Ventilation

Michael Schauf, RRT

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe common features and characteristics of mechanical ventilators (p 228).
2. Differentiate between positive-pressure and negative-pressure ventilators (pp 229–230).
3. Differentiate among pressure ventilators, volume ventilators, and flow- and time-cycled ventilators (pp 237–238).
4. Differentiate between invasive and noninvasive ventilation (p 232).
5. Explain the types and uses of nasal cannulas (pp 232–234).
6. Define the various modes of mechanical ventilation (pp 240–241).
7. Define the ventilator parameters of tidal volume, fraction of inspired oxygen, respiratory rate, ratio of the length of inspiratory-to-expiratory (I:E) ratio, mode, and positive end-expiratory pressure (PEEP) (p 244).
8. Explain the use of PEEP (p 245).
9. Differentiate between respiratory distress and respiratory failure (p 248).
10. Describe measures the CCTP may take to ensure proper ventilator function and keep the patient's ventilatory status stable (pp 248–249).
11. Explain the difference between volume-delivered breaths and pressure-delivered breaths (p 249).
12. Describe the use of mechanical ventilation in managing common lung diseases and conditions (p 256).
13. Discuss how the graphics displayed by ventilators aid the clinician (pp 269–271).
14. Troubleshoot problems with mechanical ventilators, including common alarms (pp 271–274).

Introduction

Ventilation may be described most simply as the supply of oxygen delivered into the lungs for adequate gas exchange to take place. Health care providers can provide ventilation manually or with a machine, referred to as **mechanical ventilation**. Mechanical ventilation applies either positive pressure or negative pressure. Positive pressure is most commonly used today and may be applied either invasively (such as through an endotracheal [ET] tube) or noninvasively (with a nasal cannula or full-face mask). The indications for mechanical ventilation include managing the work of breathing, improving the distribution of inhaled gases, protecting the airway, and managing conditions such as apnea and ventilatory or respiratory failure.

Breathing Terminology

The terms used to describe a patient's breathing are sometimes confused and misused. Here are their formal definitions:

- **Ventilation:** The physical act of moving air into and out of the lungs
- **Respiration:** The exchange of oxygen and carbon dioxide in the alveoli and the tissues of the body
- **Oxygenation:** The process of loading oxygen molecules onto hemoglobin molecules in the bloodstream

Overview of Mechanical Ventilation

A major goal when ventilating a patient is to provide appropriate minute ventilation to meet the patient's metabolic demands. To identify which modality best meets their respiratory needs, the clinician must understand the patient's current lung physiology. Lung function may be assessed through pressure and flow measurements, which provide valuable information such as respiratory volume, resistance, compliance, and work of breathing. Clinicians use this information to evaluate respiratory mechanics and lung function to optimize mechanical ventilatory support.

Review of Common Respiratory Terminology

Dead Space Ventilation

Dead space ventilation, also referred to as wasted ventilation, refers to the volume of gas that moves into and out of the lungs but does not take part in gas exchange. Areas in which dead space ventilation occurs, called **anatomic dead space**, include the airways in the mouth and nose and the terminal bronchioles. The anatomic dead space for an adult male is approximately one-third of the **tidal volume** breathed in; the remaining two-thirds of gas inhaled is considered alveolar ventilation. When adding additional pieces, such as in-line suction catheters and heat moisture exchangers, to the ventilator circuit proximal to the wye, you are, in essence, adding dead space (mechanical dead space) to the delivered breath **FIGURE 7-1**. This consideration may be more critical in the neonatal/pediatric population, so using appropriate-size products is essential when caring for these patients.

Alveolar-to-Arterial Oxygen Gradient

The main purpose in calculating an alveolar-to-arterial oxygen (A-a) gradient is to determine the source of **hypoxemia**. This will help narrow the location of the problem to either inside the lungs or outside the lungs. The A-a gradient is calculated as $PAO_2 - PaO_2$ (ie, partial pressure of alveolar oxygen – partial pressure of arterial oxygen), with the component values being determined by an **arterial blood gas (ABG)** analysis. The alveolar gas equation is used to estimate alveolar oxygen pressure:

$$PaO_2 = (P_{atm} - PH_2O)\,FIO_2 - PaCO_2/RQ$$

where P_{atm} is the atmospheric pressure, PH_2O is the partial pressure of water, FIO_2 is the fraction of inspired oxygen, $PaCO_2$ is the partial pressure of carbon dioxide in the alveoli, and RQ is the respiratory quotient. The main variables that affect the alveolar gas equation are the amount of FIO_2, the level of carbon dioxide, and the atmospheric pressure.

A normal A-a gradient equals (Age + 10)/4. Patients with a condition such as pneumonia would typically have an elevated A-a gradient due to the excessive secretions within the lung, which create a physical barrier to gas exchange within the alveoli. This condition would result in **ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch**. Hypoxemia with a normal A-a gradient would indicate hypoventilation, in which carbon dioxide overrides alveolar oxygen.

Ventilation-Perfusion Mismatch

When searching for the underlying cause of hypoxemia, it is helpful to understand the $\dot{V}/\dot{Q}$ ratio. In healthy lungs, 4 L of air enters the respiratory tract system while 5 L of blood passes through the pulmonary capillary system. That equates to a $\dot{V}/\dot{Q}$ ratio of 0.8. Any number that is higher or lower than this ratio would be considered a $\dot{V}/\dot{Q}$ mismatch. The goal is to quickly identify the cause of the mismatch and develop a plan to correct the condition.

A ventilation problem is referred to as a **shunt**. Typical shunt presentations include pneumonia, asthma, chronic obstructive pulmonary disease (COPD) or emphysema, atelectasis, and pulmonary edema. Any condition that prohibits gas from crossing the alveolar-capillary membrane may be considered a shunt.

On the perfusion side of the $\dot{V}/\dot{Q}$ ratio, anything that prohibits normal blood flow through the pulmonary capillary system is considered dead space ventilation. For example, a patient with a pulmonary embolism is experiencing some form of dead space ventilation. A pulmonary embolism may be suspected in the face of hypoxemia with an elevated D-dimer level and confirmed with a computed tomography (CT) pulmonary angiogram.

Minute Volume

Minute volume is measured to determine how many liters of air move into or out of the lungs per minute. It is calculated by multiplying the exhaled tidal volume by the current respiratory rate. The minute volume has a direct correlation to the Pa_{CO_2} and $ETCO_2$ (end-tidal carbon dioxide) results. Having a higher than normal minute volume will theoretically lower the Pa_{CO_2} and $ETCO_2$, whereas having a lower than normal minute volume will theoretically increase the Pa_{CO_2} and $ETCO_2$. A normal minute volume for an adult is anywhere from 5 to 8 L/min, though it can increase with exercise. Methods for calculating minute volume and adjusting the ventilator to meet the patient's needs are discussed later in this chapter.

Features of Mechanical Ventilators

Mechanical ventilation devices range from simple to complex, depending on the needs of the patient and the capabilities of the machine. At one time, the classification and description of ventilators were simple; however, with the increased use of biotechnology, microprocessors, and sophisticated flow-sensing devices in mechanical ventilation, the classification of these devices has become ever more complicated. All ventilators, however, share several common characteristics:

1. **Power source.** All ventilators require an external power source. This source can be electric (AC), battery (DC), or pneumatic (requiring a 50-psi [pounds per square inch] gas source).
2. **Cycling.** This feature refers to which variable terminates the inspiratory phase of a breath. Pressure, volume, time, and flow can terminate a breath, depending on the ventilator.
3. **Breath delivery.** The ventilator can deliver a breath using either negative pressure **FIGURE 7-2** or positive pressure **FIGURE 7-3**. It is important to understand the changes that take place when a positive-pressure system is applied to a system that normally functions as a negative-pressure system.

4. **Parameters.** Mode, tidal volume or inspiratory pressure, respiratory rate, set minute volume, inspiratory-to-expiratory ratio, flow or I time, fraction of inspired oxygen (FiO_2), and positive end-expiratory pressure (PEEP) are all ventilator settings selected by the clinician. Modes and parameters are discussed in detail later in this section.
5. **Ventilator circuit.** An external circuit, which varies depending on the ventilator, is used to connect the ventilator to the patient. Some transport ventilators use a single-limb circuit, some use a dual-limb circuit, and some incorporate the dual-limb circuit into a coaxial circuit.
6. **Alarms.** Varying types of audio and/or visual alarms warn of ventilator malfunction or parameters outside the set alarm limits. They should be set for each individual patient and *never* disabled. Guidelines for alarm settings are discussed later in this chapter. The most important alarms to monitor for volume-targeted breathing are those for the peak inspiratory pressure (PIP) and the plateau pressure. The most important alarm to monitor for pressure-targeted breathing is the low-minute-volume alarm, which will detect a decrease in tidal volume.

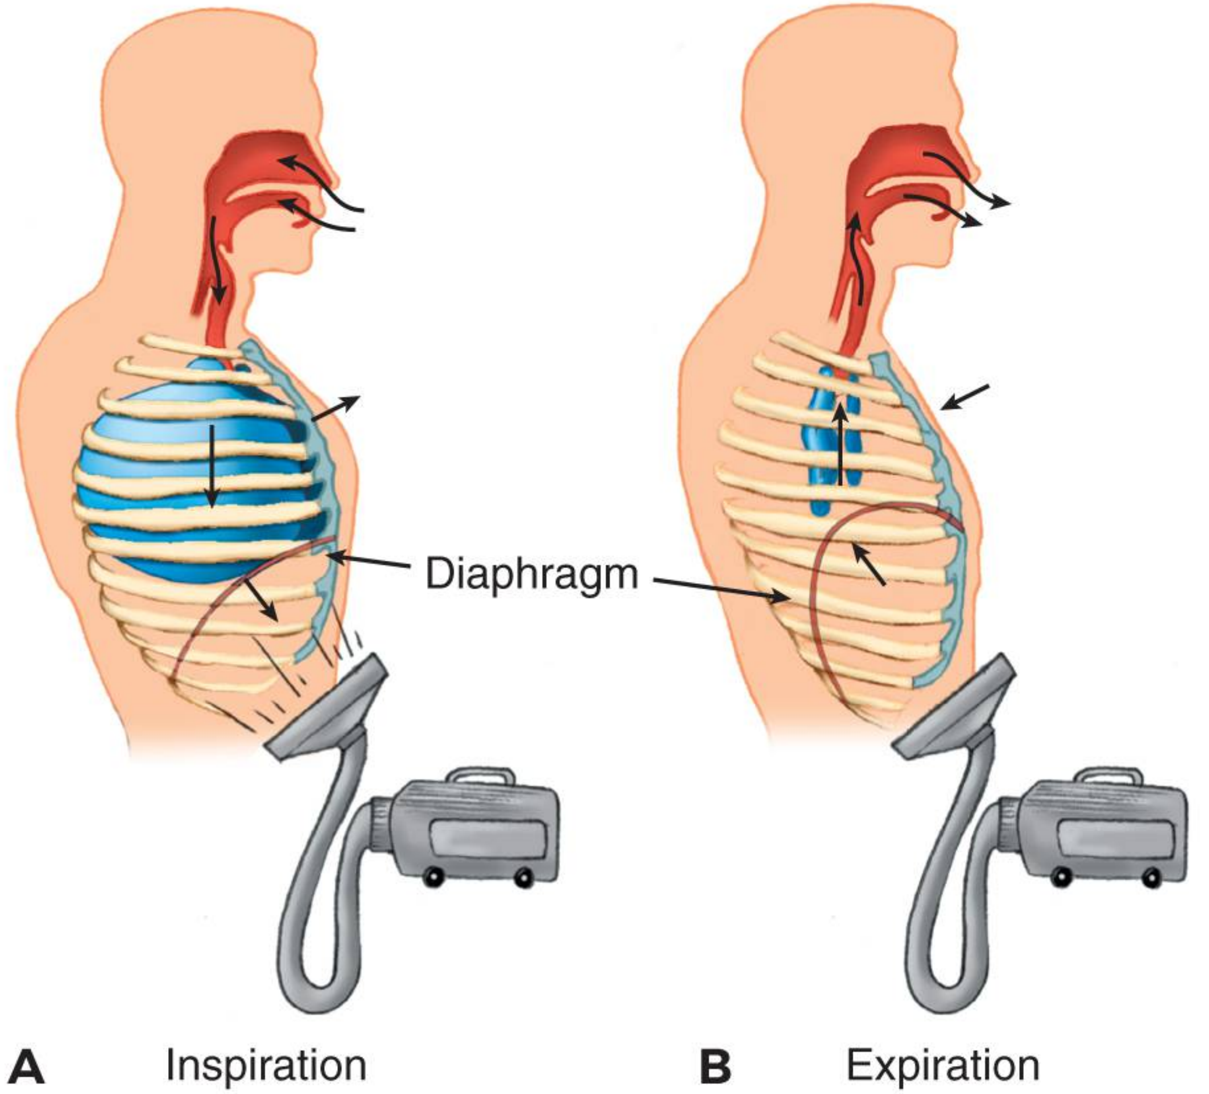

FIGURE 7-2 Normal ventilation is negative-pressure ventilation, which is similar to how a vacuum cleaner works. **A.** The diaphragm contracts, expanding the size of the thoracic cavity and creating the negative pressure to help fill the lungs. **B.** When the pressure is released, the diaphragm relaxes and the lungs empty.

Description

Basic Types of Mechanical Ventilators

Greater use of mechanical ventilation has led to a steadily growing industry to provide these devices. These sophisticated machines may be designed specifically for adult, pediatric, or neonatal patients. Some ventilators safely ventilate only patients up to a certain weight limit, whereas others accommodate patients of all weights. Moreover, these ventilators vary widely in their complexity to accommodate different settings: Some are designed for stationary use, such as in an intensive care unit (ICU) or operating room, and others are portable units for use during transport, whether in the hospital or in the out-of-hospital environment.

Transport ventilators are chosen based on a number of factors. The most important consideration should be the patient population whom the transport team serves. Population characteristics include patient age and weight, patient acuity, type of transport (eg, intrafacility versus interfacility), length of transport, means of transport (ground, rotor aircraft, fixed-wing aircraft), and budget for the equipment and supplies associated with the ventilator.

More sophisticated ventilators may have a flow-sensing device that is attached in close proximity to the patient's airway and transmits information to the ventilator necessary for accurate feedback, allowing the patient to trigger a breath with better synchrony to the ventilator settings. This flow sensor can also provide feedback in the form of pressure, volume, and flow waveforms, allowing providers to adjust the ventilator settings for the specific patient and lungs being ventilated. Pressure/volume and flow/volume loops are available on some of these ventilators, and may be used to visually detect compliance changes, air leaks, and air trapping. Specific training in waveform interpretation is needed to take full advantage of these features.

The transport ventilator's ability to meet a patient's flow demand must be considered prior to use of a specific device. Some transport ventilators are simply unable to meet extremely high flow demands. For example, a patient with severe acute respiratory distress syndrome (ARDS) who is on high levels of PEEP, has a high respiratory rate, and has high pressures may need a transport ventilator that can provide flow ranges from 160 to 240 L/min to effectively oxygenate and ventilate the patient. These higher-flow generators, which are typically turbine driven, are often called blower-driven ventilators. They send gas directly to the output section, and manipulation of a flow control valve enables them to deliver specific ventilator settings. Just as providers should understand the ventilator's ability to meet the patient's needs before connecting the device to the patient, they should also understand the patient's lung condition (if possible) to select the appropriate lung protection strategy.

Transport ventilators can be categorized according to three levels of performance: sophisticated ventilators with features similar to those used in the ICU, midlevel transport ventilators, and simple transport ventilators.

Sophisticated transport ventilators have the following characteristics:

- Turbine/blower driven to reach available flows greater than 150 L/min
- Waveform and loop monitoring available
- Many modes of ventilation available
- Triggering delay less than 100 ms
- Tidal volume control more accurate than with midlevel transport ventilators
- Flow manipulation with rise time (P-ramp) and flow termination in a pressure-delivered breath
- Leak compensation feature
- Measure plateau and auto-PEEP
- Measure static compliance
- Precise F_{IO_2} delivery
- Many alarm settings available
- Allow for hot-swapping of batteries (ie, changing batteries without cutting the power to the unit)

Advantages of sophisticated transport ventilators include the following:

- Deliver consistent ventilator parameters in the presence of dynamic changes in lung mechanics
- Offer performance and modes similar to ICU ventilators
- Provide accurate monitoring and feedback from lung mechanics

- Provide comprehensive alarm settings
- Some are altitude compensated

Disadvantages of sophisticated transport ventilators include the following:

- Extensive training required to master all available functions
- Bias flow during flow triggering may contribute to higher gas consumption (During high-frequency oscillatory ventilation, bias flow is the continuous “background” flow of gas through the ventilator circuit during expiration. When the ventilator detects a deviation in the set flow, a breath is delivered to the patient.)
- Cost

Midlevel transport ventilators have the following features:

- Pneumatic or piston driven
- Typical available flows of 60 to 100 L/min
- Simple user interface
- Basic scalars available
- Mediocre trigger performance
- Triggering delay greater than 120 ms
- Selective F_{IO_2} delivery
- Lower pressurization performance

Advantages of midlevel transport ventilators include the following:

- Simple user interface
- Basic modes available
- Lower cost

Disadvantages of midlevel transport ventilators include the following:

- Challenging to ventilate patients with poor-compliance and high-resistance lung conditions
- Can create distress in the air-hungry patient receiving noninvasive ventilation

Simple transport ventilators have the following features:

- Pneumatic or compressor driven
- Basic ventilator settings

Advantages of simple transport ventilators include the following:

- Lowest cost
- Ease of use
- Less training required
- Useful during CPR

Disadvantages of simple transport ventilators include the following:

- F_{IO_2} may be fixed
- Poor trigger performance
- Minimal alarms

It is important to know the battery life for each transport ventilator you are managing. According to the American Association for Respiratory Care, transport ventilators should have a minimum of 4 hours of battery life. Many factors affect battery duration, including the patient's pressure or volume, the respiratory rate, the PEEP level, the temperature of the operating environment, and the number of charge cycles the battery has been through. Always check the manufacturer's information on the battery life before operating the ventilator. The ventilator should be plugged into an appropriate external AC power source whenever possible.

Another transport concern is oxygen tank duration. Many variables contribute to oxygen consumption—most importantly, how much F_{IO_2}

the patient requires. The lower the FIO_2, the less oxygen that will be used. The next most important concern is the minute volume the patient requires, which is calculated as respiratory rate × exhaled tidal volume. Some ventilators use a bias flow throughout the breathing cycle to augment patient triggering, which in turn increases oxygen consumption.

The critical care transport professional (CCTP) is responsible for becoming familiar with the operating characteristics, capabilities, and features of the ventilator being used and to troubleshoot and adapt as necessary. The goal when applying any mechanical ventilation is to maximize the potential benefit and to minimize any potential harm to the patient. Planning each trip on a case-by-case basis will ensure patient safety and comfort.

Noninvasive Ventilation Methods

For years, conventional ventilation required **invasive ventilation** by placing an artificial airway—chiefly the ET tube or a tracheostomy tube. Because of the hazards and complications associated with ET tubes, however, other interfaces began to emerge. Mouthpieces and masks of varying sizes and styles were attached to conventional ventilators, giving rise to "noninvasive" ventilation. By definition, **noninvasive ventilation** is any form of mechanical ventilation without an artificial airway. It includes methods such as **high-flow nasal cannula (HFNC) therapy**, **continuous positive airway pressure (CPAP)**, and **bilevel positive airway pressure (BPAP)**, which deliver a preset pressure or volume to the lungs during a preset or spontaneous breathing pattern.

This chapter focuses primarily on invasive ventilation techniques. Because emergency medical services (EMS) providers are quite familiar with most noninvasive techniques, they are not detailed in this chapter. However, the more advanced noninvasive techniques—HFNC therapy, CPAP, and BPAP—warrant a brief discussion.

In broad terms, each of these techniques has a primary indication. HFNC therapy is most appropriate for patients with purely hypoxemic respiratory failure. CPAP is typically selected to treat hypoxia associated with increased work of breathing. BPAP, commonly referred to by the brand name BiPAP, is extremely effective for patients with hypercarbic respiratory failure.

Nasal Cannula Therapy

When caring for the acutely hypoxic patient, it is common practice to place the patient on supplemental oxygen via a nasal cannula with liter flows ranging from 1 to 6 L/min, often referred to as a low-flow nasal cannula (LFNC). The oxygen percentage that the patient receives with this setup is limited by the patient's minute volume; it is a fixed liter flow of oxygen applied to the variable rate and depth that the patient is breathing on room air (21%). The estimated percentage of $\mathrm{FIO_2}$ a LFNC can deliver at 1 to 6 L/min would be 0.24 to 0.44 $\mathrm{FIO_2}$. If the patient requires more $\mathrm{FIO_2}$, the clinician may try to deliver 35% to 55% oxygen with a simple face mask, 85% to 95% with a nonrebreathing mask, or 100% using an HFNC.

Because of the design of these devices, they cannot create any measurable pressure to provide some level of CPAP, nor do they decrease the work of breathing. Instead, they are designed solely to deliver supplemental oxygen to the patient and do nothing to aid in ventilation.

Furthermore, administering a dry gas such as oxygen can dry out the mucosa within the nasal passages and lungs, potentially causing mucus plugging. Providers should avoid any potential for formation of a mucus plug because it may cause severe hypoxemia due to a $\dot{V}/\dot{Q}$ mismatch. This possibility is especially concerning in a patient with excessive secretions, as occurs in bacterial/viral pneumonia.

The best choice for a more comfortable delivery and precise $\mathrm{FIO_2}$ target might be an HFNC. Initially introduced under the brand name Vapotherm, these devices can deliver flows of up to 60 L/min of humidified oxygen through a larger-lumen nasal cannula; they reduce both inspiratory resistance and work of breathing by providing flows that exceed the patient's demand. Such a device is designed with an oxygen blender that delivers 0.21 to 1.0 $\mathrm{FIO_2}$ as well as providing heat and humidification through a special cartridge that pulverizes the water molecules to ensure greater patient comfort. The HFNC requires external AC power and a source of oxygen at 50 psi and medical air at 50 psi to be blended to provide a predetermined F_{IO_2}.

Used to treat hypoxic respiratory failure, HFNCs deliver high flow rates that equate to a form of noninvasive ventilation. The high oxygen flows required typically have made HFNC therapy impractical for use during interfacility transports, but prototypes suitable for EMS and critical care transport (CCT) use are in development. The potential need to transport a patient being treated with HFNC therapy makes it important for the CCTP to be familiar with this form of respiratory support.

HFNC therapy uses soft, large-bore nasal prongs (cannulas), humidification and heating mechanisms, and a gas blender. Heating and humidification are accomplished by placing a heater/humidifier similar to those used on mechanical ventilator circuits in line with the HFNC. The delivered gas is a blended mixture of compressed air and oxygen, set from 0.21 to 1.0 F_{IO_2}, that runs through the heater/humidifier, where it is warmed to body temperature and humidified to approximately the same 80% to 90% humidification seen physiologically with air inspired through the mouth and nose. The heating and humidification remedy the major causes of discomfort associated with conventional oxygen therapy: The added moisture can help to liquefy mucus and facilitate expectoration. The high flow washes out nasopharyngeal dead space, improving ventilation and oxygenation. Moreover, some level of PEEP, which is difficult to quantify, results from the high flow. Theoretically, every 10 L/min of gas flow generates PEEP of 1 cm H_2O. This PEEP (or CPAP) effect also decreases the work of breathing and improves oxygenation.

Initiation and titration of HFNC therapy have not yet been studied extensively. Application of this technology typically uses the maximum flow: 40 to 60 L/min for adults, depending on the brand of equipment used, and up to 8 L/min for infants. F_{IO_2} should initially be set at 1.0 (100%). The flow can be adjusted for patient comfort and to target respiratory rates between 25 and 30 breaths/min in adults. Before weaning the patient from the flow, F_{IO_2} should be gradually decreased to at least 0.4 (40%). Once F_{IO_2} reaches 0.4, the flow can be decreased, typically in increments of 5 L/min, with effects continuously assessed. The temperature of the circuit is usually set to normal body temperature (37°C [98.6°F]) but can be adjusted up or down for comfort. Patients are often more comfortable with a setting lower than body temperature.

Neonatal and pediatric populations have also benefited from the favorable effects of the higher flows delivered by HFNC. Proper fit, flow levels, and oxygen concentration are even more essential in these populations due to their fragility. Much discussion has focused on the optimal flow for these younger patients. The range that is typically considered is 2 to 8 L/min, titrated to decrease the patient's work of breathing and optimize oxygenation status. Recent guidelines for flow selection have included using 1 to 2 L/kg/min as a starting point with a maximum flow rate set.

HFNC therapy can be used as a bridge to support the patient's respiratory status while other therapies and medications are being administered. In the face of respiratory distress, the goal is to prevent respiratory failure while using the least invasive methods. Some common conditions that may benefit from early application of HFNC therapy include bronchiolitis, respiratory syncytial virus, asthma, and postextubation somnolence.

There is some debate over the application of HFNC and how much PEEP it may create, as the PEEP level is difficult to measure when this therapy is applied. Many variables may increase the level of pressure in the lungs, including the applied flow and the use of open- versus closed-mouth breathing. In addition, the patient's size and current lung condition play major roles in how much PEEP the lungs may receive. However, HFNC therapy has been shown to increase **functional residual capacity** and contribute to washing out physiologic dead space.

People normally rebreathe approximately one-third of their exhaled breath. Therefore, a major benefit of the high flows provided by HFNC is to provide continuous fresh gas to the airways, allowing for the presence of more oxygen and less carbon dioxide in the lungs.

This action makes this modality a good choice for patients who present with COPD exacerbation or with hypercarbia and hypoxia. Specifically, patients with the following conditions may benefit from HFNC therapy:

- COPD, including emphysema
- Pneumonia
- Coronavirus disease 2019 (COVID-19)
- Asthma exacerbation
- Pulmonary fibrosis
- Cystic fibrosis
- Lung cancer

This approach may also be useful in providing comfort care or preoxygenating patients for rapid sequence intubation.

Thorough planning for the transport of a patient on HFNC therapy is imperative. The high flows required to support this modality present a challenge during transport because the quantity of gas available is limited and, therefore, time sensitive. Some suggested solutions are to carry more oxygen, reduce the flow if tolerated, and/or reduce the F_{IO_2} if tolerated. Heat and humidification are essential when applying such high concentrations of oxygen at high flows. Several manufacturers offer options to account for this added challenge **FIGURE 7-4**.

If ventilation cannot be maintained in a patient on an HFNC, the gas flow may be increased to meet the patient's demands. However, a patient who is still experiencing respiratory distress may be heading toward respiratory failure, and the decision needs to be made to change modalities. CPAP or BPAP are often viable alternatives. CCTPs should consult with medical control when making this decision.

Another device that is popular in neonatal and pediatric patients is the RAM cannula. This nasal cannula has a 15-mm adapter on the end and can be attached to a ventilator circuit. Considered an interface to deliver noninvasive ventilation, it is often applied in the transport arena and can lead to successful results when used with the appropriate patient population. Using a RAM cannula as an interface with a transport ventilator allows the provider to deliver two levels of pressure with a respiratory rate applied.

While it is possible to transport most HFNC assemblies, doing so can be challenging. The heater/humidifier will require AC power, and the HFNC device requires a level and secure platform to ensure the heater/humidifier remains upright. The high gas flows necessitate large cylinders of both oxygen and compressed air, both connected to a blender that facilitates F_{IO_2} titration. In most cases, trying to move a HFNC setup is neither practical nor recommended. When impractical, the CCTP will need to choose an equivalent device to provide respiratory support during transport.

Combining a nonrebreathing device with a nasal cannula might be sufficient to match a given HFNC flow and F_{IO_2}, especially when the HFNC settings are not maximized. **Pulse oximetry** is a necessity for continual monitoring. Not to be overlooked in a patient with HFNC is the PEEP effect. A patient on HFNC at 50 L/min is likely receiving 5 cm H_2O of PEEP from the gas flow. Switching to a nonrebreathing mask might provide the same amount of oxygen, but if the PEEP had served to reduce the work of breathing and improve oxygenation, loss of those benefits might not become evident for 15 to 20 minutes, which would probably coincide with the beginning of the actual transport.

A more suitable replacement for HFNC therapy is CPAP. CPAP or BPAP, when delivered using a transport ventilator, allows providers to adjust the FIO_2 level and enables some degree of PEEP to continue. Disposable CPAP devices can deliver equivalent PEEP but, depending on the manufacturer, may not be able to deliver adequate FIO_2. These units entrain a significant amount of atmospheric air to achieve the gas flows needed, thereby lowering the delivered FIO_2. Adding a nasal cannula under a disposable CPAP mask might provide an adequate level of FIO_2.

Continuous Positive Airway Pressure

Introduced to the medical community in 1971, CPAP found its niche in neonatal ICUs, supporting premature newborns with respiratory distress resulting from underdeveloped lungs. Ten years later, it was tried experimentally in adults with obstructive sleep apnea who, until then, underwent tracheostomies to avoid apnea-related asphyxiation. Today, CPAP is the primary therapy for both premature neonates and people of all ages with obstructive sleep apnea. CPAP indications have also expanded to include acute pulmonary edema (APE) plus a wide variety of clinical conditions associated with acute shortness of breath.

The physiologic action of CPAP involves continuous positive pressure applied to the upper airway. The “continuous” aspect of CPAP implies that the pressure remains the same regardless of whether the patient is inspiring or expiring. Airway pressure applied during expiration increases the work of breathing, depending on the pressures used. Higher pressures may interfere with exhalation. Despite the slightly increased work needed to breathe against CPAP during exhalation, the overall effect is a significantly decreased work of breathing owing to its benefits during inspiration and on the airways themselves.

Use of CPAP for APE illustrates a dramatic, immediate, and effective application for CPAP. APE can result from a variety of conditions but is most commonly associated with right-side heart failure resulting from left-side heart failure. In patients with heart failure, significantly elevated pulmonary vascular pressures cause fluid to leak from the pulmonary vessels into the airways. In what is often described as “flash” pulmonary edema, pulmonary vascular fluid quickly fills the terminal airways. CPAP offers multiple benefits for patients with APE, with clinically significant improvement usually seen within the first minute following its application.

For patients with APE, CPAP prevents additional fluid from leaking out of the pulmonary vessels and entering the airways through the creation of a continuous, positive-pressure gradient. Theoretically, CPAP may force fluids congesting the lower airways back into the pulmonary blood vessels. At a minimum, it assists in splinting lower airways open, thereby preventing the collapse of the fluid-filled airways. CPAP also leads to a significant reduction in transpulmonary pressure—the pressure needed inside the chest to draw air into the lungs. In a healthy person, transpulmonary pressures of negative 1 or negative 2 cm H_2O are sufficient to draw air into the lungs. In the presence of significant obstruction caused by fluids, secretions, mucus plugs, or bronchial spasm, however, pressures as high as negative 8 cm H_2O may be needed to inhale. These negative pressures produce retractions in the chest musculature, a telltale clinical finding associated with APE.

In APE, the left ventricle is ejecting blood against a high afterload. Elevated blood pressure, added to a high transpulmonary pressure, is the root cause of the pulmonary edema seen in this condition: The heart simply cannot overcome the resistance it is pushing against. CPAP directly lowers transpulmonary pressures, as seen in **FIGURE 7-5**. The seemingly small decrease in transpulmonary pressure achieved with CPAP is such a powerful force in reducing afterload that patients with APE often improve within seconds following initiation of CPAP. Clinical outcomes are improved through the combined effects of improving oxygenation through oxygen delivered with continuous positive pressure and splinting open terminal airways.

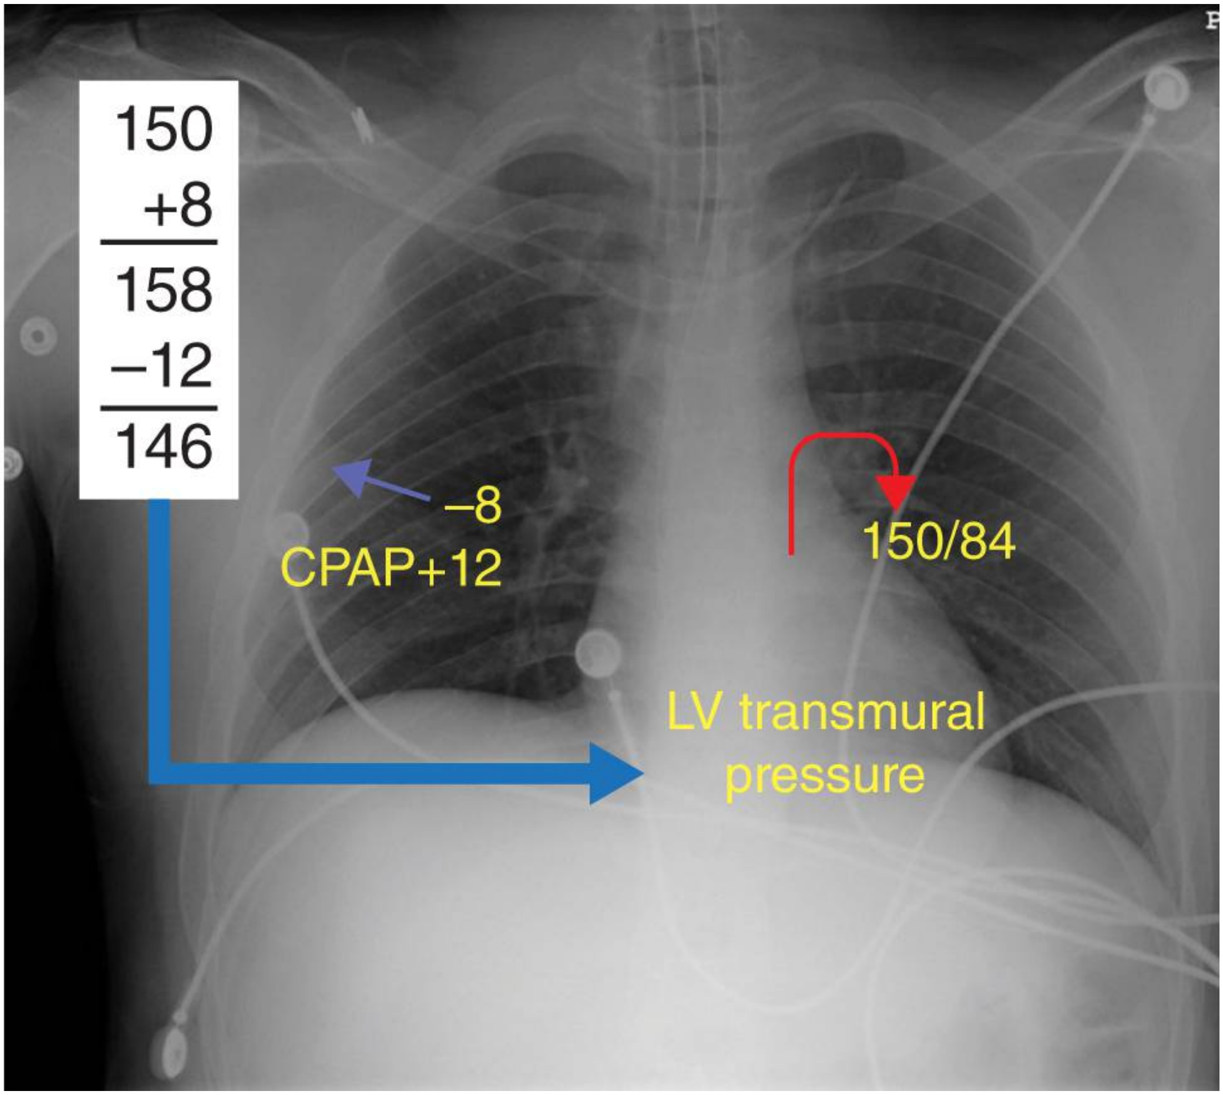

FIGURE 7-5 Transpulmonary pressure in acute pulmonary edema includes systolic blood pressure of 150 (afterload) plus the increased inspiratory force of −8 (normal is −1 to −2). Continuous positive airway pressure quickly reduces both afterload and the work of breathing by lowering the transpulmonary pressure.

Abbreviation: LV, left ventricular

Bilevel Positive Airway Pressure

BPAP, as *bi*level would imply, delivers two different pressures: an inspiratory positive airway pressure (IPAP) and a lower, expiratory positive airway pressure (EPAP). This method allows a higher pressure to be delivered during inspiration, and a lower pressure during expiration, thereby reducing the work of exhaling. The difference between the pressures, a value called pressure support or delta P, is directly related to the patient's tidal volume. The greater the difference in pressures, the higher the patient's tidal volume is likely to be. The ability of BPAP to increase tidal volumes, and thereby lower carbon dioxide levels, is what most differentiates this approach from CPAP. BPAP offers the same support as CPAP, but with the added benefits of further decreasing the work of breathing during exhalation and improving tidal volumes; thus, it clears more carbon dioxide from the patient's respiratory system compared to CPAP. It is a reasonable alternative for patients who are unable to tolerate CPAP, those who require high CPAP pressures, and those whose respiratory failure is primarily related to hypercarbia (high carbon dioxide levels).

The most significant issue with BPAP is apnea induced by higher levels of pressure support than a patient requires. This condition can occur on initial setup or if a patient's respiratory status recovers during transport. All ventilators and machines configured to deliver BPAP monitor respiratory rates and, if they detect apnea, are preset to initiate mechanical ventilation. This level of monitoring and backup support is not available on disposable BPAP units, however. In consequence, providers should remain hypervigilant when using BPAP without respiratory rate monitoring and apnea ventilation capabilities.

BPAP can present a challenge to providers when they are selecting and subsequently adjusting the IPAP and EPAP settings. The IPAP is always set higher than the EPAP; most references suggest an initial IPAP setting of 8 to 10 cm H_2O and EPAP of 3 to 5 cm H_2O. Increasing the IPAP will clear more carbon dioxide, whereas increasing the EPAP will improve oxygenation (in the same way that increasing CPAP pressures improves oxygenation). Patients who are intolerant of high EPAP levels may benefit from an increased IPAP level.

Negative-Pressure Ventilators

During the polio epidemics of the 1950s, iron lungs were commonly used to ventilate patients experiencing the respiratory effects of this disease. Recall that in normal spontaneous breathing, a breath is initiated by a drop in the transrespiratory pressure gradient. **Negative-pressure ventilators** operate in the same way. A negative pressure is transmitted by the ventilator to the chest wall, thereby enabling **inspiration**.

The original iron lung is no longer used, but has instead been replaced by smaller, more convenient devices. The two devices most commonly used as negative-pressure ventilators are the cuirass, or turtle shell, and the poncho type. The cuirass resembles a chest plate of armor and is strapped onto the patient's chest **FIGURE 7-6**. A hose connected to the ventilator sucks on the chest during inspiration. In contrast, the poncho requires a lightweight frame that is fitted onto the patient's chest, with a lightweight airtight jacket placed over the patient's frame. The ventilator hose is then attached to the jacket. Both the cuirass and the poncho require that a tight seal be maintained.

These negative-pressure ventilators are sometimes used in acute care facilities, but are more often used in rehabilitation and long-term care facilities or in the home. They are used chiefly on patients with neuromuscular diseases who still have airway control.

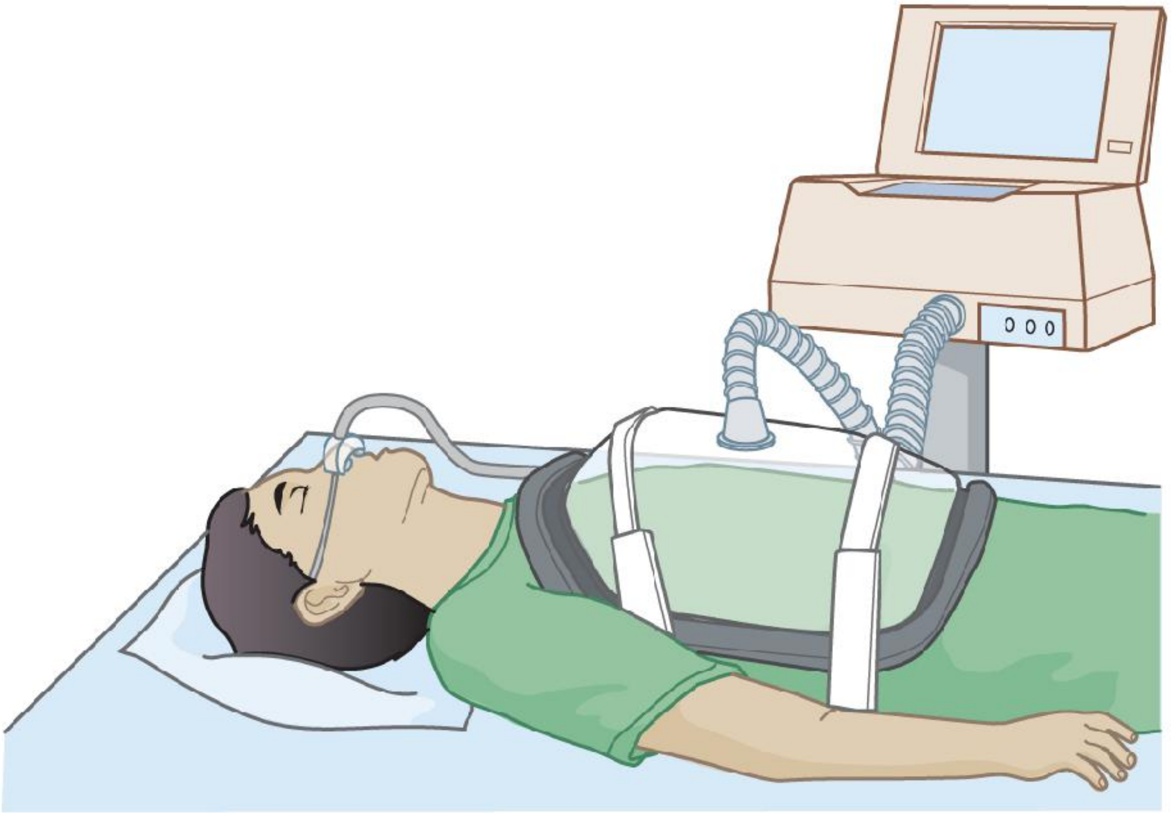

FIGURE 7-6 Biphasic cuirass ventilation.

Positive-Pressure Ventilators

Positive-pressure ventilators are more prevalent than negative-pressure ventilators. With these devices, the tidal volume is delivered at pressures greater than ambient pressure; thus, the process is paradoxical to spontaneous breathing.

Several potential hazards are associated with this type of life support. Pulmonary **barotrauma** is of major concern because it can lead to pneumothorax, subcutaneous emphysema, pneumomediastinum, and pneumoperitoneum. Another major concern while applying positive pressure to the lungs is **volutrauma**, defined as trauma from excessive lung inflation volumes. Volutrauma is typically a result of overdistending the alveoli. It may occur at minimal tidal volumes due to regional differences in compliance within the lungs. This concern often arises in patients with ARDS because their lung compliance is poor, their airway resistance is high, and heterogeneous lung injury is likely. Positive pressure will overdistend the compliant alveoli, causing volutrauma. Strategies to minimize these complications are discussed later in the chapter. The main consideration is keeping plateau pressures below 30 cm H_2O.

CONTROVERSY

Barotrauma, injury due to excessive pressure, is often considered synonymous with *volutrauma*, injury resulting from excessive volume. Both terms remain in use, although barotrauma is more frequently used when referring to injury resulting from overdistention in the lungs.

Positive-pressure ventilators come in various sizes, power sources, and capabilities, and can be as small and portable as a laptop computer or as large as a desk. Institutions typically select ventilators based on their capabilities and patient needs, as well as their cost and operational factors **FIGURE 7-7**.

FIGURE 7-7 A critical care ventilator.

© Yon Marsh/Alamy Stock Photo.

Positive-pressure ventilators are often described in terms of which variable the clinician controls to terminate the inspiratory phase of the breath. A **pressure ventilator** ends the delivery of the tidal volume based on the pressure preselected by the clinician. With a **volume ventilator**, the breath ends when the predetermined tidal volume is achieved. A **flow-cycled ventilator** ends inspiration when a predetermined **flow rate** is achieved, and a **time-cycled ventilator** ends inspiration after the selected inspiratory time has been achieved. Many of the ventilators in use today allow clinicians to choose which variable terminates the inspiratory cycle, while focusing on patient comfort/synchrony and patient safety. Each of these variables may have a unique benefit to accomplish oxygenation and ventilation but may be accompanied by some limitations. Understanding how each variable works and interacts with patient demand is of utmost importance.

When working with pressure ventilators, remember that the machine terminates inspiration when a preset pressure is reached. Therefore, if the patient is biting down on the ET tube or the patient's airway is obstructed with mucus, the ventilator will still deliver the pressure, but the tidal volume will be significantly decreased. Increased airway resistance and decreased thoracic compliance will also produce this effect. Careful monitoring of breath sounds, oxygen saturation, and $ETCO_2$; visual inspection for adequate chest expansion; and monitoring delivered tidal volume and exhaled minute volume are essential when pressure ventilation is being used. Some ventilators have extensive alarm settings that allow for monitoring minute volume and tidal volumes. When using pressure ventilation, it is strongly suggested that these alarms be used and set to tight ranges to prevent any large deviations from targeted minute volumes.

Volume ventilators deliver a preset volume using varying pressures. The pressure required by the ventilator depends on the size of the tidal volume, flow rate, airway resistance, and lung–chest wall compliance. Because volume ventilators use different pressures, it is important that the CCTP monitor the **peak airway pressure**. The high-pressure alarm will sound if excessive pressures are being used to deliver the tidal volume. This alarm is set at approximately 10 cm H_2O greater than the patient's average peak pressure. Secretions, bronchospasm, and a decrease in thoracic/pulmonary compliance may all result in increased airway pressures. Peak airway pressures may also rise when the patient is asynchronous with the ventilator ("bucking the vent") or is experiencing auto-PEEP. Continuous monitoring and trending of the peak pressure values are extremely important while caring for the patient who is being mechanically ventilated. In any event, an increased PIP requires immediate attention to detect and resolve the issue.

All ventilators, regardless of type, rely on an external circuit that connects the ventilator to the patient. Intrinsic to this circuit is some method for venting the patient's exhaled gas to the environment. On some ventilators, this is accomplished through the exhalation limb of the circuit connected to the ventilator; an internal exhalation valve then regulates exhalation as well as PEEP. Other ventilators use an external exhalation valve.

It is strongly recommended that each circuit be equipped with an in-line heat-moisture exchanger, placed close to the ET tube. This device also acts as a bacterial/viral filter. Note that adding anything proximal to the ET tube will increase dead space to the circuit and may increase $Paco_2$ levels to a slight extent. This possible increase is of particular importance in the neonatal and pediatric populations.

In every case, a closed system must exist between the ventilator and the patient. Any loose connections, cracks, or disconnections will result in ventilator malfunction and can be life threatening. The integrity of the patient–ventilator connection via the circuit, as evidenced by the pressure, should be checked per the manufacturer's procedure and visually inspected throughout transport, and all clinicians operating the ventilator should be familiar with the process of troubleshooting these connections. In the CCT environment, it is imperative that the CCTP read and understand the alarms and troubleshooting guide in the ventilator's operation manual. Each ventilator may display specific codes to identify potential problems and classify their priority level. Some manufacturers' manuals include guidance on potential remedies to correct the alarm. This information should be readily available to the CCTP in the event of an alarm trigger.

A major concern relating to the positive pressure exerted during mechanical ventilation is the effect it has on the patient's hemodynamics. Hypovolemia, high levels of PEEP, and increased **mean airway pressure (MAP)** values may all contribute to hemodynamic compromise. This issue is often overlooked and needs to be monitored closely.

- Positive-pressure ventilation increases intrathoracic pressure, which can result in barotrauma or volutrauma (pneumothorax).
- An increase in intrathoracic pressure can result in reduced venous return to the right side of the heart, leading to a reduction

in right ventricular output associated with alveolar inflation that compresses the pulmonary vascular bed.

- The diminished venous return to the right side of the heart leads to poor cardiac output, and possibly hypotension.
- Reduced hepatorenal blood flow may mislead the body into believing it is volume depleted, resulting in changes in hormone levels, such as increased vasopressin and aldosterone activity and decreased levels of atrial natriuretic hormone. All of these changes result in fluid retention.

There is no one-size-fits-all approach to mechanically ventilating patients. Protocols and guidelines offer general guidance, but ultimately a strategy should be developed on a case-by-case basis. The main goal when mechanically ventilating any patient is to support their respiratory needs while focusing on safety and comfort.

Special Populations

Pregnant patients at term have an increased (by approximately 40%) tidal volume and live in a state of compensated respiratory alkalosis. Keep this factor in mind when adjusting ventilator settings.

Calculating Oxygen Cylinder Duration

When oxygen administration is required, how long the available oxygen supply will last is a critical consideration. Although many reliable apps are readily available that you can use on your computer or smartphone, it remains important to learn the following formula to calculate tank duration:

Oxygen tank time (min) = Tank pressure (psi) × Tank conversion factor ÷ Flow rate (L/min)

where the oxygen tank conversion factors are as follows:

D tank = 0.16

E tank = 0.28

G tank = 2.41

H or K tank = 3.14

M tank = 1.56

For example, suppose the patient is on a nonrebreathing mask running at 15 L/min. Your D tank has a 1,600 psi reading on the gauge. To calculate time in minutes until the tank is completely empty, you would perform the following calculation:

1,600 psi × 0.16 ÷ 15 L/min = 17 min

It is recommended that you subtract 500 psi from the tank pressure as a safety factor when using this formula. Thus, in the preceding example, the tank time would more safely be calculated as a little less than 12 minutes: 1,100 psi × 0.16 ÷ 15 L/min = 11.7 min.

Knowing the tank size is crucial. Keep this chart of conversion factors available to calculate oxygen cylinder duration prior to launching the mission. Some ventilators may have an oxygen cylinder duration feature that requires input from the provider.

Ventilator Modes and Parameters

Volume and pressure are often thought of as modes the CCTP can choose when setting up a ventilator. In reality, both volume and pressure are flow targets set to determine when the ventilator should end the inspiratory cycle. Ventilator *modes* describe the *types* of breaths being delivered to the patient—that is, whether the breath is a mandatory or machine breath or a spontaneous breath. Ventilator *parameters* refer to the other settings that may be adjusted and should be monitored continuously by the clinician. The availability of modes, alarms, and other parameters can vary from machine to machine. The basic considerations are discussed in the following sections.

Modes

The various modes of mechanical ventilation may ensure a particular minute ventilation rate and control the work associated with the patient's spontaneous breathing efforts. The result is an alphabet soup of acronyms that can be confusing to the novice ventilator user. You may encounter a situation where you are picking up a patient who is on a ventilator mode with which you are unfamiliar. For every CCTP, it is important to understand what the patient's pulmonary status is and why they were placed on this particular mode. If possible, involve the patient's respiratory therapist in the process of transitioning the patient to your ventilator. Strategies for changing patients to transport ventilators are discussed in detail later in this chapter. Note, however, that not all ventilators have all modes available. As technology changes at a rapid pace, you will find more transport ventilators able to mirror the more advanced modes commonly available on hospital ICU ventilators. **TABLE 7-1** lists the most common modes of ventilation.

TABLE 7-1 Modes of Mechanical Ventilation

Mode	Definition	Indication
Control, or continuous, manual ventilation (CV)	Ventilator delivers a specific set respiratory rate and volume or pressure, controlled by the ventilator. The patient is not allowed any other breaths. (Rarely used mode.)	Used when a specific minute volume is required, such as with a head injury. Can also be used when a patient is fighting, or bucking, the ventilator. The respiratory center is controlled by using a neuromuscular blockade agent and sedation.
Assist/control (AC)	The ventilator guarantees a minimum breath rate or flow. The patient is allowed to breathe over the set rate, but each breath is at the preset tidal volume or preset pressure. Requires properly setting the **sensitivity** (the ventilator control that regulates the amount of negative pressure or flow required by the patient to initiate, or trigger, a breath).	Controls the work of breathing, but allows the patient to set their own respiratory rate. Be aware of the potential for air trapping in the patient with tachypnea.
Synchronized intermittent mandatory ventilation (SIMV)	A set respiratory rate and tidal volume or pressure are delivered and synchronized with each patient-initiated breath. Each patient breath is at the patient-initiated volume. The machine will deliver a preset number of mandatory breaths. All other breaths are spontaneous breaths at the patient’s own rate and depth.	Allows the patient to assume some or most of the work of breathing, depending on the mandatory rate. Can also be used as a weaning technique and is often combined with pressure support to overcome airway resistance within the airways, ventilator circuit, and ET tube. The pressure support does not have an inspiratory time attached to it. Careful monitoring of the exhaled volume on the pressure support breath is important; titrate the pressure support for desired volumes.

Mode	Definition	Indication
Pressure control ventilation (PCV)	The machine is set to deliver a preset pressure rather than a preset volume. The PIP or PAP is set and flow is delivered until the set PIP or PAP is reached. Tidal volume may vary significantly with changes in patient pulmonary status.	Used when volume ventilation requires too much pressure, such as in acute respiratory distress syndrome. Commonly used in conjunction with inverse-ratio ventilation (see below). One of the lung-protective strategies. A suggested strategy when fixing a plateau pressure.
Pressure-regulated volume control ventilation (PRVC)	The machine will deliver the desired tidal volume at the least amount of pressure using a decelerating waveform.	Used when both pressure and volume regulation are needed.
Inverse-ratio ventilation	The ventilator is set so that the inspiratory phase is longer than the expiratory phase.	Used to increase oxygenation when the FIO_2 is too high (>0.60). Must ensure that all volume is exhaled to prevent breath stacking and hyperinflation. Often used with PCV. The patient should be sedated or paralyzed.
Pressure support	A clinician-selected amount of positive pressure augments a spontaneous breath. There is no set inspiratory time in a pressure support breath.	Used to augment a spontaneous breath. The pressure overcomes the superimposed resistance of the airway and ventilator circuit and improves lung compliance. The patient must be able to initiate a breath.
Continuous positive airway pressure (CPAP)	The baseline pressure for spontaneous breathing is raised above the ambient pressure, increasing both oxygenation and the mean airway pressure.	Improves oxygenation during spontaneous breathing by increasing functional residual capacity. May also increase lung compliance.

Mode	Definition	Indication
Bilevel positive airway pressure (BPAP)	CPAP with the ability to sense inspiration and deliver additional positive pressure. An inspiratory and expiratory pressure is set. A respiratory rate may be added on some ventilators.	Improves oxygenation and ventilation with spontaneous breathing.
Airway pressure release ventilation (APRV)	Uses an inverse I:E ratio strategy. Allows the patient to breathe throughout the respiratory cycle.	Used for acute lung injury, acute respiratory distress syndrome, and atelectasis.
Adaptive support ventilation (ASV)	Maintains an operator-set minute volume percentage and automatically determines an optimal tidal volume/respiratory rate combination based on the Otis equation (calculated by the ventilator).	Full or partial support with low PIP and guaranteed minute volume.

Abbreviations: F_{IO_2}, fraction of inspired oxygen; I:E ratio, inspiratory-to-expiratory ratio; PAP, pressure above positive end-expiratory pressure (PEEP); PIP, peak inspiratory pressure

© Jones & Bartlett Learning.

A potentially confusing concept in mechanical ventilation is the mode of ventilation. With more than 170 different names being used for modes, medical professionals have a wide range of choices available. Providers must understand that no one mode fits all situations; all contributing factors must be considered before choosing an appropriate mode. Knowing how the specific lung condition will respond to positive-pressure ventilation is paramount.

The CCTP must be able to safely control the ventilator to increase or decrease oxygenation, adjust ventilation, or liberate the patient from the ventilator. Simply put, a mode can determine whether the delivered breaths are volume or pressure targeted, whether the breaths are mandatory (set) or spontaneous, or a combination of the two, and which situational effects can trigger a change in ventilator response. The main concerns when choosing a mode are ensuring patient safety and comfort (referred to as patient synchrony with the ventilator) and implementing a lung-protective strategy that meets the desired oxygenation and ventilation goals.

Airway Pressure Release Ventilation

Whether referred to as airway pressure release ventilation (APRV) or a different name, such as BiLevel, BiVent, BiPhasic, DuoPAP, or BPAP, the same basic concept is at work with this strategy: using high levels of CPAP with a brief, intermittent release in pressure while applying an inverse **inspiration-to-expiration (I:E) ratio**. Used primarily for patients with severe ARDS, this mode has also demonstrated positive results when implemented for patients in the early stages of ARDS. Once ARDS progresses, the vascular permeability increases and the edema fluid that enters the alveoli will wash out the surfactant and cause further lung instability. In the face of this lung instability, homogenous ventilation is difficult to achieve with a conventional mode that has typical inspiratory times less than 1 second. Some alveoli may need more time to open effectively, allowing gas exchange to take place. This is where the benefits of APRV come into play.

The longer inspiratory times with APRV give the damaged or collapsed alveoli the opportunity to participate in the gas exchange process. The patient may also breathe spontaneously throughout the breathing cycle, which is more comfortable for the patient than inverse-ratio ventilation.

Typical ventilator settings for APRV are a high pressure (P-high) that is sufficient to recruit the alveoli and regain any functional residual capacity. Aim for a P-high with a desired plateau pressure of 20 to 30 cm H_2O. Time high (T-high) should be set equal to 90% of one breath cycle, typically 4 to 6 seconds. Pressure low (P-low) should always be set to 0 cm H_2O. If time low (T-low) is set appropriately, there will always be some PEEP remaining at end expiration. The T-low is the most important setting. It should be set at 75% of the peak expiratory flow rate, which is difficult to accurately measure unless you have high-resolution flow graphics and the ability to freeze the trend and measure the expiratory flow to isolate the 75% mark. Typically, the T-low is less than 5 seconds.

APRV settings may appear as follows:

P-high: 25 cm H_2O

P-low: 0 cm H_2O

T-high: 5 s

T-low: 0.4 s

F_{IO_2} titrate for saturation greater than 92%

If you achieve the optimal P-high setting, then the T-high setting becomes the means of adjusting oxygenation and ventilation. Lengthening the inspiratory time would aid in oxygenation by holding the alveoli open longer and increasing the surface area at the alveolar-capillary membrane. Shortening the inspiratory time would increase the number of releases and, therefore, increase the minute volume. By changing these settings, you can fine-tune the adjustments for ventilation. The patient's spontaneous breaths will also contribute to the minute ventilation. If your ventilator does not have this mode of ventilation, do not attempt to change the mode—a weaning process must occur before any changes are made. Any deviation from this mode should be further discussed with the provider managing the patient and your medical control.

Adaptive Support Ventilation

Adaptive support ventilation (ASV) is a closed-loop controlled mode that receives feedback related to the patient's lung mechanics and makes adjustments to the pressure applied and respiratory rate received by the lungs to optimize the patient's work of breathing. In addition, it adjusts the inspiratory and expiratory times using time constants. This is accomplished with software that relies on the Otis equation, a formula used to calculate the optimal minute ventilation, tidal volume, and rate using the least amount of pressure when the patient is passive, with the respiratory rate being adjusted to meet the minute volume target set by the clinician. The settings on a ventilator providing ASV may look different from the conventional settings. The most important information input by the clinician is the patient’s height and sex, which are used to determine the predicted body weight (PBW). For an adult patient, the normal predicted minute volume is calculated as follows:

$$\text{Minute volume} = 0.1 \text{ L/kg of PBW}$$

For example, an adult patient with a PBW of 80 kg and normal lung function would have an 8 L/min volume requirement.

The percentage of minute volume that should be set as a target depends on the patient’s current pulmonary ventilation status. If the patient is experiencing respiratory acidosis due to hypercapnia alone, then increasing the percentage of minute volume would be advantageous to lower the $\text{Pa}CO_2$. Also, the percentage of minute volume should be increased with increasing altitude or when adding mechanical dead space in the circuit. These increases are subtle and should be confirmed with the ventilator’s manufacturer.

The clinician must also set the limits and alarms designed to protect the lungs. Set the high-pressure limits not to exceed a chosen plateau pressure and tidal volume. Next, set the oxygenation portion of PEEP and $\text{F}IO_2$. There is no tidal volume, respiratory rate, inspiratory time, or I:E ratio to set. The ventilator’s software adjusts for those considerations to reach the desired percentage of minute volume and will automatically make changes based on the patient’s lung mechanics and the preset limits.

Although ASV might sound like the perfect mode for all patients, it does have limitations. In a patient experiencing metabolic acidosis with a high respiratory drive, it may become a challenge for the ventilator to match the patient’s respiratory demand. Likewise, a patient in diabetic ketoacidosis with Kussmaul breathing may be difficult to ventilate using this mode. Because the patient can breathe spontaneously independent of the set parameters, this mode would be considered pressure-limited, volume-targeted, synchronized intermittent mandatory ventilation.

ASV settings may appear as follows:

% minute volume: 115

PEEP: 5 cm H_2O
FIO_2: 0.6 s

Parameters

The clinician must be familiar with the ventilator being used and should be proficient in its use, understand its application to the patient, be able to set appropriate alarm settings, and know how to perform the troubleshooting process. Gaining competence with these machines may require additional specific training in ventilator management. **TABLE 7-2** describes some key ventilator parameters and alarms, though it is not intended to be a comprehensive list. Some ventilators have many more audio/visual alarms that the CCTP must understand prior to transporting a patient on the ventilator. Reading and understanding the ventilator's operator manual is essential to safely caring for the mechanically ventilated patient.

TABLE 7-2 Ventilator Parameters

Parameter	Definition	Setting Range
Tidal volume	Amount of air delivered with each machine breath. Measured in millimeters.	Approximately 6–8 mL/kg of ideal weight; 4–6 mL/kg if poor lung compliance (eg, from acute lung injury or restrictive or obstructive disease) is present. Smaller volumes may be used to prevent alveolar overdistention.
Respiratory rate	Number of breaths delivered in 1 minute. Measured in breaths per minute.	12–14 based on desired mandatory minute ventilation. Confirm minute volume adequacy with arterial blood gas or $ETCO_2$.

Parameter	Definition	Setting Range
Fraction of inspired oxygen	Percentage of inhaled oxygen, expressed as a decimal.	0.21–1.0. Titrated to achieve adequate oxygenation (oxygen saturation, 0.90%). For initial management, an FIO_2 of 1.0 (100%) is used and then titrated downward in an attempt to maintain adequate arterial saturation at the lowest FIO_2 possible (50% or less) to avoid oxygen toxicity.
Peak flow	Speed at which the tidal volume is delivered. Measured in liters per minute.	Can vary greatly between 35 and >120 L/min.
Inspiratory time	The time set to deliver the desired flow or tidal volume. Measured in seconds.	Can vary between 0.25 and 1.5 s depending on the patient population.
Peak inspiratory pressure	The peak pressure generated during ventilation. May vary with volume ventilation. Measured in cm H_2O.	Set this parameter with pressure ventilation. Should be maintained at the lowest value possible to minimize the risk of barotrauma/volutrauma. It is the proximal airway pressure.
Driving pressure	The change in pressure between the plateau pressure and PEEP. Determined by the elastic properties of the respiratory system and the delivered tidal volume. Measured in cm H_2O.	Not an actual setting. The goal is to keep the driving pressure at <15 cm H_2O.
Inspiratory plateau pressure	The pressure applied in volume ventilation to the small airways and alveoli. Measured by applying an inspiratory pause. Measured in cm H_2O.	Plateau pressure should be maintained at <30 cm H_2O in patients with poor lung compliance to minimize the risk of volutrauma. Adult patients with normal lungs should be maintained at <20 cm H_2O.

Parameter	Definition	Setting Range
Percentage of minute volume	Amount of desired minute volume, set according to normal minute volume equation (Minute volume = 0.1 L/kg predicted body weight for adult). Measured in liters per minute.	100% for normal lung conditions. Increase for hyperventilation. Decrease to encourage spontaneous breaths or liberation from mechanical ventilation.
Low-pressure alarm	Alerts the clinician to a leak in the system or a patient disconnect.	Set 5–10 cm H_2O lower than the average cycling (peak) pressure.
High-pressure alarm	Alerts the clinician that the ventilator is using high pressures to deliver the tidal volume.	Set 10 cm H_2O higher than the peak inspiratory pressure.
Power failure/low-battery alarm	Alerts the clinician to a ventilator failure due to a loss of power.	Varies from ventilator to ventilator.

Abbreviations: $ETCO_2$, end-tidal carbon dioxide; FIO_2, fraction of inspired oxygen; PEEP, positive end-expiratory pressure

© Jones & Bartlett Learning.

Note that expiratory time is not a set parameter in most ventilators. Rather, it is a function of the set respiratory rate and inspiratory time, and is “left over” after inspiration is completed. More important to understand is the inspiratory-to-expiratory ratio, more simply known as the I:E ratio, which the provider can set on some ventilators. Recognizing what constitutes the total cycle time helps with understanding the I:E ratio and its effect on the respiratory rate. The total cycle time for the breath to take place (inspiratory and expiratory phases) is calculated by dividing the respiratory rate into 60 seconds. For example, a respiratory rate of 20, divided into 60 seconds, would give a total cycle time for one breath of 3 seconds. In such a case, if the inspiratory time is set at 1 second, the expiratory time is 2 seconds (ie, total cycle time of 3 seconds minus inspiratory phase of 1 second) and the I:E ratio is 1:2.

Any change in the rate or inspiratory time (I time) will affect the I:E ratio and should be a major concern when setting up or making changes on a ventilator. This consideration is extremely important with patients who have an obstructive disease process such as COPD or asthma. These patients require longer expiratory times as a by-product of their lower respiratory rates and shorter inspiratory times. If the expiratory time is not sufficient for the patient, auto-PEEP becomes a worrisome risk.

Some hospital ventilators and transport ventilators do have a specific setting for the I:E ratio. When setting a specific I:E ratio, the inspiratory time fluctuates with any change in the respiratory rate. Notably, too short of an inspiratory time coupled with a small-diameter ET tube in an adult may cause increased turbulent flow, which will increase the PIP. When setting the I:E ratio, be certain to monitor the inspiratory time when respiratory rate changes are made. Inspiratory times of 0.7 to 1.2 seconds in an adult patient are considered an acceptable range to start with, with these values then being titrated as needed.

Positive End-Expiratory Pressure

PEEP occurs at the end of each breath. Instead of allowing a full exhalation back to ambient pressure, exhalation is set to be stopped at a prescribed pressure. The result is an increase in the amount of air in the alveoli, which increases the functional residual capacity and improves oxygenation. PEEP also reduces the shunt fraction and may increase lung compliance, as determined by a targeted transpulmonary pressure measured via esophageal manometry. Detrimental effects of PEEP may include decreased venous return, a resultant decrease in cardiac output, increased intracranial pressure, decreased renal and portal blood flow, and increased risk of barotrauma. When PEEP is increased, the MAP increases correspondingly. PEEP is contraindicated in patients with untreated pneumothorax or bronchopleural fistula.

PEEP values are usually determined by the ability to improve the partial pressure of oxygen in arterial blood (PaO_2) and decrease the FIO_2. An important consideration during transport is to maintain PEEP levels even when using a bag-mask device. An external PEEP valve should be attached to the bag with the appropriate PEEP value set. The patient's hemodynamic status, as well as oxygenation, should be carefully monitored when applying and adjusting PEEP.

If high levels of PEEP are present and the patient must be disconnected from the ventilatory circuit, clamping the ET tube may be required to prevent alveolar collapse even for a moment. This step may be necessary in patients with severe ARDS because the inflammation process may make it difficult to re-recruit alveoli that were once open. Special training is necessary to ensure ET tube integrity and patient safety during the disconnection/reconnection procedure. The goal is to maintain the same level of PEEP while the disconnect takes place as swiftly as possible. Keeping the patient sedated to avoid unwarranted spontaneous breathing is suggested, as this strategy may prevent the patient from taking a breath while the ET tube is clamped. Such a breath could trigger negative-pressure pulmonary edema, owing to the increased negative intrathoracic pressure during the patient's spontaneous breath. This skill should be practiced on a mechanically ventilated manikin, if possible. The goal is to clamp the ET tube and change over the circuit in less than 5 seconds.

Inhaled Gases

When managing a mechanically ventilated patient, the CCTP must adjust the ventilator settings to correct any imbalances in the patient's oxygenation/ventilation status based on ABG values or $ETCO_2$ and SpO_2 readings. Certain scenarios may warrant using inhaled gases to correct these imbalances. The CCTP should be familiar with the most commonly encountered gases and their indications.

Clamping an ET Tube

Special care must be taken when the decision to clamp an ET tube has been made. Clamping the ET tube during a ventilator change protects against any viral or bacterial exposure to the environment, but patients receiving high levels of PEEP may need that level of support to be maintained to facilitate their oxygenation and ventilation. Any interruption in the PEEP level may have disastrous results, as it may take a long time to re-recruit the alveoli lost during a disconnect procedure in patients with some lung conditions (eg, ARDS). Additionally, patients may need to be sedated if spontaneous breathing is present. Clamping the airway on an alert, anxious patient on high levels of PEEP is not recommended without adequate sedation.

Materials needed for this procedure include a clamping device (with a smooth clamp surface, if possible), gauze for protecting the integrity of the ET tube **FIGURE 7-8A**, and a second pair of hands to turn the ventilators first off and then on. This procedure should be done as quickly as possible, and a bag-mask device connected to oxygen should be ready to use if necessary. The steps are as follows:

1. Prepare the receiving ventilator with appropriate settings for the transport, and have it on stand-by to deliver a breath with no delay.
2. Have one person shut off the sending facility's ventilator while a different team member simultaneously clamps the ET tube **FIGURE 7-8B**.
3. Remove the circuit, quickly apply the receiving ventilator's circuit, and turn on the ventilator **FIGURE 7-8C**.
4. Once the ventilator is confirmed "on," remove the clamp.

Nitric Oxide

Nitric oxide (or nitrogen monoxide) is seeing increased use during critical care transports. This is due in part to the introduction of portable inhaled nitric oxide (iNO) administration units and the expansion of the patient populations in whom iNO has been shown to be effective. Research into use of iNO is ongoing, and many institutions have standing agreements with their institutional review boards to allow compassionate use of iNO in adults with refractory hypoxemia from a wide range of clinical syndromes. Note that nitric oxide (iNO) is not the same as nitrous oxide (N_2O).

When administered as a gas, iNO increases blood flow by promoting vasodilation. This mechanism involves the endothelial blood vessel linings, which receive a signal from the iNO that stimulates smooth muscle to relax. iNO also discourages smooth muscle contraction of the blood vessels. Therefore, when hypoxia results from pulmonary vascular vasoconstriction, iNO can significantly improve flow and oxygenation. However, an overabundance of iNO can contribute to reperfusion injury—for example, if an excess is produced after an ischemic injury.

iNO gas is bled into the inspiratory limb of a ventilator circuit at a dilution measured in parts per million (ppm). Published studies list effective doses ranging from 0.25 to 80 ppm, although the recommended doses may vary by institutional policy and practice. The recommended starting dose for neonates with acute hypoxic respiratory failure is 20 ppm. For adults, the recommended starting dose ranges from 5 ppm to 20 ppm. Doses greater than 20 ppm are not recommended. Effects of iNO vary and are patient specific.

Parameters for titration of iNO need to be defined prior to initiating therapy. Patient assessment modalities, however, vary considerably by institution. Typical measurements that suggest a favorable response to iNO include a 20% improvement in oxygenation and/or a 30% decline in pulmonary vascular resistance. When invasive monitoring is not available, improvements in oxygenation, hemodynamic stability, and less frequent desaturations may be used to gauge the effectiveness of this therapy (or lack thereof).

Abrupt discontinuation of iNO has been associated with a rebound phenomenon, characterized by significant desaturations and hemodynamic instability. Given this risk, CCTPs should calculate the gas volumes and battery lifespan needed and ensure that the needed equipment and supplies will be available to continue iNO administration throughout the entirety of the transport.

iNO gas readily reacts with other gases, including oxygen and water vapor found in ventilator circuit tubing. This oxidative process produces highly corrosive nitrogen dioxide, which poses a significant risk of causing acute lung tissue injury with resultant pulmonary edema. Nitrogen dioxide concentrations are monitored by the commercially available iNO administration device; elevated levels can be remedied by purging the iNO gas system or lowering the iNO bleed rate. Occupational exposure of health care providers to iNO and nitrogen dioxide is a theoretical risk of treatment, but the severity of this risk has yet to be demonstrated in published research.

Methemoglobinemia is another potential complication of iNO therapy. It is caused by oxidation of hemoglobin to methemoglobin, a dyshemoglobin that cannot carry oxygen. In patients receiving iNO therapy, monitoring methemoglobin levels at least daily is important to prevent induction of an iatrogenic hypoxia. Pulse carbon monoxide oximeters capable of measuring methemoglobin are helpful for spot assessment or continual monitoring of methemoglobin levels.

iNO can be a valuable adjunct for CCT of extremely hypoxic patients, to optimize conventional therapies, to continue care started prior to transfer, or as a bridge to more advanced therapies such as extracorporeal membrane oxygenation (ECMO) or high-frequency jet ventilation. The greatest dangers during transport are iatrogenic overdoses of iNO with resultant acute lung injury and pulmonary edema and/or methemoglobinemia. Because abrupt discontinuation of iNO therapy due to gas loss or equipment malfunction can result in catastrophic rebound effects, it is extremely important to have a bag-mask device at the ready that can be used to deliver breaths with the iNO delivery device attached. Use of iNO during transport requires the CCTP to be thoroughly familiar with iNO equipment operation, troubleshooting, and emergency procedures in case of failure. Often a respiratory therapist will accompany the patient and manage the delivery of iNO during the transport.

Epoprostenol

Inhaled epoprostenol is often used in hospitals for treating hypoxemia related to pulmonary hypertension and ARDS. When administered through the ventilator circuit via a specific vibrating mesh device, it produces selective pulmonary vasodilation, which can lead to improvements in the $\dot{V}/\dot{Q}$ mismatch without any systemic hemodynamic compromise. Note that the duration of action for inhaled epoprostenol is 3 to 5 minutes; any interruption in delivering this medication puts the patient at risk for rebound pulmonary hypertension. Precise planning for transporting a patient on epoprostenol is vital, and providers should have enough medication in the event of any unplanned delays.

Heliox

Heliox is a specific blend of helium and oxygen. Combinations of 80% helium and 20% oxygen (80/20) and of 70% helium and 30% oxygen (70/30) are the most commonly encountered mixtures. Because helium is less dense than air, it can contribute to turning turbulent flow into laminar flow and decreasing airway resistance. This therapy is often used to decrease airway resistance in the presence of foreign body obstruction, stridor, and vocal cord dysfunction as a bridge to correcting the underlying issue.

While there is minimal research on its use in asthma or COPD exacerbations, heliox may be used in these scenarios when other interventions have failed. Patients with an intubated asthma exacerbation are sometimes given heliox through a specifically designed ICU mechanical ventilator. These ventilators have a dedicated port to receive this lighter gas and to ensure equivalency of flows and volumes. The evidence base is not currently robust enough to recommend its widespread use in this capacity.

Respiratory Distress and Respiratory Failure

Respiratory distress is a medical emergency that demands immediate treatment. Signs and symptoms include tachypnea, tachycardia, increased anxiety, increased work of breathing, and pallor. Respiratory failure is a medical emergency that may present initially as respiratory distress, but signs and symptoms eventually worsen into cyanosis, hypercapnia, hypoxia, bradycardia, fatigue, shallow breathing, and loss of consciousness. At this point, the pulmonary system fails to meet the body's metabolic demands for oxygenation and ventilation.

There are four classifications of respiratory failure:

- **Type 1 (hypoxemic).** In this type of respiratory failure, the lung loses its ability to deliver adequate amounts of oxygen to the pulmonary vasculature. Typically, the ABG analysis will reveal a Pao_2 of less than 50 mm Hg on room air. Hypoventilation, $\dot{V}/\dot{Q}$ mismatch (low $\dot{V}/\dot{Q}$ ratio), and shunt are common physiologic causes of hypoxemia. Typical origins of a shunt may include atelectasis, pneumonia, cardiogenic pulmonary edema, ARDS, and a lung hemorrhage. Therapies are aimed at recruiting the collapsed alveoli and removing any excess fluid from the lungs.
- **Type 2 (ventilatory).** This type of respiratory failure presents in patients with airflow obstruction, increased work of breathing, poor lung compliance, increased airway resistance, and decreased respiratory drive. If the patient is not chronically retaining carbon dioxide, then a $Paco_2$ of greater than 50 mm Hg is a classic sign of type 2 respiratory failure. Some physiologic reasons for hypercapnia include a decrease in the respiratory rate, a decrease in the tidal or minute volume (drug overdose), or an increase in carbon dioxide production (eg, sepsis, burns, fever). Another consideration for hypercapnia is dead space ventilation, in which blood flow to the alveoli is severely

diminished due to pulmonary embolus, hypovolemia, and poor cardiac output.

- **Type 3 (perioperative).** This type of respiratory failure can be a subtype of type 1 and is commonly seen in postoperative patients. The main culprit is atelectasis due to anesthetic effects, accompanying pain, and shallow breathing, which collectively contribute to a decrease in functional residual capacity and airway secretions. The therapy of choice is to reverse the atelectasis.
- **Type 4 (shock).** Hypoperfusion can lead to respiratory distress and failure. The underlying causes may be septic, cardiogenic, or hypovolemic shock. Identifying and treating the underlying cause is the ultimate goal.

Recognizing the underlying type of respiratory failure and its appropriate treatment is essential. The CCTP may benefit from reviewing a recent ABG analysis and correlating the Pa_{CO_2}, Pa_{O_2}, and calculated oxygen saturation with the transport monitor's $ETCO_2$ and Sp_{O_2} readings. A recent chest radiograph and radiologist report to rule out any abnormalities (eg, a small pneumothorax) that may present an issue on transport, and to confirm ET tube placement, would be helpful.

Ventilator Management

Use of a portable ventilator during patient transport may be necessary in the following situations:

- Impending or actual respiratory failure
- Inadequate respiratory drive or apnea
- Inadequate gas exchange
- To decrease the work of breathing and oxygen cost

Complications of using a portable ventilator include the following possibilities:

- Mechanical failure
- Patient anxiety
- Improper settings
- Increased intrapulmonary pressure
- Cardiovascular compromise
- Gastrointestinal disturbances
- Infection
- Impaired clearance and drying of secretions
- Ventilator unable to meet the patient’s flow demand

Most of today’s ventilators can match most patients’ demands. The most important consideration is to know the capabilities of the equipment and be able to match them to the patient’s lung condition. For example, if a patient is on pressure-regulated volume control (PRVC) and your ventilator does not have this mode, find out why the patient is using this mode; based on this information, you can then decide whether you can support the patient’s needs with your ventilator. If volume- and pressure-delivered breaths are available with your equipment, you very likely can meet the patient’s demands.

During transport of a critically ill patient receiving mechanical ventilation, only necessary adjustments to the ventilator should be made. These adjustments usually focus on maintaining adequate oxygenation, minute ventilation, and patient comfort and safety. If mechanical ventilation is instituted, it is recommended that the guidelines listed in this section be followed after securing a patent airway. In most cases, the CCTP will use the settings already in place, provided the patient's respiratory status is deemed sufficient for the transport. A recent ABG analysis (or venous blood gas analysis, in some institutions) and chest radiograph may be helpful at this time. These guidelines should be considered by the CCTP who is intubating and establishing the patient on the ventilator.

The CCTP may also be called on to transport a patient on an unfamiliar device or mode. For example, a low-stretch lung strategy might call for use of a high-frequency oscillator to ventilate the patient. Although rarely seen today, this strategy may still be employed with a specific patient population. This approach employs a constant MAP to open the lung, similar to the effects of PEEP delivered via a conventional ventilator, and then ventilates the patient at rates of 180 to 900 breaths/min, with small volumes being delivered with each breath. Some transport ventilators use a similar technology. If your equipment consists of a conventional transport ventilator, however, it is helpful to know if the patient can be weaned from the high-frequency oscillator to a conventional ventilator prior to transport. The adult patient should have a MAP of less than 24 cm H_2O before considering any change to conventional ventilation.

Keep in mind that any occult pneumothorax or pneumomediastinum may worsen with the initiation of positive-pressure ventilation. Always perform a pre-use check of the ventilator and circuit per the manufacturer's guidelines before placing the patient on the ventilator. It is recommended to perform this test prior to arrival at the sending facility to troubleshoot any malfunctions.

Adult Ventilation

Suggested guidelines for adult ventilation are as follows:

1. Choose either a volume- or pressure-delivered breath.
2. Choose a target tidal volume of 6–8 mL/kg using the PBW (see Table 7-3).
3. Select an appropriate mode of delivery for the transport, typically assist/control or synchronized intermittent mandatory ventilation.
4. Select an appropriate respiratory rate of 12–14 breaths/min.
5. Select an inspiratory time. Start at 1 second.
6. Start with a PEEP of 5 cm H_2O.
7. Start with an F_{IO_2} of 6. Titrate for target saturation levels.
8. Set the sensitivity at 3–5 L/min or minus 2 cm H_2O.
9. Set the heat moisture exchange at circuit Y.
10. Set all alarms that involve high pressure, low pressure, minute volume, and apnea.

CCTPs must understand the difference between volume-delivered breaths and pressure-delivered breaths. In volume-delivered breaths, the flow available to the patient is limited to the set (dialed-in) tidal volume and the inspiratory time, although some minor adjustments can be made to increase the flow. In pressure-delivered breaths, the pressure is set and the flow available to the patient is unlimited—at least up to the ventilator's maximum flow capabilities. It follows that pressure control may deliver a more comfortable breath for the air-hungry patient. Because of its decelerating flow pattern, this technique can improve distribution of ventilation in the lungs of patients with acute lung injury. In addition, it is the breath delivery of choice in patients with uncuffed tracheostomies, in patients with uncuffed ET tubes, and in any patient whose airway cannot be sealed. In such circumstances, the ventilator will continue to pressurize the airway until the I time expires, with the volume breath terminating once the volume is delivered. In contrast, with volume-delivered breaths, the PIP varies depending on lung compliance. In pressure-delivered breaths, the exhaled tidal volume becomes the variable and is also dependent on lung compliance. Many transport ventilators allow the CCTP to manipulate how much flow is delivered at the initiation of the breath (rise time, P-ramp) and when the flow terminates (flow termination, expiratory trigger sensitivity) in a pressure-targeted breath. This allows the CCTP to fine-tune the flow to meet the patient’s demand.

It is extremely important to monitor PIP and exhaled minute volume during ventilation. Some ventilators can deliver a pressure breath with a volume target, an approach referred to as dual-control ventilation or PRVC. This mode gives a pressure-delivered breath with a guaranteed minute volume due to the targeted tidal volume.

It has been suggested that using low tidal volume ventilation might reduce volutrauma and should be the standard of care for mechanically ventilated patients with ARDS. Studies have used the 4–8 mL/kg PBW ratios given in **TABLE 7-3** as a strategy; they are based on the following equations:

$$\text{Males: PBW (kg)} = 50 + 2.3\,[\text{height (inches)} - 60]$$

$$\text{Females: PBW (kg)} = 45.5 + 2.3\,[\text{height (inches)} - 60]$$

Abbreviation: PBW, predicted body weight
Data from ARDSNet Studies.

Description

This is suggested only as a starting point, because some patients require more tidal volume. As always, the patient's lung condition and disease process should be considered when setting up or making changes on a ventilator.

When transporting a patient who is on a hospital ventilator, it is wise to match their current settings, provided those settings are adequately ventilating and oxygenating the patient. These values can be quickly confirmed using a recent ABG analysis. Again, before making any major adjustments to the current ventilator settings, it is prudent to consult the respiratory therapist, sending facility physician, or medical control. A quick and easy way to choose transport settings for an adult patient is to choose a target tidal volume of 6 to 8 mL/kg of PBW (4 to 6 mL/kg of PBW for a patient with ARDS) and a respiratory rate of 12 to 16 breaths/min, and to draw an ABG if possible or monitor the ETCO_2. Confirm the target tidal volume is not approaching a plateau of less than 30 cm H_2O and the I:E ratio is sufficient to allow time for passive exhalation and not contribute to auto-PEEP (which causes air trapping).

The formula to predict minute volume for an adult patient while accounting for volume loss at the alveolar level due to dead space is 100 mL/min/kg of PBW. For example, suppose you need to determine the minute volume for a male patient with a PBW of 75 kg and no known lung history:

$$75 \times 100 \text{ mL} = 7{,}500 \text{ mL} = 7.5 \text{ L/min}$$

Theoretically, this patient should receive a minute volume of 7.5 L/min. To achieve this goal, you must first determine an adequate target tidal volume. Using the 6 to 8 mL/kg guideline and the PBW of 75 kg, you can start on the low end of 6 mL/kg:

$$6 \text{ mL/kg} \times 75 \text{ kg} = 450 \text{ mL}$$

Thus, the target tidal volume would be 450 mL.

Using the formula “Minute volume = Rate × Tidal volume,” plug in the numbers just obtained to determine the respiratory rate:

$$7.5 \text{ L/min} = \text{Rate (breaths/min)} \times 450 \text{ mL}$$

Equation for Adjusting $Paco_2$

Providers can use a simple formula to calculate a target minute volume and $PaCO_2$, and thereby improve the accuracy of acid–base adjustment in mechanically ventilated patients:

$$\text{Target minute ventilation} = \frac{\text{Known } Paco_2 \times \text{Known minute volume}}{\text{Target } Paco_2}$$

In this equation, the provider knows the current $PaCO_2$ and current minute volume, and wants to calculate the target minute volume and target $PaCO_2$. To illustrate this calculation, suppose a patient's status is indicated by the following values:

- Ventilator settings: Assist/control rate, 12 breaths/min; tidal volume, 0.5 L; PEEP, 5 cm H_2O; FIO_2, 0.6
- ABG values: pH, 7.13; $PaCO_2$, 68 mm Hg; PaO_2, 100 mm Hg; HCO_3^-, 23 mEq/L; O_2 saturation, 95%

Suppose further that the provider wishes to arrive at a $PaCO_2$ of 40 mm Hg. The provider will use the known values ($PaCO_2$, 68 mm Hg; minute volume, 6 L/min) to determine the target minute volume (*X*) that will produce a $PaCO_2$ of 40 mm Hg. Plugging these values into the equation, the provider can calculate the target minute volume:

$$X = 68 \text{ mm Hg} \times 6 \text{ L/min}/40 \text{ mm Hg}$$

$$X = 10.2 \text{ L/min}$$

Provided that this target tidal volume is ideal for this patient (6 to 8 mL of PBW), the provider can then adjust the ventilator settings. Using the tidal volume of 0.5 L and the calculated minute volume of 10.2 L, the provider determines the respiratory rate as follows:

$$10.2 \text{ L/min}/0.5 \text{ L} = 20.4 \text{ breaths/min}$$

The adjusted ventilator settings are as follows: assist/control rate, 20 breaths/min; tidal volume, 0.5 L; and FIO_2 0.6.

This formula does not take into consideration alveolar ventilation and any specific lung physiology. A major concern when adjusting the respiratory rate is the effect on the I:E ratio. Changes should be monitored closely, and providers should also monitor for auto-PEEP.

Three important caveats apply to the end results obtained with the target minute ventilation formula:

- The patient should exhibit a steady metabolic state, where carbon dioxide production is constant. (“Steady” is generally considered 30 minutes of unaltered function.)
- The ratio of dead space to tidal volume needs to remain fixed; thus, any changes to the minute ventilation should be achieved by changing the respiratory rate, not the tidal volume.
- The patient must accept the adjusted minute ventilation without attempting to overbreathe the ventilator.

When respiratory rates are already high and peak pressures allow for upward adjustment of the tidal volume, the actual results will often not correspond to the results calculated with the formula owing to changes in dead space.

To complete the math operation, convert the 7.5 L into milliliters, then divide the minute volume by the tidal volume:

$$7.5\text{ L} = 7{,}500\text{ mL}$$

$$7{,}500/450 = 16.6\text{ breaths/min}$$

This calculation results in a tidal volume of 450 mL and a respiratory rate of 16 or 17 breaths/min. A slight adjustment with the inspiratory time or I:E ratio setting may be necessary to allow for more passive exhalation in a patient with an obstructive lung condition.

The mode of delivery also requires considerable attention. The patient will be traveling either by ground or by air during transport, and the environment may change rapidly. For patients who are alert and awake, all of their senses will be stimulated, causing potential stress and anxiety. Gravitational forces and barometric pressure changes may also affect patients’ cardiorespiratory status. Some patients may be susceptible to motion sickness. All of these factors need to be considered before placing a patient on the transport ventilator. In addition, if a patient is in the process of weaning off the ventilator, make sure the settings are appropriate for the transport that lies ahead, as active weaning efforts should generally be suspended during transport unless specifically requested.

The respiratory rate should be set and adjusted as necessary for patient demand, and careful monitoring of capnography is necessary throughout the transport. Remember, an increase in the respiratory rate shortens the expiratory time. Check the I:E ratio and adjust the inspiratory time if necessary. The I:E ratio for a healthy lung should be in the range of 1:2 to 1:3 I:E, whereas that for a diseased lung may be 1:3 or greater **TABLE 7-4**.

TABLE 7-4 Adjusting I Time Versus Respiratory Rate

Example: Respiratory rate = 10 breaths/min

Total cycle time	6 s (60 s ÷ 10 breaths = 6 s/breath) I time = 1.0 s E time = 5.0 s I:E ratio = 1:5 (expiratory time divided by inspiratory time)	
	Decreasing I Time	***Decreasing Respiratory Rate***
Respiratory rate	10 breaths/min	6 breaths/min
Total cycle time	6 s	10 s
I time	0.75 s	1.0 s
E time	5.25 s	9.0 s
I:E ratio	1:7	1.9

Abbreviations: E time, expiratory time; I time, inspiratory time; I:E, inspiration-to-expiration ratio

© Jones & Bartlett Learning.

The inspiratory time can be adjusted slightly to ensure greater patient comfort. Any change in inspiratory time will also affect the I:E ratio, however, so be sure to monitor this ratio. Rarely should you set an inspiratory time of less than 0.7 second for an adult patient, as this might increase turbulent flow within the respiratory tract.

For adults, PEEP should initially be set at 5 cm H_2O to account for physiologic dead space. If more PEEP is needed for oxygenation, it is suggested to make these changes slowly, as PEEP is proportional to MAP. If the patient has a high oxygen requirement and adjusting PEEP would be of benefit, one strategy suggests raising PEEP to a level at which the CCTP could lower the F_{IO_2} at the bedside and wait for PEEP to take effect. Then, if the patient becomes hypoxic during transport, the CCTP can consider the option of raising the F_{IO_2}. This strategy depends on what is initially causing the hypoxia. In a patient with severe ARDS, it may take many hours before any positive results from increasing the PEEP appear. Any adjustment in PEEP levels should be discussed with medical control before being applied.

The adult guidelines suggest starting with an F_{IO_2} of 0.6 and titrating until Sp_{O_2} is greater than 92%. Knowing the patient's baseline oxygen requirement, lung history, age, and Pa_{O_2} are helpful in meeting this goal.

Setting the sensitivity at minus 2 is a safe place to start. With this setting, the patient would need to trigger a breath by inhaling minus 2 cm H_2O of pressure or flow. If the patient has an uncuffed tracheostomy or ET tube and the ventilator is auto-cycling due to a leak from this device, the sensitivity needs to be increased until the auto-cycling stops. Once this is accomplished, the setting can be adjusted to a sensitivity of minus 2 cm H_2O past the leak-related value. Some ventilators have a leak compensation feature that automatically adjusts the sensitivity for a stable leak. Keep in mind that CCTPs work in a dynamic environment and a leak from an uncuffed tracheostomy or ET tube is rarely stable during patient transport.

As noted earlier, a heat moisture exchanger (HME) is important to use during ventilation because oxygen is a dry gas. The HME is designed to capture the moisture and heat from the patient's exhaled breath and hold it for the next inhaled breath. The CCTP should monitor the integrity of this device throughout the transport, ensuring no mucus or excessive moisture is restricting the flow through it, and in turn causing back pressure and auto-PEEP.

Alarms should be set according to the ventilator manufacturer's guidelines. A suggested starting point is to set the high-pressure limit at 10 cm H_2O above the average PIP. Set the low-pressure alarm at 5 cm H_2O below the average PIP. Set the low-minute-volume alarm at 25% below the resting minute volume. Setting the apnea alarm for 20 seconds is also recommended, but you should check with the manufacturer for the default apnea settings.

Special Considerations: Auto-PEEP and Hyperinflation

Auto-PEEP (intrinsic PEEP) can be described as an incomplete expiration before the next positive-pressure breath is delivered, causing air trapping **FIGURE 7-9**. It is often the culprit when a patient becomes asynchronous with the ventilator and is having trouble triggering a breath. Auto-PEEP can be measured by performing an expiratory hold maneuver on the ventilator, if the ventilator has this capability. Check the ventilator manual to determine its ability to measure auto-PEEP.

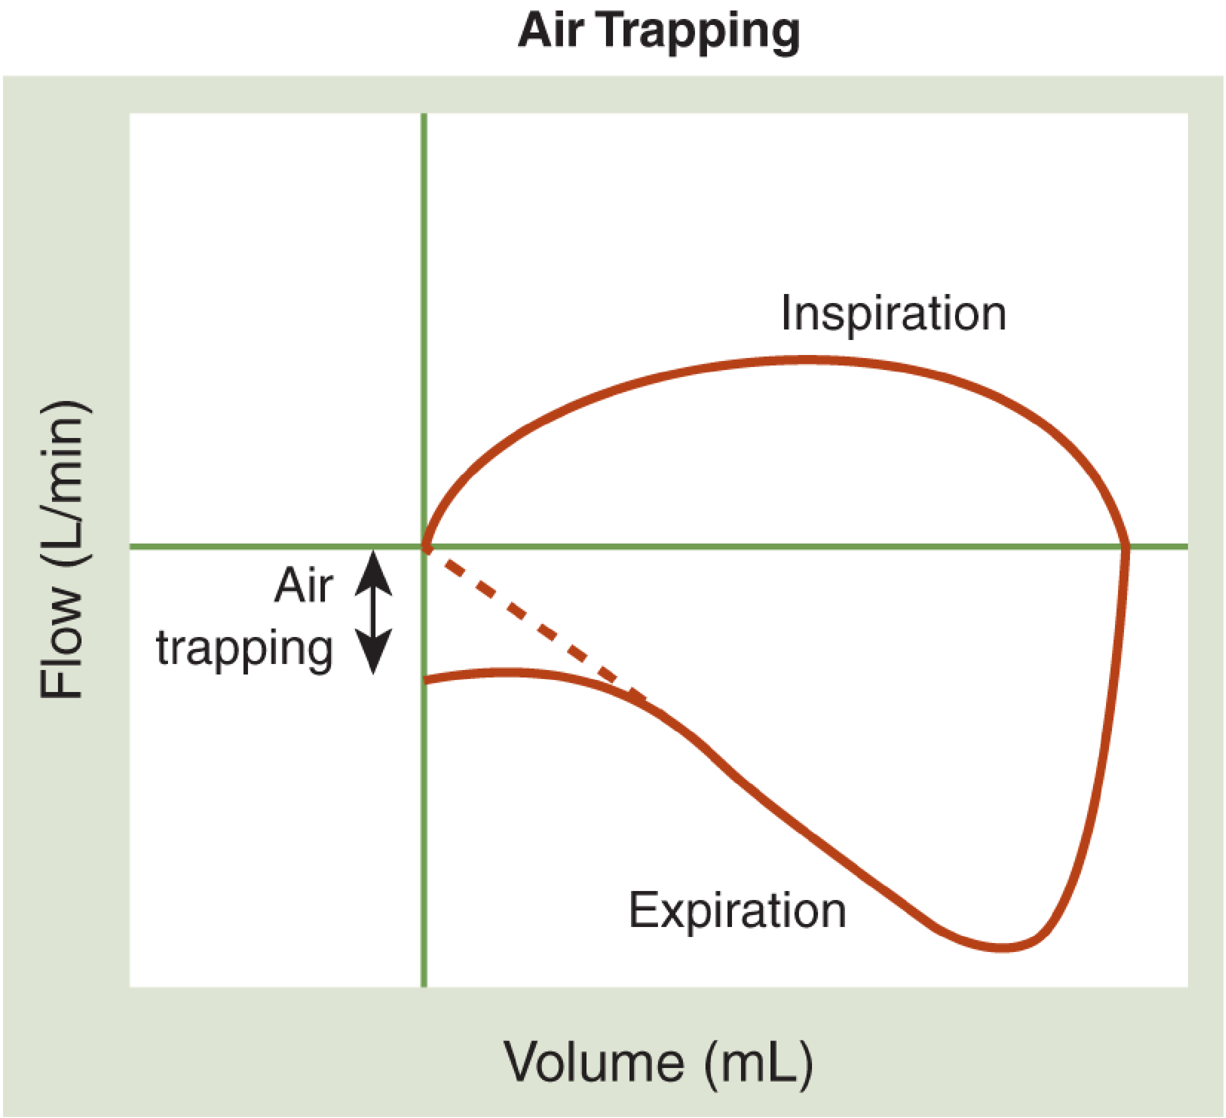

FIGURE 7-9 Auto-PEEP (positive end-expiratory pressure) occurs when an incomplete expiration causes air to become trapped in the lungs.

© Jones & Bartlett Learning.

Description

Patients who have a high airway resistance are especially susceptible to auto-PEEP when mechanically ventilated. These populations include individuals with asthma or any obstructive disease such as emphysema, as these patients are susceptible to hyperinflation **FIGURE 7-10**.

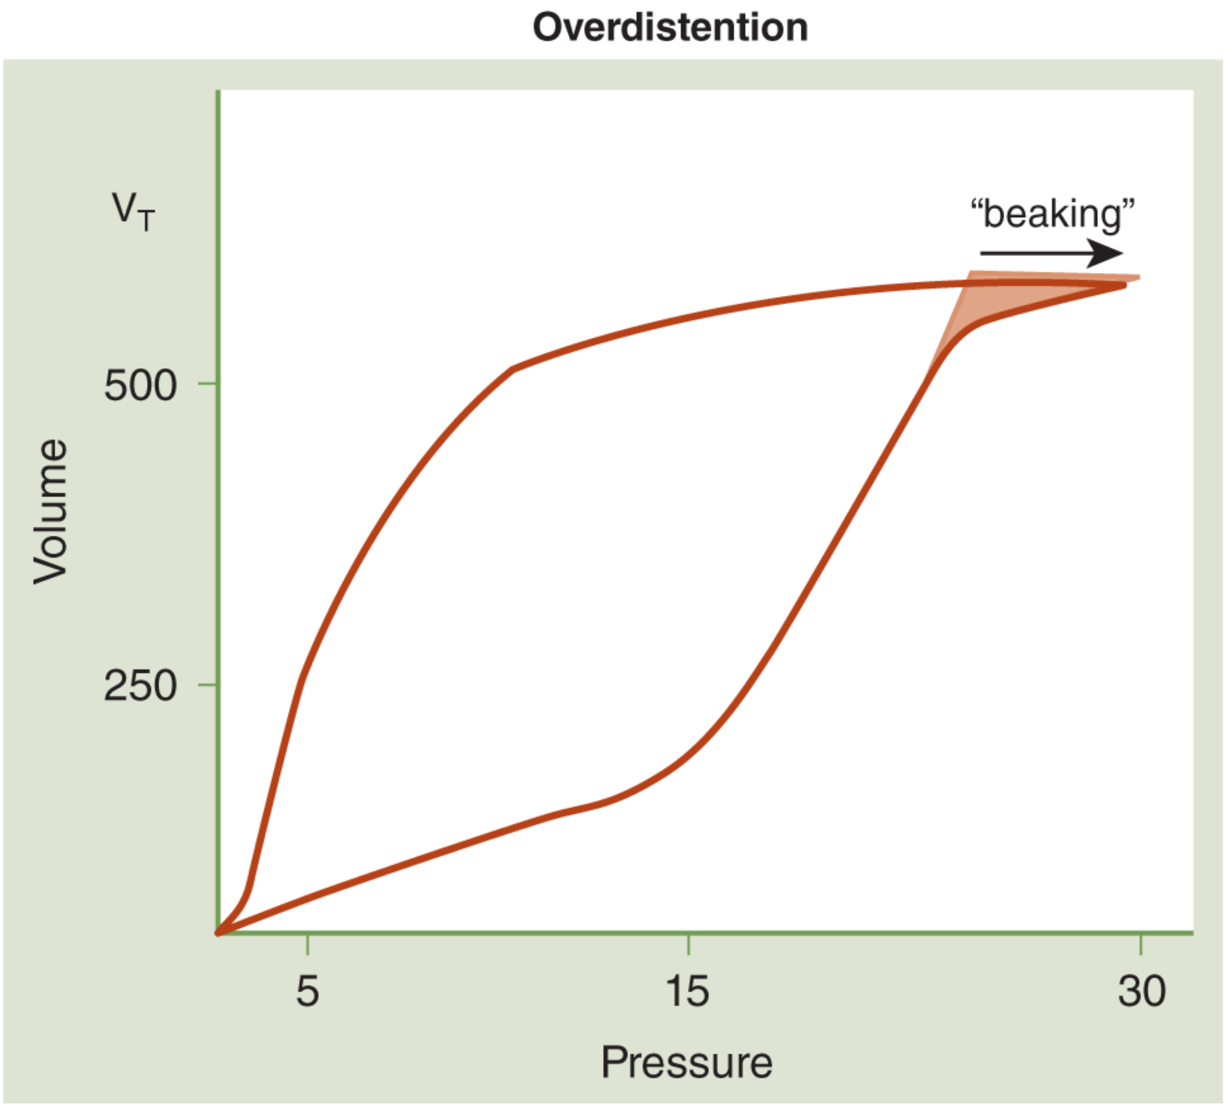

FIGURE 7-10 Hyperinflation.

© Jones & Bartlett Learning.

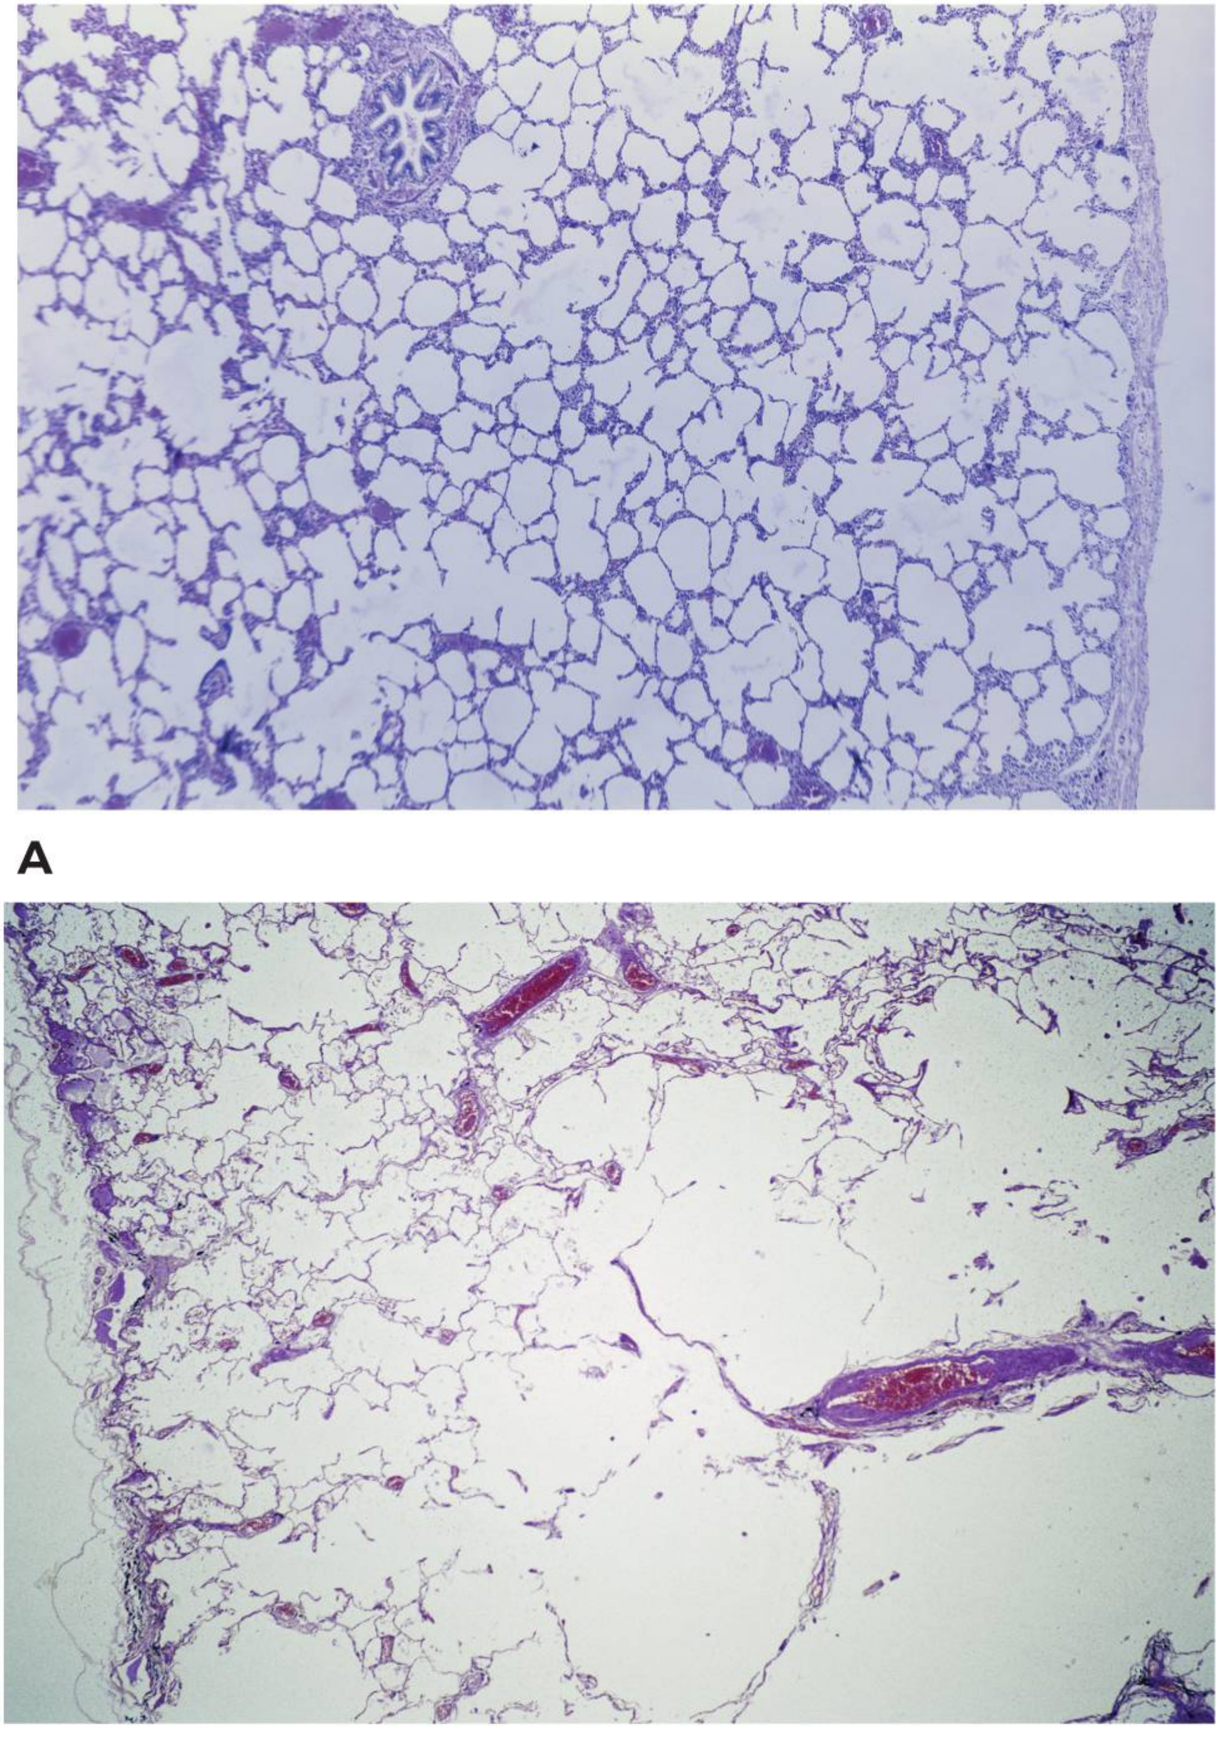
Description

When auto-PEEP or hyperinflation occurs, it may benefit the patient to administer bronchodilators, chest percussion, suction, and possibly steroids. To decrease the risk of barotrauma/volutrauma, consider lowering the respiratory rate and possibly the inspiratory time, and discuss permissive hypercapnia as an option. Raising the PEEP level to 2 or 3 cm H_2O below the measured auto-PEEP may help with synchrony and lead to decreased work of breathing. This strategy should be discussed with medical control before raising the PEEP level.

Another consideration that may help reduce air trapping is decreasing the airway resistance by shortening the ET tube. The length of the tube is standardized, and is based on its size. Once you verify proper ET tube placement, it is acceptable to shorten the ET tube (thereby removing dead space) in a patient with obstructive or restrictive disease.

Management of Lung Diseases and Conditions

Knowing the patient’s lung condition is imperative to ensure proper use of ventilation. Many strategies may be employed to ventilate patients with different lung processes. For example, a patient with severe ARDS might require high levels of PEEP and pressure due to the inflammatory process, whereas a patient with severe emphysema might require a lower respiratory rate and a shorter inspiratory time to allow for more expiratory time, along with limiting the tidal volume **FIGURE 7-11**.



A

B

FIGURE 7-11 Healthy lung tissue **(A)** and lung tissue affected by emphysema **(B)**. In terms of ventilation, a patient with severe emphysema might require a lower respiratory rate and a shorter inspiratory time to allow for more expiratory time, along with limiting the tidal volume.

© Biophoto Associates/Science Source.

The following sections suggest strategies to oxygenate and ventilate patients with some common lung diseases. Note that each patient should be thoroughly evaluated on a case-by-case basis to develop a strategy for ventilator settings. No single mode or setting will fit every lung condition. Instead, providers must interpret the feedback from the ventilator's monitored values, graphics, scales, and loops (if available) and make adjustments to ensure patient safety and maintain patient synchrony with the ventilator. When setting up the ventilator, it is wise to discuss the settings with the sending facility's physician, the respiratory therapist, and your medical control.

Acute Respiratory Distress Syndrome

ARDS is characterized by diffuse damage at the alveolar-capillary membrane, resulting in hypoxemia that is not attributed to cardiogenic pulmonary edema. This cascade of events includes neutrophil activation, cytokine storm, deficiencies in surfactant, and increased permeability of the alveolar-capillary membrane, ultimately resulting in alveolar collapse. As the process continues, some patients with ARDS develop fibrosis, contributing to worsening lung compliance and added dead space ventilation, which may then lead to pulmonary hypertension.

The Berlin definition for ARDS includes the following criteria:

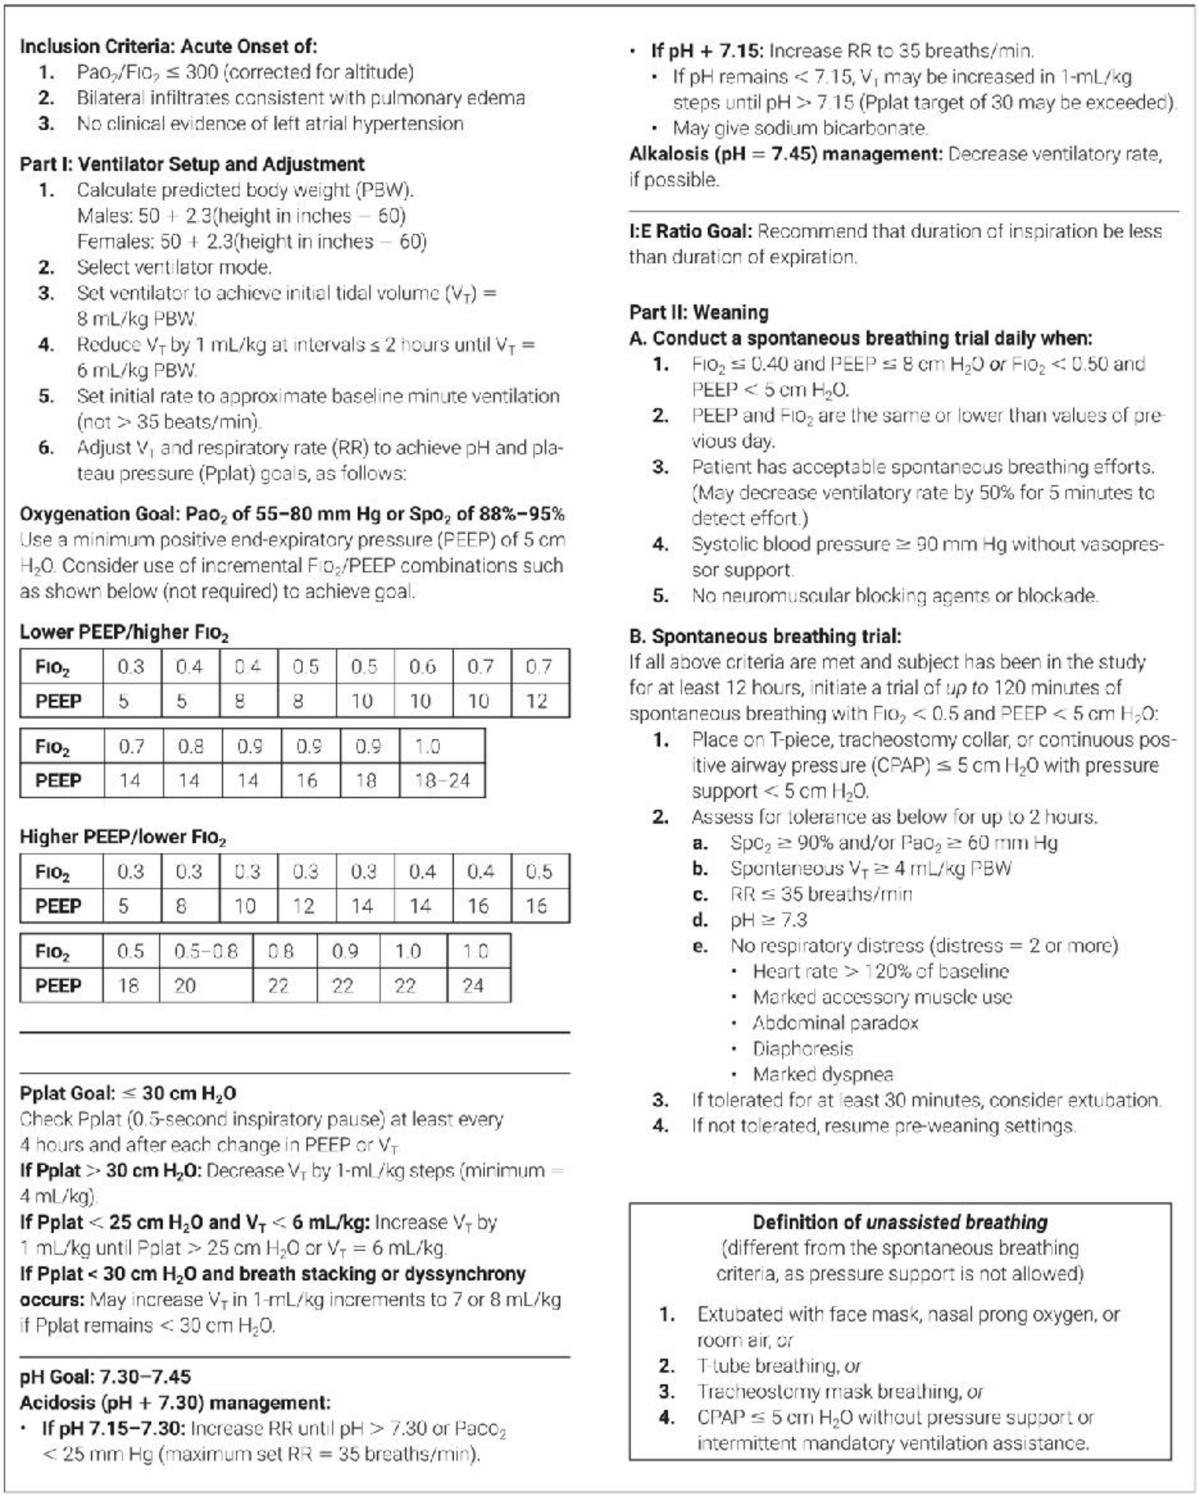
- Respiratory symptoms must have begun within 1 week of a known clinical insult.

- The chest radiograph must reveal bilateral opacities consistent with pulmonary edema not fully explained by pleural effusions, pulmonary nodules, lobar collapse, cardiac failure, or fluid overload.
- A moderate to severe deficit in oxygenation must exist, as defined by the $Pa{O_2}$:$F{IO_2}$ ratio (which requires an ABG analysis). The severity of the hypoxemia defines the severity of ARDS:
  - Mild: $Pa{O_2}$:$F{IO_2}$ ratio of 200–300
  - Moderate: $Pa{O_2}$:$F{IO_2}$ ratio of 100–200
  - Severe: $Pa{O_2}$:$F{IO_2}$ ratio of less than 100

For example, if $Pa{O_2}$ is 88 and $F{IO_2}$ is 1.0, the $Pa{O_2}$:$F{IO_2}$ ratio is 88. If the first two conditions are met, the patient would be classified as having severe ARDS.

Typically, patients presenting with pulmonary contusions, pneumonia, inhalation of toxic gases, near drowning, and aspiration of gastric contents are susceptible to primary ARDS. Patients who present with sepsis, multiple traumas, pancreatitis, drug overdose, and transfusion of blood products may experience a secondary presentation of ARDS.

Many different strategies may be used to manage the respiratory status of the patient with ARDS. The main goal in treating this patient population is to establish adequate gas exchange while diminishing the negative effects of positive-pressure ventilation. When lung-protective ventilation is the main goal, the strategy may focus on a low tidal volume (4 to 6 mL/kg of PBW), a high level of PEEP, and an increased respiratory rate while maintaining a plateau pressure at less than 30 cm H_2O. The ARDS Network developed a specific protocol for managing the patient with a $Pa{O_2}$:$F{IO_2}$ ratio less than 300 **FIGURE 7-12**.



Inclusion Criteria: Acute Onset of:

1. $PaO_2/FIO_2 \leq 300$ (corrected for altitude)
2. Bilateral infiltrates consistent with pulmonary edema
3. No clinical evidence of left atrial hypertension

Part I: Ventilator Setup and Adjustment

1. Calculate predicted body weight (PBW).
   Males: 50 + 2.3(height in inches − 60)
   Females: 50 + 2.3(height in inches − 60)
2. Select ventilator mode.
3. Set ventilator to achieve initial tidal volume (V_T) = 8 mL/kg PBW.
4. Reduce V_T by 1 mL/kg at intervals ≤ 2 hours until V_T = 6 mL/kg PBW.
5. Set initial rate to approximate baseline minute ventilation (not > 35 beats/min).
6. Adjust V_1 and respiratory rate (RR) to achieve pH and plateau pressure (Pplat) goals, as follows:

Oxygenation Goal: PaO_2 of 55–80 mm Hg or SpO_2 of 88%–95%
Use a minimum positive end-expiratory pressure (PEEP) of 5 cm H_2O. Consider use of incremental FIO_2/PEEP combinations such as shown below (not required) to achieve goal.

Lower PEEP/higher FIO_2

FIO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12

FIO_2	0.7	0.8	0.9	0.9	0.9	1.0
PEEP	14	14	14	16	18	18–24

Higher PEEP/lower FIO_2

FIO_2	0.3	0.3	0.3	0.3	0.3	0.4	0.4	0.5
PEEP	5	8	10	12	14	14	16	16

FIO_2	0.5	0.5–0.8	0.8	0.9	1.0	1.0
PEEP	18	20	22	22	22	24

Pplat Goal: ≤ 30 cm H_2O
Check Pplat (0.5-second inspiratory pause) at least every 4 hours and after each change in PEEP or V_T.
If Pplat > 30 cm H_2O: Decrease V_T by 1-mL/kg steps (minimum = 4 mL/kg).
If Pplat < 25 cm H_2O and V_T < 6 mL/kg: Increase V_T by 1 mL/kg until Pplat > 25 cm H_2O or V_T = 6 mL/kg.
If Pplat < 30 cm H_2O and breath stacking or dyssynchrony occurs: May increase V_T in 1-mL/kg increments to 7 or 8 mL/kg if Pplat remains < 30 cm H_2O.

pH Goal: 7.30–7.45
Acidosis (pH + 7.30) management:

- **If pH 7.15–7.30:** Increase RR until pH > 7.30 or $PaCO_2$ < 25 mm Hg (maximum set RR = 35 breaths/min).
- **If pH + 7.15:** Increase RR to 35 breaths/min.
  - If pH remains < 7.15, V_1 may be increased in 1-mL/kg steps until pH > 7.15 (Pplat target of 30 may be exceeded).
  - May give sodium bicarbonate.

Alkalosis (pH = 7.45) management: Decrease ventilatory rate, if possible.

I:E Ratio Goal: Recommend that duration of inspiration be less than duration of expiration.

Part II: Weaning

A. Conduct a spontaneous breathing trial daily when:

1. $FIO_2 \leq 0.40$ and PEEP ≤ 8 cm H_2O *or* $FIO_2 < 0.50$ and PEEP < 5 cm H_2O.
2. PEEP and FIO_2 are the same or lower than values of previous day.
3. Patient has acceptable spontaneous breathing efforts. (May decrease ventilatory rate by 50% for 5 minutes to detect effort.)
4. Systolic blood pressure ≥ 90 mm Hg without vasopressor support.
5. No neuromuscular blocking agents or blockade.

B. Spontaneous breathing trial:
If all above criteria are met and subject has been in the study for at least 12 hours, initiate a trial of *up to* 120 minutes of spontaneous breathing with FIO_2 < 0.5 and PEEP < 5 cm H_2O:

1. Place on T-piece, tracheostomy collar, or continuous positive airway pressure (CPAP) ≤ 5 cm H_2O with pressure support < 5 cm H_2O.
2. Assess for tolerance as below for up to 2 hours.
   a. SpO_2 ≥ 90% and/or PaO_2 ≥ 60 mm Hg
   b. Spontaneous V_T ≥ 4 mL/kg PBW
   c. RR ≤ 35 breaths/min
   d. pH ≥ 7.3
   e. No respiratory distress (distress = 2 or more)
      - Heart rate > 120% of baseline
      - Marked accessory muscle use
      - Abdominal paradox
      - Diaphoresis
      - Marked dyspnea
3. If tolerated for at least 30 minutes, consider extubation.
4. If not tolerated, resume pre-weaning settings.

Definition of *unassisted breathing*
(different from the spontaneous breathing criteria, as pressure support is not allowed)

1. Extubated with face mask, nasal prong oxygen, or room air, *or*
2. T-tube breathing, *or*
3. Tracheostomy mask breathing, *or*
4. CPAP ≤ 5 cm H_2O without pressure support or intermittent mandatory ventilation assistance.

FIGURE 7-12 ARDS Network protocol for managing a patient with a PaO_2:FIO_2 ratio less than 300.

Abbreviations: ARDS, acute respiratory distress syndrome; F_{IO_2}, fraction of inspired oxygen; Pa_{CO_2}, partial pressure of carbon dioxide, arterial; Pa_{O_2}, partial pressure of oxygen, arterial; Sp_{O_2}, oxygen saturation as measured by pulse oximeter

From NIH NHLBI ARDS Clinical Network: Mechanical Ventilation Protocol Summary. ARDSnet website. http://www.ardsnet.org/files/ventilator_protocol_2008-07.pdf. Accessed December 8, 2021.

Description

As yet, no clinical evidence has been published that confirms whether setting a volume target or a pressure target produces better outcomes. If a patient with ARDS is being transported on a mechanical ventilator, it is, as always, best to match the patient's current settings on the hospital ventilator, provided the oxygenation and ventilation goals are met. The CCTP must be aware of the transport ventilator's capabilities, as a patient on high levels of PEEP and high minute volume requirements is best matched with a transport ventilator that can deliver high flow rates, such as a turbine-driven ventilator.

Another ventilation strategy for the patient with ARDS is to focus on an inverse I:E ratio, also known as inverse-ratio ventilation. This is achieved by adjusting the inspiratory time to be longer than the expiratory time **FIGURE 7-13**. The goal with this approach is to increase oxygenation by increasing the MAP. The MAP, which is measured at the opening of the airway, is an average over the complete respiratory cycle. The main factors contributing to the MAP are the inspiratory pressure, PEEP, and length of time spent in each phase of the breathing cycle. The target scheme is a pressure-delivered breath, and the PEEP and inspiratory time are set to achieve the desired goal. Because the inverse-ratio strategy can be extremely uncomfortable, patients receiving this therapy are often given neuromuscular blocking agents (NMBAs).

Description Description

The more current form of the inverse-ratio strategy is APRV. As discussed previously, this modality has many other names, but is best described as a high level of CPAP with intermittent drops in pressure.

Recruitment maneuvers may also be implemented to improve oxygenation and minimize the risk of atelectrauma in patients with ARDS. Often a CPAP of 40 to 50 cm H_2O for 30 to 40 seconds is applied to the lungs in an attempt to stabilize the collapsed lung areas. This strategy may produce a short-term improvement in oxygenation, but the benefit does not appear to last long.

Recently, esophageal manometry has been implemented in the ICU setting to measure transpulmonary pressures (pressure at the airway opening, minus the pressure in the pleural space) for patients with ARDS. Because the PIP is a poor indicator of lung stress, transpulmonary pressures are often useful to determine the true distending pressures applied to the lungs. This information is extremely valuable for making essential adjustments to the ventilator to prevent atelectrauma and overdistention of the lungs. In this case, the patient will have an esophageal balloon catheter placed in a specific location to monitor transpulmonary pressures.

Another maneuver used in the hospital setting is prone positioning of the patient, often simply called proning, for a specific time. Shifting the gravitational forces may reduce atelectasis, redistribute lung densities, increase lung elastance, minimize alveolar shunting, and improve the $\dot{V}/\dot{Q}$ ratio. Proning the patient is labor intensive. It is associated with significant risk and is not commonly done in transit. It would be advantageous to coordinate the timing to have the patient transported during the supine portion of the prone positioning cycle.

Selective pulmonary vasodilators are often used for patients with ARDS who have developed refractory hypoxemia. Inhaled nitric oxide and inhaled epoprostenol are sometimes administered during transport, and the CCTP should be familiar with the devices employed to deliver these gases. Specifically trained personnel should accompany these transports, and a respiratory therapist will commonly assist with the patient's care.

Administration of NMBAs is considered when providing mechanical ventilation of the patient with ARDS and tachypnea, because the high respiratory rate may cause auto-PEEP. NMBA administration is a short-term solution, however; the goal is to withdraw the NMBA as soon as possible.

Another consideration is fluid management. It becomes a delicate balancing act in patients with ARDS to provide enough fluid to adequately perfuse the organs while not adding unnecessary fluid to the lungs, which may increase compression atelectasis and hinder gas exchange.

ECMO is on the rise as a rescue therapy and is often used during transports when patients need a higher level of care. This intervention requires specialty teams to accompany the transport team, including a perfusionist or specifically trained RN to manage the ECMO device and a clinician to treat the patient. Implementing ECMO is considered when the patient's PaO_2:FIO_2 ratio is less than 50 and plateau pressures are greater than 32 cm H_2O. The most common form of ECMO support consists of removing the blood from the vena cava (superior or inferior) and infusing it into the right atrium, a practice referred to as veno-venous access.

COVID-19

Most experts agree that patients with COVID-19 who are receiving care in the ICU should be treated similarly to patients who have ARDS if their condition matches the Berlin definition. As with any critically ill patient, treatment decisions for these patients should be made on a case-by-case basis.

Observations and detailed discussions of this patient population have revealed different patterns in their ventilatory response to hypoxemia. Interestingly, some patients present with normal compliant lungs, yet still experience hypoxemia. The assumption is the lungs are being adequately ventilated but the perfusion at the alveolar-capillary membrane is diminished. It is believed that this particular virus can invoke microthrombi in the pulmonary vessels, causing a $\dot{V}/\dot{Q}$ mismatch and high rates of coagulation anomalies throughout the body. Because of this potential diffusion deficiency and good lung compliance, extremely high levels of PEEP have been avoided in patients with COVID-19. PEEP levels typically range from 10 to 14 cm H_2O in these patients, although the ARDS Network's protocol allows PEEP levels as high as 24 cm H_2O in severe cases at an F_{IO_2} of 1.0. The goal is to keep plateau pressures at less than 30 cm H_2O and driving pressures at less than 15 cm H_2O, if possible, to reduce further lung injury.

Common complications of COVID-19 include elevated liver enzymes, acute kidney injury, and cardiac injury presenting as a late-onset complication. Some patients may develop atypical coagulation profiles leading to thrombosis. The most prominent finding in critically ill patients with COVID-19 is acute hypoxemic respiratory failure. Rarely do these patients present in a hypercapnic state. For most patients with COVID-19, providing supplemental oxygen early in the progression of the infection is paramount. The options available are listed here:

- **Low-flow oxygen.** Typically, a nasal cannula administering 4 to 6 L/min is used to administer low-flow oxygen.

- **Oxypendant.** This nasal cannula incorporates a larger luminal diameter and an oxygen reservoir that is designed to deliver a higher oxygen concentration in each breath, similar to a nonrebreathing mask reservoir.
- **Simple face mask.** A simple face mask may deliver higher F_{IO_2}, ranging from 0.3 to 0.6, with flows up to 10 L/min.
- **Nonrebreathing mask.** A nonrebreathing mask delivers F_{IO_2} of approximately 0.85 to 0.95.
- **HFNC.** This device may deliver flows up to 60 L/min, with F_{IO_2} ranging from 0.21 to 1.0, and the ability to heat and humidify the blended gas.
- **Noninvasive ventilation.** The preferred noninvasive approach uses a full-face mask and either CPAP or BPAP.
- **Self-proning.** Self-proning has been encouraged in this patient population to better ventilate the dorsal lung regions and potentially improve $\dot{V}/\dot{Q}$ matching.

The World Health Organization suggests a targeted Sp_{O_2} of greater than 90% for maintenance oxygen. Hyperoxia should be avoided. Because the transport arena is a dynamic environment, close attention to the oxygenation status of this patient population is warranted. If these applications fail to improve the ventilation/oxygenation status of the patient with COVID-19, mechanical ventilation would be the next strategy.

CONTROVERSIES

Research suggests that patients who have, or are suspected of having, COVID-19 may benefit from transport in the prone position. This position has been shown to improve oxygenation and reduce mortality in patients who are awake and undergoing mechanical ventilation when transport time is longer than 15 minutes. Improving oxygenation via this simple technique may help avoid the need to intubate these patients, which is a higher-risk intervention.

A limiting factor in using the prone position is patient tolerance, as patients may find the position uncomfortable, particularly given a long transport. If this position is used, providers should try to make the patient more comfortable by padding the stretcher with pillows and blankets.

Research into this intervention is limited. Providers should follow local protocols when considering transport of a patient in the prone position.

Chronic Obstructive Pulmonary Disease

COPD is an umbrella term for a group of progressive lung diseases that include chronic bronchitis and emphysema. Increased airway resistance and decreased elastic recoil are factors contributing to dynamic hyperinflation in patients with COPD, and they present challenges when applying positive-pressure ventilation. One of the major causes of COPD is tobacco smoking. If possible, obtain a smoking history from any patient about to receive positive-pressure ventilation.

Another characteristic of COPD is airflow restriction, which may lead to further complications if too much pressure/volume is applied at too high a rate. This patient population is susceptible to air trapping or auto-PEEP and typically needs more time for passive exhalation. Special attention must be focused on the I:E ratio to allow enough time for the exhalation phase. A 1:4 or 1:5 I:E ratio may be necessary for the patient with COPD. Accomplishing this goal becomes particularly challenging in such patients, due to the abundance of variables within the lung mechanics to consider.

Before transporting a patient with COPD, ensure the patient has received all of the medications that are prescribed and due before transport. Medications commonly used to treat these lung diseases include long- and short-acting bronchodilators (beta-2 and anticholinergic), corticosteroids, and antibiotics. The goal is to maximize the lung’s ability to oxygenate and ventilate with the least amount of airflow restriction. The patient should be suctioned prior to transport if rhonchi are present.

Noninvasive positive-pressure ventilation (NIPPV) plays an important role for patients with COPD exacerbation and has been widely accepted as the first strategy for treating such patients who present with respiratory distress. Early application of this modality may avoid the need for intubation, and consequently the negative ramifications of mechanical ventilation. Prior to placing a patient on NIPPV, it would be beneficial to obtain a recent chest radiograph, ABG analysis, and some history of oxygen requirements. Placing any patient on positive-pressure ventilation carries an inherent risk of barotrauma, volutrauma, and hemodynamic compromise. Because the patient with COPD may already have damaged alveoli due to the nature of the disease process, applying judicious amounts of pressure/volume is essential.

Typical starting pressures for NIPPV using a full-face mask may be a PIP of 10 cm H_2O and a CPAP of 5 cm H_2O, followed by assessment for patient compliance, breath sounds, work of breathing, and oxygenation and ventilation status. Titration of inspiratory pressures assists in achieving the intended exhaled tidal volumes, which may be necessary to reach the target goals for ventilation. The CPAP setting can be adjusted to increase the surface area at the alveolar-capillary membrane, and $F\text{IO}_2$ can be increased to improve oxygenation.

It is important to fully understand how your transport ventilator delivers the pressure-delivered breath. For example, if the ventilator delivers a PIP and your settings are an IPAP of 10 cm H_2O and an EPAP of 5 cm H_2O, and if your strategy is to increase the EPAP to 8 cm H_2O to aid in oxygenation, the change in pressure (delta P) decreases from 5 cm H_2O to 2 cm H_2O, as the PIP will remain the same. This outcome is of great concern because the tidal volume may be drastically reduced, causing increased work of breathing, anxiety, and elevated $Pa\text{CO}_2$ levels in the patient due to the decreased minute volume. However, if your transport ventilator uses PAP for a pressure-delivered breath, and you make the same adjustment from an IPAP of 10 cm H_2O and an EPAP of 5 cm H_2O (which is a PIP of 15 cm H_2O) to an IPAP of 10 cm H_2O and an EPAP of 8 cm H_2O (which is a PIP of 18 cm H_2O), then the change in pressure is unaffected.

Of particular concern is the patient with bullous emphysema—a condition in which the air-filled space in the lung is greater than 1 cm in diameter, and which results from alveolar destruction in the lung parenchyma. The main causes of bullous emphysema are tobacco smoking and alpha-1 antitrypsin deficiency, an inherited genetic condition. Although diagnosing someone with bullous emphysema on a physical exam is impossible, gathering a history and CT scan, chest radiograph, and ABG analysis can be important in formulating a strategy for transporting such a patient **FIGURE 7-14**. Administering positive-pressure ventilation to the patient with end-stage COPD or emphysema may lead to disastrous results, including a pneumothorax. Such patients are often on home oxygen via nasal cannula or an oxypendant. They might do well on a nonrebreathing mask, HFNC, or even a minimal level of CPAP. Treat each case individually to ensure patient safety at all times.

Ventilator settings for this patient population are challenging. If the patient's hospital ventilator settings are acceptable for the transport, then try to match them on your own ventilator. Recognize, however, that the ventilation provided with the transport ventilator will not feel exactly the same as that provided by the hospital ventilator. Some adjustments or a mode change may be necessary to meet the patient's demands. Choosing the right flow target is a great place to start. In a volume-targeted breath, the flow delivered is fixed and is set by the desired volume and inspiratory time. If the tidal volume target has already been set, the only way to increase flow to the air-hungry patient is to lower the inspiratory time. For an air-hungry patient, you might consider setting a pressure target, as the ventilator will deliver the flow in a decelerating pattern and provide as much flow as the machine is rated for. Some ventilators also allow for manipulation of that decelerating flow in the initial inspiratory phase by decreasing the rise time or P-ramp setting, which will send the desired pressure slightly faster. A low tidal volume strategy (6 to 8 mL/kg of PBW) is the best choice, keeping the plateau pressures at less than 30 cm H_2O. If auto-PEEP is present, confirm the settings are appropriate for the patient and aim for an I:E ratio of 1:4 or 1:5, if possible. This may be accomplished by reducing the respiratory rate and decreasing the inspiratory time.

Three factors contribute to dynamic hyperinflation: (1) the I:E ratio, (2) the minute volume (tidal volume × respiratory rate), and (3) the expiratory time constant, a dynamic measurement that is the product of compliance and resistance. If auto-PEEP is accurately measured, a suggested strategy is to set external PEEP at 75% less than auto-PEEP to avoid any increased hyperinflation or hemodynamic compromise. Some ventilators may allow for auto-PEEP measurement by applying an expiratory hold maneuver and then calculating actual PEEP in the circuit minus the set PEEP. Other ventilators will give an estimate of auto-PEEP along with flow graphics, which can visually alert the CCTP to auto-PEEP; that is, the CCTP can observe the expiratory flow tracing and ensure it returns to the isometric line before the next breath is delivered **FIGURE 7-15**.

Initial ventilator settings for a patient with COPD who is in respiratory failure might appear as follows:

- Pressure or volume target
- Assist/control mode
- Tidal volume: 6 mL/kg of PBW, ensuring plateau pressures less than 30 cm H_2O
- Respiratory rate: 10–12 breaths/min, aiming for an I:E ratio of 1:4 to 1:5

- Inspiratory time: 0.8–1.0 s, aiming for an I:E ratio of 1:4 to 1:5
- PEEP: 5 cm H_2O
- FIO_2: titrate for desired saturation

Some sedation may be necessary, and aiming to keep the patient in a fluid-neutral state is important.

Example ABG values for a patient with COPD might be pH, 7.35; $PaCO_2$, 75 mm Hg; PaO_2, 98 mm Hg; serum bicarbonate (HCO_3), 49 mEq/L; base excess, 18.7; calculated oxygen saturation (calc sat) 94%; patient on FIO_2 at 1.0. It is important to know the patient's baseline condition before "chasing numbers." For a patient with these ABG values, you would treat the pH, not the hypercapnia, as many patients with COPD have chronic hypercarbia. Decreasing the FIO_2 would be indicated.

Pneumonia

Pneumonia is most commonly triggered by a bacterial infection in the lungs, which sets off the invasion of fibrinous exudate and leukocytes, impeding the lung's ability to oxygenate and ventilate effectively. However, it may also be triggered by a viral or fungal infection. In severe cases of pneumonia, the patient may develop ARDS. Empiric antibiotics should be started based on regional guidelines. Ensure blood and, if possible, sputum cultures are sent prior to initiating antibiotic therapy when possible.

If you are transporting a patient with pneumonia on NIPPV, it is important to consider using a heated-wire circuit. This device provides warmed humidification to minimize the risk of drying of secretions that then leads to a mucus plug. Be mindful of these secretions, and perform deep suction whenever possible prior to beginning the transport. Chest physiotherapy and postural drainage are other options to consider for loosening the secretions. The dynamic environment that the transport arena presents may loosen up secretions unexpectedly, and monitoring the PIP can provide a good indicator of airway resistance. The same ventilator strategy used for patients with ARDS may be implemented in this patient population, though they may require more F_{IO_2} to reach the target saturation levels due to the shunting effect that excessive secretions precipitate.

Pulmonary Fibrosis

Pulmonary fibrosis is a respiratory condition that causes scarring of the lung tissue. This incurable disease is thought to have a genetic component, but in most cases its cause is unknown; therefore, the condition is referred to as idiopathic pulmonary fibrosis. Treatment is aimed at slowing the process and improving the patient's quality of life. Patients with idiopathic pulmonary fibrosis receive oxygen when their saturation level falls below 88%. Medications such as pirfenidone and nintedanib may be prescribed to slow the scarring process. Pulmonary rehabilitation is essential to teach patients how to better live with this condition. Because prognoses are poor and life expectancy from the time of diagnoses ranges from 2 to 5 years, lung transplant is a strong consideration. Mechanical ventilation and ECMO may be considered as a bridge to transplant.

You may be tasked with transporting a patient with idiopathic pulmonary fibrosis. Discussion of the strategy for such a transport should involve all parties. Some lung transplant centers may cancel the transplant procedure if the patient is receiving mechanical ventilation. Often supporting the patient with a nonrebreathing mask or HFNC will suffice. Consider using NIPPV at a comfortable level of CPAP and high levels of F_{IO_2} if necessary. Because of the scarring of the lung tissue, adding high levels of PEEP typically will not increase oxygenation.

Asthma

Asthma is a common lung disorder that causes shortness of breath due to inflammation of the airways and increased mucus production. When a patient presents with an asthma exacerbation, rapid assessment and treatment should be the priority, as patients experiencing status asthmaticus need immediate attention to support their ventilation and ultimately oxygenation. It is imperative to recognize the difference between respiratory distress and respiratory failure (explained earlier in the chapter).

Another potential strategy for reducing the increased airway resistance is to administer heliox, as this therapy will help to decrease the work of breathing. A small number of patients may show signs of improvement with intramuscular administration of epinephrine or terbutaline.

A trial of NIPPV can be considered, but if the patient's condition is not improving or is worsening, then intubation and mechanical ventilation would be the next step. Because airway resistance is of great concern with this patient population, choosing an ET tube with the largest appropriate diameter would be prudent due to the potential for auto-PEEP. Ventilator settings should account for the time needed for passive exhalation, meaning the I:E ratio should be near 1:4 or 1:5. A pressure-delivered breath is often used in these scenarios because it limits the pressure delivered; it should be targeted at less than 30 cm H_2O. The mode of choice is often assist control until the patient's respiratory status becomes more stable. Tidal volumes can be on the low side (6 mL/kg or less of PBW) until the patient's lungs respond to medical therapy.

Some patients may need to be heavily sedated or paralyzed to slow their respiratory rate and prevent auto-PEEP. This intervention, termed permissive hypercapnia, is not a goal per se, but rather an end result of preventing volutrauma, barotrauma, and air trapping. It is not uncommon to allow for higher-than-normal $Pa\text{CO}_2$ and ETCO_2 values during the initial stages of caring for a newly intubated patient with asthma exacerbation. Constant monitoring of exhaled tidal volume and minute volume is essential when such patients are receiving pressure-delivered breaths. If you choose a volume target, always monitor and trend the PIP values.

Heart Failure

Acute pulmonary edema (APE) can occur in heart failure patients. When assessing a patient for APE, the initial step to identify whether this condition involves a pump-filling problem (diastolic malfunction) or a pump-contractility problem (systolic malfunction).

When transporting a patient with APE, the goal may be to support oxygenation and ventilation. On auscultation, it is common to hear crackles on end inspiration along with scattered rhonchi, and pulmonary edema may be evident on the chest radiograph or thoracic ultrasonography. If the patient appears dyspneic, NIPPV in the form of CPAP is the first-line strategy to support the patient's respiratory status in addition to standard pharmacologic treatment. Starting at a CPAP of 5 cm H_2O and titrating the pressure up to meet the patient's respiratory demand is a sound initial strategy. Many patients do well with CPAP but may require more assistance if they appear air hungry. Switching to BPAP is another option to help decrease the work of breathing. Typical BPAP settings start with an IPAP of 10 cm H_2O and an EPAP of 5 cm H_2O, which are then titrated upward to obtain the desired results. Using a full-face mask would be beneficial to provide more accurate pressures, but the CCTP needs to be acutely aware of the risk of aspiration. Increasing the gradient between IPAP and EPAP should increase the minute volume and potentially decrease the work of breathing; increasing the EPAP should help with oxygenation.

If intubation is inevitable, using a low tidal volume (6 to 8 mL/kg of PBW) is the best initial strategy. The choice between a volume or pressure target may be determined by how the patient's lungs respond to mechanical ventilation while monitoring for volutrauma and barotrauma. The goal should be to keep the plateau pressures at less than 30 cm H_2O. Initially, use of assist/control mode may benefit the patient until ABG values are stable. Maintain a cautious attitude when applying PEEP. In a patient with low end-diastolic volume, increasing PEEP levels may negatively affect preload. One benefit from PEEP may be improved left ventricular function, as a result of decreasing the left ventricular afterload.

Another benefit of PEEP in the patient with APE is that this therapy moves extravascular lung fluid from the alveoli back into the pulmonary vasculature. Start with a PEEP of 5 cm H_2O; then, if more

PEEP is to be applied, do so in small increments of pressure, allowing sufficient time to achieve the desired results while monitoring the patient’s hemodynamics and ventilatory status. Adjusting the respiratory rate to achieve a target Pa_{CO_2} of 35 to 45 mm Hg is common practice.

When weaning from the ventilator is considered for a patient, including the patient with APE, it may be useful to switch the mode to synchronized intermittent mandatory ventilation. In this mode, a set rate and target volume/pressure are established, and the patient can breathe spontaneously between the set rate. A minimum of 5 cm H_2O of pressure support might be added to address any airway resistance within the circuit. Pressure support may then be increased to target a specific exhaled tidal volume if needed.

Patient Monitoring

The CCTP's goal is to deliver the same level of ongoing care and treatment during transport as would be provided in an inpatient critical care unit. All patients with significant respiratory concerns should be continuously monitored with pulse oximetry and continuous waveform capnography. Nasal capnography is readily available for spontaneously breathing patients and can also be used to monitor the effects of noninvasive ventilation. Make sure you have performed a pre-use check, including a circuit check, on the ventilator prior to placing a patient on this device.

During transport, it is crucial to monitor the values measured for the patient and displayed on the ventilator. Some of these values are summarized here.

Peak Inspiratory Pressure

Record a baseline PIP and monitor this value regularly. If PIP rises, it may indicate compliance/resistance changes or obstruction in the circuit. This finding could also indicate a patient who is asynchronous with the ventilator settings. Corrective action may include assessing the patient's lung sounds, applying suction, or giving bronchodilators if indicated. Inspect the circuit components for malfunctions, including the ET tube and HME. The patient biting on the ET tube, a kinked ET tube, and a closed suction catheter that is not fully withdrawn are common problems and need to be addressed immediately. Always reassess the ventilator settings for patient demand.

Respiratory Rate

Record a baseline respiratory rate and monitor this value regularly, watching for tachypnea. If the patient's respiratory rate increases rapidly, first check the circuit for leaks; such an event could cause the ventilator to autocycle or trigger an unwanted breath. Adjusting the sensitivity should correct this problem if the leak cannot be fixed. If the patient appears air hungry, consider changing the mode, adjusting the volume delivered, increasing the respiratory rate, adjusting the inspiratory time to match the patient's need, and switching to a pressure-delivered breath, which offers the ability to adjust the flow to the patient through rise-time adjustments and flow termination.

Exhaled Tidal Volume

Record a baseline exhaled tidal volume and monitor this value closely. If extreme fluctuations are noted (in the range of 50 to 100 mL), first check the components of the circuit (HME, closed suction catheter, $ETCO_2$ adapter, and ET tube cuff) for leaks. It may be helpful to measure for auto-PEEP by performing an expiratory hold maneuver. If you cannot obtain an exhaled tidal volume measurement, you may instead assess the patient's breathing pattern and breath sounds. If fluctuations in exhaled tidal volume are observed, suction and administer bronchodilator therapy as necessary. Adjusting the ventilator settings may prove beneficial as well.

I:E Ratio

Monitor the I:E ratio, remembering that a ratio of 1:2 or 1:3 is normal for a healthy lung. Patients with obstructive or restrictive lung diseases might need a longer expiratory time, indicated by a 1:4 or 1:5 I:E ratio.

Documentation

Charting of the ventilator settings and monitored values should include the following elements:

- **Settings**
  - Volume or pressure breath
  - Mode
  - Respiratory rate

    - Inspiratory time
    - Tidal volume or pressure
    - PEEP
    - F_{IO_2}
    - Sensitivity
- **Values**
    - PIP
    - Exhaled tidal volume
    - Respiratory rate
    - I:E ratio
    - Minute volume
    - $ETCO_2$
    - Pulse oximetry (Sp_{O_2})

This information is valuable when troubleshooting ventilation-related problems during transport. The frequency of the charting is up to the CCTP. It is recommended to record values at least every 30 minutes or after making any changes to the ventilator settings.

Quick Reference: Ventilator Settings for Adult Patients

I. Selection of pressure or volume ventilation
A. Choose mode
1. Assist/control (A/C)
2. Synchronized intermittent mandatory ventilation (SIMV)
3. Pressure-regulated volume control (PRVC)
4. Pressure support ventilation (PSV)
5. Continuous positive airway pressure (CPAP)
6. Adaptive support ventilation (ASV)
B. Choose a target tidal volume: 6–8 mL/kg predicted body weight
C. Choose a respiratory rate: 12–14 breaths/min
D. Choose a PEEP level: 5 cm H_2O
E. Choose an inspiratory time: 1 s
F. I:E ratio: 1:2 to 1:3 (healthy lung)

G. FIO_2: 0.21–1.0; adjust for saturation >92% to 94%
H. Sensitivity: 2 L/min (increase for autocycling due to leak)
II. Alarms
A. High-pressure alarm: 10 cm H_2O above PIP
B. Low-pressure alarm: 5 cm H_2O below PIP
C. Low-minute-volume alarm: 25% below baseline minute volume

Always consider the patient's lung condition before placing them on a ventilator. Suctioning and bronchodilator therapy may enhance lung compliance or decrease airway resistance. Monitor for high PIP and auto-PEEP, and adjust the ventilator accordingly.

Ongoing Care

The transport team is responsible for ensuring that proper ventilator function and the patient’s ventilatory status are maintained during the transport. This can be accomplished by ensuring the following tasks are completed:

- Maintain a stable and patent airway.
- Verify and document the ventilator settings and monitored values before, during, and after arrival.
- Ensure a proper power supply and oxygen are available during the transport.
- Assess and document breath sounds before, during (if possible), and after transport.
- Continuously monitor Spo_2 and $ETCO_2$.
- Have a bag-mask device available at the head of bed if there is any doubt about the ventilator’s functioning.

Quick Reference: Ventilator Settings for Pediatric Patients

I. Selection of pressure or volume ventilation
A. Choose mode
1. Assist/control (A/C)
2. Synchronized intermittent mandatory ventilation (SIMV)
3. Pressure-regulated volume control (PRVC)
4. Pressure support ventilation (PSV)
5. Continuous positive airway pressure (CPAP)
6. Adaptive support ventilation (ASV)
B. Choose a target tidal volume: 6–8 mL/kg predicted body weight
C. Choose a respiratory rate: 15–20 breaths/min
D. Choose a PEEP level: 5 cm H_2O
E. Choose an inspiratory time: 0.5–1 s
F. I:E ratio: 1:2 to 1:3 (healthy lung)
G. FIO_2: 0.21–1.0; adjust for saturation >92% to 94%

H. Sensitivity: 2 L/min (increase for autocycling due to leak)
II. Alarms
A. High-pressure alarm: 10 cm H_2O above PIP
B. Low-pressure alarm: 5 cm H_2O below PIP
C. Low-minute-volume alarm: 25% below baseline minute volume

Always consider the patient's lung condition before placing them on a ventilator. Suctioning and bronchodilator therapy may enhance lung compliance. Monitor for high PIP and auto-PEEP, and adjust the ventilator accordingly.

Skill Drill 7-1 summarizes the steps for using a portable ventilator, which are described here:

3. Select the ventilator rate, inspiratory rate, flow rate, and oxygen concentrations **Step 3**.
4. Make mode selections: CPAP and PEEP, IMV/SIMV, and assist/control **Step 4**.

Flight Considerations

Not all ventilators are able to compensate for changes in altitude in their delivery of tidal volumes. Some studies have shown a 10% increase in tidal volumes at the cabin pressures experienced at 8,000 feet of altitude, a relationship explained by Boyle's law (discussed in Chapter 4, *Aircraft Fundamentals and Flight Physiology*). Boyle's law should also be considered when transporting a patient who has potential for any gas to become trapped in a body cavity, such as happens with pneumothorax. Air in the body cavities can expand as much as 25% at higher altitudes. In such a case, the CCTP should discuss with the pilots whether it is possible to fly at an altitude that would maintain a sea-level cabin pressure to reduce the negative effects on the patient.

In-Line HME and Bacterial/Viral Filters

The air delivered to patients requiring mechanical ventilation should be heated and humidified. By placing an ET tube in the trachea, the physiologic mechanism of the superior airway is bypassed, preventing it from contributing heat or moisture to the lungs. In the ICU, heated humidifiers are often used to supply the delivered breath at a set temperature and humidification. The ventilator circuits have heated wires to prevent temperature drops along the path to the lungs. These heated, humidified units are expensive, run on AC power supply, and require a steady flow of sterile water. To circumvent these factors in the out-of-hospital setting, use of an HME placed in-line between the ET tube and circuit is becoming more common. The HME is designed to capture the heat and moisture from the patient's expired breath and then release the heat and moisture during the inspiratory phase of the delivered breath.

The CCTP should be aware of a few concerns when using an in-line HME. First, the placement of the HME in the circuit will add dead space to the circuit. For this reason, it is important to have the appropriate-size HME for the patient being transported **FIGURE 7-16**. Three sizes are available: neonatal, pediatric, and adult. Another factor to consider is the resistive load associated with the HME for the critically ill patient. This added resistance to the circuit will be minimal unless excessive moisture accumulates from copious secretions and mucus, potentially causing auto-PEEP and making it more difficult for the compromised patient to trigger a breath. Monitor the integrity of the HME and keep spare replacements available.

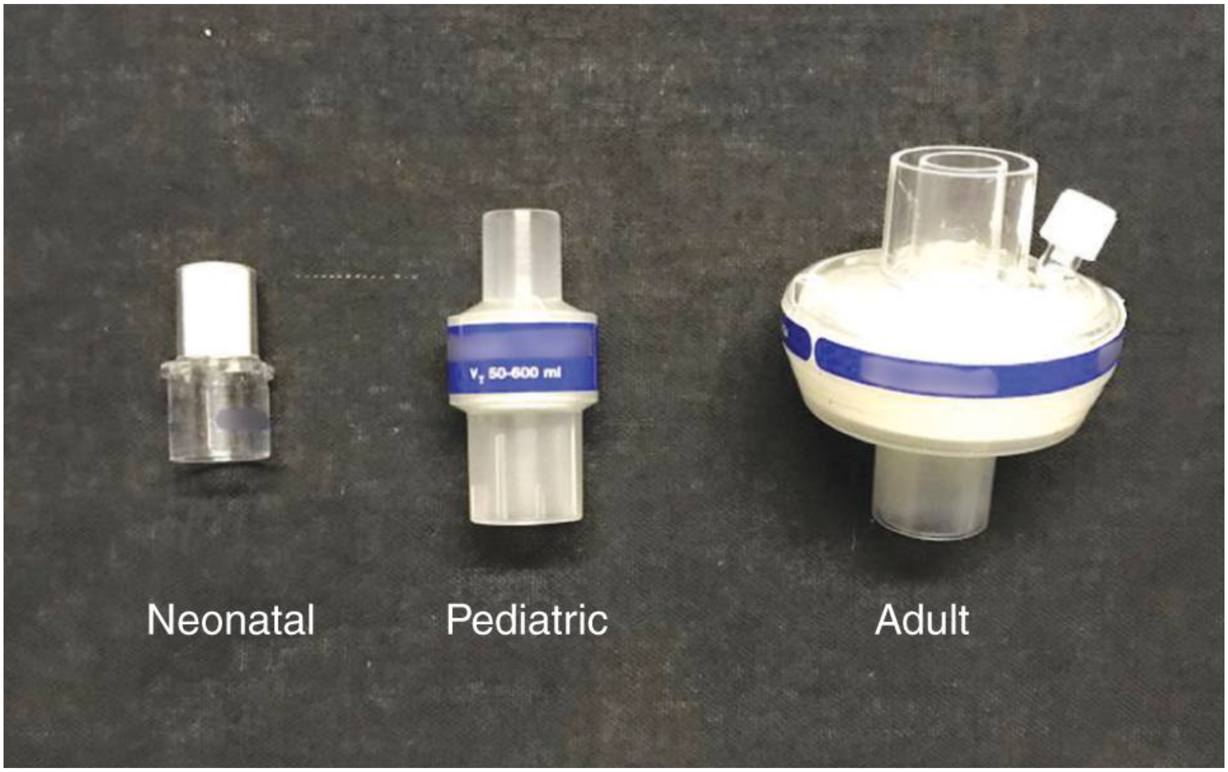

FIGURE 7-16 Example of additional dead space added to the ventilator circuit through placement of an HME.

Courtesy of Vent-Pro Training.

Providers must also consider the need to add bacterial and viral filters to the ventilator circuit to protect against infection by airborne organisms. These filters are rated according the particle sizes they can block from entering the environment. Understanding where to place these filters is essential, as different ventilator circuits have exhalation valves at various positions within the circuit. The most common choice is to use an HME that provides bacterial/viral protection, placed close to the patient, as guided by the product's specifications for dead space, resistive load, and particle size filtration.

In-Line Suction Catheters

In-line suction catheters allow providers to suction the patient without opening the circuit and exposing the environment to airborne organisms or losing PEEP **FIGURE 7-17**. Because the transport environment is dynamic, the patient's secretions may become mobilized during transport. The CCTP must closely monitor the patient through auscultation of the lungs and watch for increased PIP in a volume target and decreased exhaled tidal volume in a pressure target.

Transport Management

- HMEs and bacterial/viral filters are beneficial until they are filled with secretions, causing increased airway resistance. Always carry spare filters.
- When using in-line suction, ensure the catheter is withdrawn to its original position and is not partially inserted into the ET tube.
- Always maximize the patient's lung condition before beginning the transport—for example, by suctioning the patient's lungs, administering medications prior to departure, evacuating unwanted air from the stomach, and positioning the patient to optimize lung compliance.

- Calculate oxygen consumption for worst-case scenarios, with the patient requiring an FIO_2 of 1.0.
- Be cautious when adjusting the minute volume and oxygenation based on $ETCO_2$ and pulse oximetry. Knowing the patient’s baseline ventilation and oxygenation requirements and current lung physiology is essential when caring for a patient on mechanical ventilation.
- When formulating a strategy for ventilator settings based on an ABG analysis, consider the pH value before manipulating the minute ventilation to correct any hypercarbic or hypocarbic condition.
- Before making any adjustments on the ventilator, consider the expected results and what those adjustments might collaterally affect, and then closely watch the monitored values from the ventilator.
- All ventilators need some time to deliver the target settings. A few breaths may be needed to adjust for lung compliance and airway resistance. Remain calm and inform the patient of this condition.

Use the appropriate-size catheter, as a catheter that is too small may not be able to remove thick secretions and a catheter that is too large may not fit or may get stuck in the ET tube. Many models contain a port where a flush syringe of normal saline can be connected to remove any remaining secretions in the catheter. Flushing the syringe is recommended because the secretions remaining in the catheter may dry out and clog the catheter, rendering it useless for the next attempt.

When suction is completed, confirm that all of the catheter has been removed from the ET tube. Pulling the catheter beyond the gasket may cause the protective plastic shield to inflate, adding more dead space to the circuit. The suction catheter should be changed out if this occurs.

When checking for leaks in the circuit, the flush port is a common culprit.

Basic Ventilator Waveform Analysis

Many ventilators display various waveforms in the form of scalars and loops that provide a great point-of-care tool. These graphics offer visual information regarding patient–ventilator asynchrony in regard to time, flow, volume, or pressure. Some transport ventilators are capable of displaying waveforms through a graphics package that incorporates sensors and signal processors **FIGURE 7-18**.

Description

On a scalar graphic, three components are plotted against time: the pressure time scalar, flow time scalar, and volume time scalar. When observing these waveforms, note that time is typically plotted on the horizontal *x*-axis, and pressure, flow, and volume are typically plotted on the vertical *y*-axis.

Loops are a two-dimensional graphic display containing two scalar values. The first display might be a pressure-volume loop, and the second might be a flow-volume loop. When viewing the pressure-volume loop, it is common to see the pressure on the *x*-axis and the volume on the *y*-axis. When viewing a flow-volume loop, the *x*-axis usually represents volume and the *y*-axis represents flow. Pressure-volume loops can assist in detecting compliance changes, overdistention of the lung, and lower and upper inflection points, which in turn can enable the CCTP to identify the steep part of the curve reflective of a high-compliance zone **FIGURE 7-19**. Flow-volume loops are useful in identifying a restrictive or obstructive lung condition and for detecting air leaks within the system.

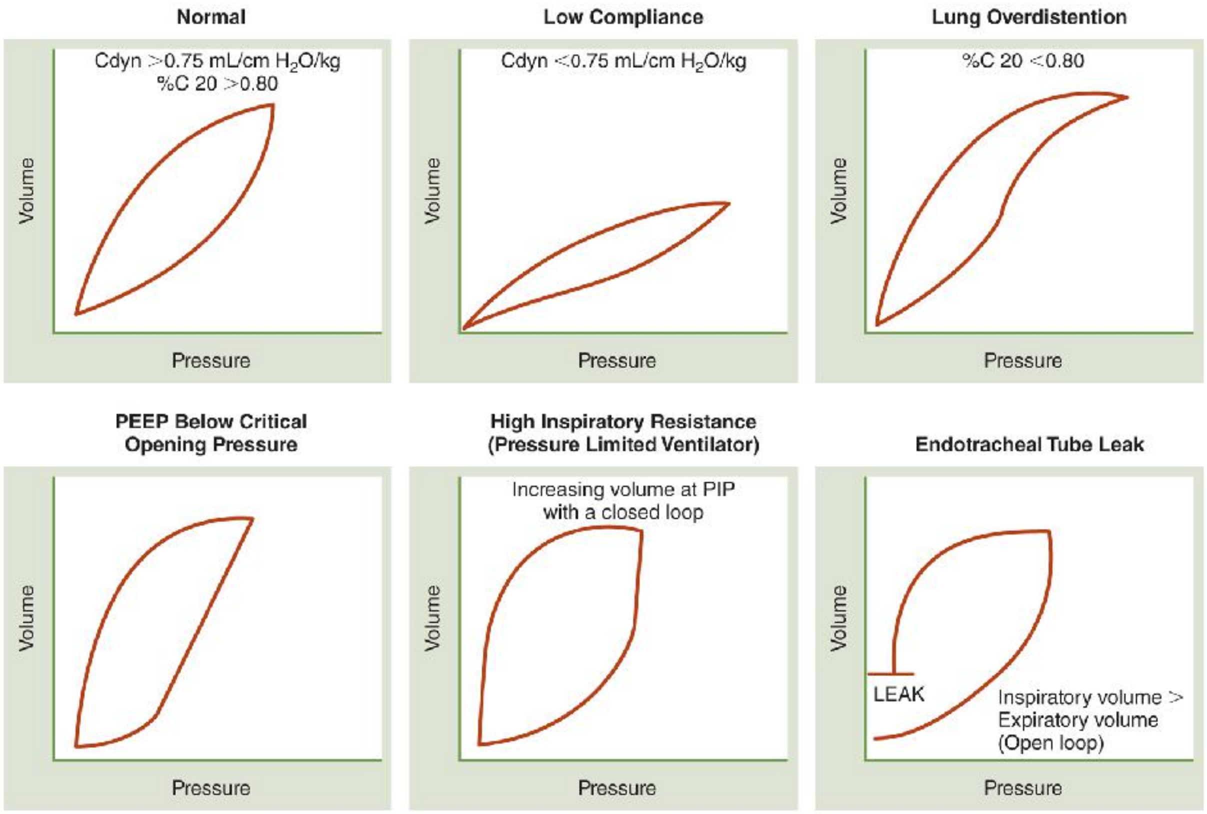

FIGURE 7-19 Pressure-volume loops.

Description

The basics of waveform analysis are discussed here to help the CCTP visually identify any issues that may complicate the transport mission. By understanding this information, the CCTP can also identify potential complications from use of the hospital ventilator in the ICU. It is recommended that CCTPs become familiar with all the options available if the transport monitor is equipped with graphic monitoring, so as to optimize the monitoring capabilities while caring for a mechanically ventilated patient during transport.

The most important scalars to monitor are the flow time scalar and the pressure time scalar. Valuable information can be obtained by observing how the flow time scalar reacts during each breath. The inspiratory flow tracing appears above the isometric line, displaying the positive flow, while the expiratory flow tracing appears below the isometric line, displaying the negative flow. Observing this flow scale can give the CCTP visual clues needed to detect air trapping or auto-PEEP. If the expiratory flow tracing does not return to the isometric line (baseline) before the next breath is initiated, then the CCTP should suspect air trapping and undertake further investigation to correct this situation (see Figure 7-15). The patient's lung history is always the first place to start the investigation.

As always, it is prudent to check the patient, first looking for specific reasons for air trapping, including tachypnea, anxiety, pain, bronchospasm, excessive secretions, and improper ventilator mode and settings. The pressure time scalar can be studied to detect the breath going in too fast by observing the slope of the breath in the initial milliseconds. An initial spike at the PIP may indicate too much flow is being delivered, causing a turbulent flow situation **FIGURE 7-20**. This setting may be fine-tuned by slightly increasing the inspiratory time in a volume-targeted breath or increasing the rise time or P-ramp in a pressure-targeted breath.

Description

Troubleshooting and Diagnosing Ventilator Problems

Troubleshooting ventilator function is not as difficult as it might seem. First, it is imperative that the CCT team carry a bag-mask device for every patient on a ventilator. If any doubts about ventilator function arise, use the bag-mask device to ensure the patient's safety. A good rule of thumb when troubleshooting equipment is to start at the patient and work methodically toward the equipment or power source.

Patient Not Tolerating the Change From the Hospital Ventilator to the Transport Ventilator

This problem is a frequent occurrence in the alert and awake patient. The two ventilators may deliver the flow in different patterns, which may feel uncomfortable to the patient. To avoid this problem, match the settings of the hospital ventilator as closely as possible, provided they are oxygenating and ventilating the patient with the lowest amount of risk to the patient's lungs.

The most common settings to match are pressure or volume target, mode, tidal volume or pressure, respiratory rate, PEEP, and F_{IO_2}. A frequently overlooked setting is the patient's inspiratory time or I:E ratio, which plays a major role in what the patient feels upon transfer. It may be difficult to find these settings on the ventilator without going deep into the settings menu. If you are unsure of the inspiratory time or I:E ratio, consult the respiratory therapist who is caring for the patient.

Prior to switching to the transport ventilator, describe the process to the patient and explain that the transport ventilator may feel different. Always assure the patient you will adjust the ventilator to make them comfortable. When you first connect the ventilator to the patient, the time it takes to reach the set volume or set pressure will vary. The machine needs to determine which pressures to apply to the patient's lungs to deliver the target volumes. Making these adjustments may take five to six breaths in some cases. The patient may experience some anxiety during this brief period, but coaching the patient may help relieve any discomfort.

If the patient appears air hungry, then adjustments may be necessary. In a volume-targeted breath, the flow may be set too low for the patient's demand. An obvious adjustment is to increase the target tidal volume, although this strategy has some limitations. The target tidal volume should be 6 to 8 mL/kg of PBW, and PIP should be limited to less than 30 cm H_2O, if possible. The next adjustment in a volume-targeted breath might be to decrease the inspiratory time to increase the fixed flow. Small increments of 0.1 second are recommended while monitoring the patient's response and PIP levels, as decreasing the inspiratory time may cause the pressure to rise.

Another strategy to increase flow to the air-hungry patient would be to change to a pressure-targeted breath. This method typically uses a decelerating flow pattern that reaches the desired pressure quickly. If you are switching from a volume target to a pressure target, note the PIP on the target volume: Do not exceed this pressure. It is important to know how the ventilator delivers the pressure. Most of today's ventilators use a pressure above PEEP (PAP). Therefore, if your PIP in volume-targeted ventilation is 20 cm H_2O and the PEEP is 5 cm H_2O, you would set the PAP at 15 cm H_2O. (PAP plus PEEP equals PIP.) If your ventilator does not set the pressure above PEEP, then you would match the set pressure with the PIP. Often the matched pressure will deliver a larger tidal volume in pressure-delivered breaths. The main concern is to monitor the exhaled tidal volume and titrate the pressure to meet your target tidal volume.

Alarms

When attempting to diagnose and correct a pressure alarm, start by using the DOPE mnemonic:

- **Displacement.** Check for ET tube displacement.

- **Obstruction.** Check the ET tube for any obstruction.
- **Pneumothorax.** Obtain a chest radiograph, observe chest excursion, auscultate the lung fields, and obtain a chest ultrasound.
- **Equipment failure**

High-Pressure Alarm

The high-pressure alarm may be the most important alarm to monitor and trend while caring for the patient on a mechanical ventilator. Typical suggested settings for this alarm, or limit, are 10 cm H_2O above the resting PIP. The high-pressure alarm is designed to prevent the ventilator from delivering pressures that are unfavorable to the specific lungs being ventilated. It is rare to set an alarm above 50 cm H_2O, but this may be necessary when lung compliance is severely diminished.

Following are some of the more common triggers of this alarm:

- Patient biting the ET tube
- Mucus plug
- Pneumothorax
- Bronchospasm
- Excessive secretions
- Patient coughing
- Patient bucking the ventilator
- Air trapping or auto-PEEP
- Circuit kinked
- HME clogged
- Closed suction catheter in ET tube
- Right main stem migration of ET tube
- Improper alarm setting
- Any worsening resistance or compliance changes

If the patient is biting the ET tube, consider sedation. If it is not possible to sedate the patient appropriately, a bite block may be helpful. Suction the patient if rhonchi are heard, and administer a bronchodilator if wheezing is detected. If this intervention is needed, it is suggested to perform it prior to transferring the patient to the transport ventilator. Visually inspect the ventilator circuit's integrity from the ET tube all the way back to the machine. Always preset the high-pressure alarm prior to connecting the ventilator to the patient. You can take a baseline PIP from the hospital ventilator or start at 30 to 35 cm H_2O and titrate accordingly.

Never silence an alarm without evaluating the patient, diagnosing the cause, and remedying the situation.

Low-Pressure Alarm

Most transport ventilators incorporate a low-pressure alarm. The typical setting for this alarm is 5 cm H_2O below the resting PIP. The main reason this alarm activates is a leak in the circuit. Many locations can present with a leak, so it is wise to pressure-check your circuit prior to placing it on the patient. Refer to the ventilator's operator manual for this procedure.

Following are some of the more common triggers for a low-pressure alarm:

- Leak in the ET tube or tracheostomy cuff
- Positional leak in the uncuffed ET or tracheostomy tube
- Open flush port in the closed suction system
- Blown seal in the closed suction catheter
- Cracked HME or removed $ETCO_2$ port cap
- Disconnected flow sensor lines
- Malfunction of the external exhalation valves
- Improvement in the patient's lung compliance

If a leak is detected in the cuff, a decision must be made to either change out the ET or tracheostomy tube or transport the patient with the leak. Both risks and benefits must be considered in regard to changing out the tube, requiring a discussion with medical control. If the team decides to transport the patient with the leak, it might be beneficial to change to a pressure-targeted breath. This method may allow the flow to be manipulated via the rise time or P-ramp to deliver each breath a little more slowly. With a faster flow, the gas will find the path of least resistance and exit through the leak. Always monitor oxygenation and ventilation when a leak is known to be present. Increasing the PEEP slightly may help overcome the leak.

It is rare for the low-pressure alarm to activate because of increased compliance or decreased resistance, but it can happen. This condition may occur following suction or because of the positive effects of a bronchodilator, which would be administered if auscultation reveals wheezing.

Low-Minute-Volume Alarm

The low-minute-volume alarm is typically set at 25% less than the resting minute volume. It essentially monitors the exhaled tidal volume and the respiratory rate. When the alarm is activated, the challenge is detecting which value is causing the alarm. Is it the low tidal volume, the low respiratory rate, or both?

Following are some of the more common triggers for a low minute volume alarm:

- Decrease in the patient’s respiratory rate
- Decrease in the patient’s expired tidal volume
- Leak in the system

If the transport ventilator is delivering a volume-targeted breath, then the baseline minute volume is set by that volume and the respiratory rate. If you set the low-minute-volume alarm at 25% below that minute volume, the alarm will activate only if there is a leak in the system.

This alarm becomes extremely important when you are delivering a pressure-targeted breath. In this situation, the exhaled tidal volume varies with lung compliance and resistance, and any decrease in exhaled volume will affect the low-minute-volume alarm. In a pressure-delivered breath, this alarm should be set to detect any changes in lung volumes.

The low-minute-volume alarm is also extremely important when caring for a patient on straight pressure support ventilation. In this mode, there is no set respiratory rate or set tidal volume. Instead, there is just a pressure that acts as a “boost” breath to help the patient breathe. The tidal volumes and rate can vary greatly in this mode.

Apnea Backup Ventilation

The apnea backup alarm is designed to deliver a breath when a specific time interval is reached to detect a patient breath. If the ventilator does not detect a patient trigger to breathe, the ventilator will automatically deliver a preset or user-set breath. It is imperative to know how the apnea backup alarm delivers a breath and at what time interval it should be set. Typically, the default time interval is 20 seconds. The type of breath that is delivered may vary from machine to machine. Do not set up a patient on a ventilator without ensuring the apnea backup alarm is set properly for that patient.

Following are common triggers for an apnea alarm:

- Ventilator not detecting a time-set breath by the patient
- Sensitivity setting too high, not allowing the patient to trigger a breath
- Patient stopped breathing spontaneously

Low-Battery Alarm

Like oxygen cylinder duration, battery duration is an important factor when planning for a transport. Many variables can affect battery life, including the battery’s age, the air temperature, hours of use, the ventilator settings, and the FIO_2 settings. Refer to the operations manual for recommendations for, and limitations of, the ventilator’s battery.

This is a high-priority alarm. Best practice is to plug the ventilator into its primary power source whenever possible, rather than relying on battery power.

High/Low-Frequency Alarm

This alarm is set to trigger when the patient's respiratory rate exceeds or falls below the set levels. The provider determines the alarm settings based on the patient's overall condition.

Following are common triggers for the high/low-frequency alarm:

- Apnea
- Agitation, anxiety, or pain
- Tachypnea
- Metabolic acidosis
- Kussmaul breathing

Consider the mode the patient is currently on. It may be necessary to adjust the default settings around the patient's baseline respiratory rate. The target tidal volume, inspiratory time, and PEEP may require adjustment.

Disconnection Alarm (Disconnect Sensor)

If this alarm triggers, inspect the circuit integrity while looking for any disconnection and leaks within the entire circuit. This inspection should be accomplished within 5 seconds. Start with the pressure at the ET tube cuff, as low pressure could trigger a disconnection alarm. Other alarms that will subsequently be triggered are the low-minute-volume alarm and the low-pressure alarm.

Oxygen Supply Failed Alarm (Low O_2 Pressure, Low O_2 Supply)

This alarm is triggered when the ventilator does not detect a specific pressure at the oxygen inlet port. Typically, transport ventilators are connected to a 50-psi source of oxygen. When the pressure drops below 35 psi, an alarm will sound, alerting the user to this extremely dangerous situation.

The most common reason that this alarm activates is failure to properly calculate oxygen consumption for the mission. Other reasons including the following problems:

- Oxygen tank valve off
- Oxygen hose not fully connected
- Oxygen tank <200 psi

Names for this alarm may vary among ventilators, so learn your specific ventilator's verbiage.

High-PEEP Alarm

This alarm activates when the PEEP level exceeds the preset PEEP level. Most ventilators have a default setting and allow adjustments to the value.

The most common trigger for this alarm is patient air trapping (auto-PEEP). Diagnosing the root cause of this auto-PEEP can be quite a challenge. First, consider the patient's lung condition. Typically, patients with an obstructive lung disease are susceptible to air trapping. Confirm that the ventilator mode, flow target, and settings are the optimal choices for this patient. Optimize the lungs' function prior to transport by performing suction and administering bronchodilators, if necessary.

Another cause of air trapping may be an in-line filter or HME in which excessive secretions are restricting airflow within the circuit. In such a case, immediately replace these filters with new filters.

It is also common for patients who have been liberated from sedation to become anxious during the transfer from hospital ventilator to transport ventilator. If the patient becomes tachypneic, the I:E ratio changes drastically. Depending on the ventilator mode, this response can create auto-PEEP. You may need to discuss other options to diminish the risk of high PEEP levels.

Low-PEEP Alarm

This alarm detects a PEEP level that has fallen below the preset PEEP. Most ventilators have a default setting that may be adjusted by the user.

The most common reason this alarm activates is a disconnect in the circuit or a faulty exhalation valve that is unable to maintain the set PEEP level. Performing another circuit pressure test should help detect any defect within the circuit.

A less common, but often overlooked cause is an air-hungry patient who is sucking air through the circuit beyond the flow delivered, causing the low-PEEP alarm to activate. It may be necessary to adjust the ventilator settings to accommodate this flow demand. Some patients do well with a pressure-targeted breath and appropriate targeted tidal volumes. Check the sensitivity setting and adjust it to allow the patient to trigger a breath with less effort.

Troubleshooting and Diagnosing the Complicated Problem

When transporting the critically ill patient, a few considerations should be prerequisites before launching the mission. First, the CCTP must have a thorough understanding of the transport ventilator's operation. The CCTP should demonstrate proficiency in its use and application to patients with various disease processes on a regular basis through hands-on experience in a ventilator laboratory. The pre-use ventilator and circuit check should always be performed prior to patient application to ensure ventilator and circuit integrity. This is where many malfunctions occur.

Second, the CCTP must be familiar with the ventilator's specifications and ability to meet the specific patient's respiratory demands. Not all transport ventilators can deliver the same flow rates to meet the targets set by the CCTP.

Third, the CCTP must account for the patient's current lung condition and how that condition might change during transport. Consider the length of transport, altitude, temperature, gravitational forces, and vibration when planning the mission. Discussing a strategy for any unforeseen problems ahead of time is a good idea.

Finally, the CCTP must calculate the anticipated oxygen consumption and verify there is enough oxygen on board to meet this demand.

Patient Appears Dyssynchronous With the Ventilator

The patient's level of pain and anxiety must be addressed before attempting to adjust the ventilator settings. Clear the airways of secretions and auscultate lung fields for any bronchospasm; administer bronchodilators, if needed, prior to beginning the transfer if possible. It is important to correct this conflict with the breathing pattern because it will increase the patient's work of breathing, increase the oxygen demand, and complicate any intracranial pressure concerns.

As discussed previously, if you are transferring the patient from the hospital ventilator to the transport ventilator, try to match the current settings, provided the oxygenation and ventilation status meet your target goals, with the monitored values within normal limits. If possible, explain to the patient that the transition to the transport ventilator will feel different and that you may make some adjustments to make them comfortable. A common complaint is patients feeling as if they are not getting enough air. This perception is often related to setting a volume-targeted breath with a fixed flow, which may be less than the hospital ventilator's flow.

Missed Triggering

When setting up the ventilator, pay close attention to the sensitivity setting. If this setting is too high (not sensitive enough), some patients may have difficulty triggering a breath. The patient population of greatest concern includes patients with myasthenia gravis, Guillain-Barré syndrome, paralyzed diaphragm, or any disorder that weakens the patient's ability to create a negative flow or pressure to trigger the ventilator. If the sensitivity level is set too low (overly sensitive), this may contribute to autotriggering or autocycling. In this situation, a stimulus other than the patient's effort triggers the ventilator to deliver a breath. Some common causes of these ominous breaths are excessive secretions in the lungs or circuit, cardiac oscillations, and abrupt motion in transit. An incorrect sensitivity setting may cause asynchrony between the patient and the ventilator. If possible, obtain the sensitivity setting from the hospital ventilator.

Another missed triggering scenario may stem from an uncuffed tracheostomy or ET tube, or even a cuff, that fails to hold pressure. As a result, the patient cannot create enough flow or pressure to signal the ventilator to trigger a breath. If the leak cannot be corrected during transport, then adjusting the sensitivity may help with patient–ventilator synchrony. If a leak in the system is causing autotriggering, one solution is to slowly increase the sensitivity (in flow sensing) to overcome the leak. Watch carefully to determine when the autotriggering stops, and then add another 2 or 3 L/min of flow to the sensitivity. If the autotriggering stops at 6 L/min and you add 2 L/min, the total sensitivity setting would be 8 L/min and the patient could theoretically trigger a breath with a minus 2 L/min inhalation.

A patient who is asynchronous with the ventilator is typically tachypneic and at risk for auto-PEEP. This can be confirmed if your equipment allows for an expiratory hold or displays an estimate of auto-PEEP; alternatively, you can visually detect auto-PEEP on a flow scalar tracing (see Figure 7-15). Another reason to suspect auto-PEEP is an increase in PIP and large discrepancies of more than 75 to 100 mL of exhaled tidal volume.

Double Triggering

Double triggering is loosely defined as two ventilator-delivered breaths with one patient inspiratory effort. It is most commonly attributed to a mismatch in the set inspiratory time on the ventilator and the patient's neural inspiratory times. Such a mismatch usually reflects a short inspiratory time in a fixed-flow, volume-targeted ventilation mode. Although it may be difficult to match the patient's neural inspiratory time, it may be beneficial to slowly increase the I time on the ventilator and observe the patient's response. Always monitor the I:E ratio when making adjustments to the I time or respiratory rate, and consider the patient's lung condition and the potential for causing auto-PEEP. Another suggested strategy is to switch to a pressure-targeted breath, as the flow will vary depending on patient demand, and possibly to increase the pressure to meet target exhaled tidal volumes.

Transporting the Patient With a Tracheostomy

As a CCTP, you may be dispatched to transport a patient with a tracheostomy. Patients may have tracheostomies for many reasons, including the following:

- Congenital anomalies of the airway
- Laryngectomy
- Tumors
- Tracheomalacia
- Subglottic stenosis
- Vocal cord paralysis
- Upper airway burns
- Obstructive sleep apnea
- Diaphragm dysfunction
- COPD-related reduction of dead space
- Severe facial or neck trauma
- Neuromuscular disease with paralysis
- Spinal cord injury
- Failure to wean from the ventilator
- Anaphylaxis

It is important to be familiar with your agency's specific guidelines for caring for this patient population. The biggest challenge is identifying the type of tracheostomy tube in place **FIGURE 7-21A**. If the patient is breathing spontaneously and not ventilator dependent, the tracheostomy tube in place is unlikely to connect well to a bag-mask device in the event of an emergency. Your first priority is ensuring you have a way to manually ventilate the patient, should the need arise.

The next concern is determining the amount of oxygen and humidification the patient will require during the transport. For the nonventilated patient, specific devices are available that can deliver oxygen and some form of heat and humidification during transport. When preparing for the transport, confirm the portable device will meet the patient's needs and match their F_{IO_2} requirements. Assessing the patient's breath sounds and having the ability to perform deep suctioning of the lungs are extremely important as well. The latter skill needs to be mastered to effectively care for a patient with a tracheostomy. Excessive secretions are common in this patient population, and without humidification and frequent suctioning, mucus plugging is an unwelcome risk. When a tracheostomy is in place, the body's natural heat and humidification system is also bypassed.

Some patients with a tracheostomy may use a speaking valve that allows them to talk **FIGURE 7-21B**. This one-way valve is placed on the end of the inner cannula to allow air into the lungs during inhalation; it closes on exhalation, allowing air to exit past the vocal cords so the patient can speak. If the patient has a cuffed tracheostomy tube, it is imperative to deflate the cuff before placing the speaking valve. Devices often used to provide low-flow oxygen to the patient with a tracheostomy include the tracheostomy collar, a T-piece with in-line suction, and a T-HME with oxygen port.

Gather as much information about the patient's tracheostomy tube as possible. When was the tube placed? Why was the tube placed? Did any complications occur during the procedure? Was it a surgical or percutaneous procedure? Are there any barriers to endotracheal intubation? What size is the tracheostomy tube?

When transporting a patient with a tracheostomy on a ventilator, many issues must be considered before transferring the patient to the transport ventilator. The first concern is the transport ventilator's ability to match the patient's current ventilatory support. The conventional settings applied in the ICU are not always the same as the those used in the long-term acute care setting. If the patient is currently on a home care ventilator, it may be beneficial to leave them on that ventilator if possible. The major benefit of this strategy is that the patient is familiar with this ventilator, so they will feel a difference in the flow delivered with the transport ventilator. The disadvantage of this plan is the CCTP may not be familiar with the home ventilator and may have difficulty troubleshooting any potential issues that arise.

When setting up the transport ventilator, the obvious settings to focus on are the mode, respiratory rate, target tidal volume, PEEP, and F_{IO_2}. Often-overlooked settings include the flow targets of a pressure or a volume. Other settings of great importance are the inspiratory time and the sensitivity setting to trigger a breath. This is where the patient will feel a difference in ventilators and why it is so important to try to match these settings. When fine-tuning the flow, note whether the two ventilators can adjust the rise time (P-ramp) and flow termination (expiratory trigger sensitivity). These features determine how the flow is initially delivered and when it terminates. Discussing these and any other concerns with the respiratory therapist would be extremely helpful to assure the patient's safety and comfort needs before transport. Note that some ventilator rehabilitation facilities may use tidal volumes of 20 mL/kg of PBW during the weaning process. In these cases, a discussion with medical control is advised.

An uncuffed tracheostomy tube or defective cuff can definitely present challenges to the CCTP. When positive pressure is applied to an uncuffed tracheostomy tube, the gas supplied to the lungs will follow the path of least resistance. Therefore, a leak caused by the uncuffed tracheostomy creates a major challenge in delivering the desired volume or pressure to the lungs. This leak may have a positional component, such that any movement of the tracheostomy tube or the patient's neck alters the size of the leak.

If it is not advisable to change out the tracheostomy tube for a cuffed version, then some alternative strategies may be helpful. Some transport ventilators provide a leak-compensation feature that can detect a stable leak and make adjustments to compensate for it. As discussed previously, a leak may create autocycling, a condition in which the ventilator delivers unwanted breaths because the leak is triggering the machine to send a breath. The sensitivity setting can be adjusted to prevent autocycling. Another strategy for dealing with a leak in the system is to perform a trial of pressure-targeted breaths. Most machines allow for manipulation of the flow delivered in a pressure target, and titrating the time the flow is delivered and terminated may prove helpful.

It is mandatory that certain items be transported with the patient. A spare tracheostomy tube and securing device of the same size should be readily available at the head of the bed in case of an emergency. If possible, a spare inner cannulas should be available as well. Appropriate-size suction catheters should be provided for deep suctioning, along with a bag-mask device. An in-line suction catheter is recommended for deep suctioning, as it eliminates the need to disconnect the circuit. Specific-size in-line catheters are available to accommodate the shorter distance needed to suction the patient with a tracheostomy. Saline flush should be used to clean the catheter after suctioning.

It is important to secure the ventilator circuit to minimize any movement that might jostle the tracheostomy tube, potentially causing a cough reflex from the patient. Devices are available that can minimize the movement of the circuit, such as flex tube adapters. Although they can make it difficult to pass a suction catheter and will add some minimal dead space to the circuit, they are still commonly used within the ventilator circuit.

Tracheostomy tube displacement is uncommon but can be fatal. The first concern is recognizing the displaced tube. Because of the dynamic nature of the transport arena, the CCTP must always ensure the tracheostomy tube is secured. If the tube becomes dislodged, an immediate assessment of the patient's respiratory status is key in deciding whether to reinsert the tube or to implement a trial of decannulation. If the patient is breathing spontaneously and needs supplemental oxygen, a nonrebreathing mask may be placed over the stoma. If the tube needs to be reinserted, it is important to evaluate the condition of the patient's stoma. If the patient has received a percutaneous tracheostomy within 14 days of an accidental decannulation, it may be necessary to orotracheally intubate the patient due to the smaller stoma size associated with this procedure. Additional concerns arise with a more recently placed (within 1 week) surgical tracheostomy tube, as the tracheal stoma is not suitably formed and may present complications during reinsertion.

Having a worst-case scenario plan in place is advisable when transporting any patient. Patients with a tracheostomy are no exception, even though they have a definitive airway in place. Replacing a dislodged tracheostomy tube presents many challenges, which may be minimized with some diligent pretransport planning. Placing the tube in a false tract/passage occurs when the tube is inadvertently inserted through the cutaneous stoma but not through the tracheal lumen. A properly placed tracheostomy tube is a clear passage through both the cutaneous stoma and the tracheal lumen. When a false passage is formed and positive pressure is applied, the patient will be in respiratory distress and signs of subcutaneous emphysema will develop. Once this condition is recognized, the tube should be removed immediately and ventilation achieved through alternative means.

The following factors increase the risk for dislodgement of the tracheostomy tube:

- Morbid obesity
- Edema of the neck
- Excessive coughing
- Improper fit of the tracheostomy tube
- Patient anxiety and pulling at the tube
- Ventilator circuit tension
- Loose tracheostomy tube ties

When transporting a patient with a tracheostomy, the CCTP should have access to (and be familiar with the use of) a tracheostomy tube securing device, a spare tracheostomy tube, an inner canula, an obturator, a bougie/Cook catheter, a bag-valve device, and all equipment necessary for endotracheal intubation. More advanced equipment would include a stoma dilator and a portable bronchoscope. Although the likelihood of tracheostomy tube dislodgement may be minimal, training for and awareness of such an event must not be overlooked.

Summary

Determining the need for and means of providing ventilatory support requires an understanding of the patient's lung function and respiratory needs. You must be familiar with any device you will use during patient transport. Gaining competence with each device may require special training and consultation with specialists, including respiratory therapists and other clinicians working with the patient at the sending facility. Before using any complicated and potentially unfamiliar device, review the guidelines provided in the device's operating manual and consult other providers, including medical control.

Concepts such as tidal volume, minute volume, and anatomic dead space are crucial to understanding respiratory function and monitoring the patient's condition, as are a variety of devices and laboratory studies. ABG analysis, if available, will reveal the acid–base balance and blood levels of oxygen and CO_2. Pulse oximetry, capnography, and $ETCO_2$ detection offer a continuous, noninvasive means of measuring these gases during transport.

Transport of the critically ill patient who is receiving ventilation must be planned carefully to ensure patient safety. First, the CCTP should be familiar with the capabilities of the ventilator and should always have a bag-mask device on hand in case of malfunction. Prepare for the transport by confirming the presence of an adequate power and oxygen supply.

Second, the CCTP should know why the patient is being ventilated and what the settings are prior to transport. Obtain baseline assessment parameters for the patient and the ventilator before beginning the transport. Continue to monitor ventilator performance and patient response during the transport. Always have continuous pulse oximetry and waveform capnography in place.

Last, the CCTP should repeat these assessments upon arrival at the destination facility. Verify and document airway patency, respiratory assessment, and parameters at the time of transfer. When these guidelines are followed, the transport should be a safe one for the CCTP and the patient.

CASE STUDY

Your team is dispatched to a rural hospital to transport a patient to a higher level of care. The receiving hospital is 135 miles (214 km) from the sending facility. Incoming weather conditions rule out transport by rotor aircraft, so your team will be transporting the patient by ground. The estimated time for the transport is 2 hours and 10 minutes. The patient is in the ICU and being mechanically ventilated.

On arrival to the ICU, your partner begins to obtain pertinent information regarding the patient's condition while you assess the patient. The patient is a 59-year-old man who weighs 216 pounds (98 kg) and is 73 inches (185 cm) tall. He came to the emergency department (ED) 3 days ago because he was having difficulty breathing and feeling lethargic. The patient has diabetes mellitus type 1 and an extensive smoking history (50 pack-years) but quit 1 year ago. The patient was quickly placed on a nonrebreathing mask; his oxygen saturation readings are in the mid-80s with a good waveform. Vital signs are heart rate, 89 beats/min, normal sinus rhythm; respiratory rate, 28 breaths/min, labored; blood pressure, 139/85 mm Hg, 103 mean; SpO_2, 84%; and temperature, 100.1°F (38.3°C).

The patient was moved to a negative-pressure room and placed on airborne precautions. A nasopharyngeal swab was sent to the lab and subsequently came back with a positive result for COVID-19. The patient was placed on an oxypendant nasal cannula reservoir device at 8 L/min and was encouraged to self-prone for increased $\dot{V}/\dot{Q}$ matching. Unfortunately, the patient was unable to tolerate proning.

The next strategy to aid in this hypoxic situation was HFNC therapy at 60 L/min and FIO_2 of 1.0. An ABG was drawn 1 hour after implementation of HFNC therapy, and a chest radiograph was taken. The ABG revealed pH, 7.21; $PaCO_2$, 51 mm Hg; PaO_2, 81 mm Hg; HcO_3, 30 mEq/L; and calculated saturation, 84%. The chest radiograph revealed bilateral patchy infiltrates with a ground-glass appearance.

Because of the patient's worsening respiratory status, the ED team placed him on a BPAP trial for 1 hour with a starting pressure of 15 cm H_2O of IPAP and 8 cm H_2O of EPAP with a full-face mask. The patient was unable to tolerate the BPAP despite multiple adjustments to improve comfort. Another ABG analysis showed no improvement in oxygenation, so the ED team prepared to intubate the patient because his condition was heading toward respiratory failure.

The patient was intubated with direct laryngoscopy on the first attempt using rapid sequence intubation. A #7 ET tube was placed in the trachea and anchored at 26 cm at the lip. Confirmation of its correct placement was made with capnography and a good waveform present with an $ETCO_2$ reading of 47 mm Hg. Another chest radiograph is pending. Mechanical ventilation was initiated with the following settings: assist/control rate, 14 breaths/min; tidal volume, 700 mL; PEEP, 5 cm H_2O; FIO_2, 1.0. The monitored values on the ventilator read as follows: PIP, 38 cm H_2O; plateau pressure, 34; total respiratory rate, 25 breaths/min; exhaled tidal volume, 600–760 mL, fluctuating; PEEP 5 cm H_2O; minute volume, 14.9 L/min. Breath sounds are diminished on the left side of the patient's chest and clear on the right side, with asymmetric chest excursion.

1. Was the patient managed appropriately on admission in the ED?
2. Do the initial impression, interventions, and lab values lead you to a diagnosis and treatment plan?
3. Was the ET tube size and depth appropriate for this patient?
4. Are the ventilator settings appropriate for this patient?
5. Do the monitored values raise any concerns?

The chest radiograph revealed a right main stem intubation, so the ET tube was withdrawn 5 cm and resecured at 22 cm at the lip. The PIP decreased to 27 cm H_2O, breath sounds were equal, and good chest excursion was present. The patient was given fentanyl 50 mcg and propofol infusion of 20 mcg/kg/min and admitted to the ICU.

You arrive at bedside. During your initial assessment, you note the patient's vital signs are heart rate, 118 beats/min; respiratory rate 23 breaths/min; blood pressure 129/68 mm Hg, 88 mean; and SpO_2, 84%. The patient is currently on a dexmedetomidine drip at 0.2 mcg/kg/h for sedation. The patient has also received dexamethasone and remdesivir since being admitted to the ICU. Breath sounds are equal but diminished throughout. Good chest excursion is noted. The hospital ventilator settings are assist/control rate, 18 breaths/min; tidal volume, 650 mL; PEEP, 8 cm H_2O; and FIO_2, 1.0. Monitored values are PIP, 35 cm H_2O; plateau pressure, 31; total respiratory rate, 25 breaths/min; exhaled tidal volume, 655 mL; PEEP, 8 cm H_2O; and minute volume, 16 L/min. A chest radiograph performed 3 hours ago reveals worsening bilateral pulmonary infiltrates. An ABG sample obtained 6 hours ago reveals pH, 7.31; $PaCO_2$, 29 mm Hg; PaO_2, 67 mm Hg; HCO_3^-, 21 mEq/L; and calculated saturation, 86%.

6. Is the sedation dose adequate for this patient?
7. Are the ventilator settings appropriate for this patient?
8. Is there a specific strategy this patient qualifies for?
9. Is there another mode of ventilation that might better oxygenate this patient?

Based on the Berlin definition of ARDS, this patient has severe ARDS:

- Onset within 1 week of a known insult or of new or worsening respiratory symptoms
- Imaging: Bilateral opacities not fully explained by effusions, lobar or lung collapse, or nodules
- Origin of edema: Respiratory failure not fully explained by heart failure or fluid overload
- PaO_2:FIO_2 ratio of 67 (PaO_2 from the most recent ABG analysis is 67 on an FIO_2 of 1.0.)

At this point, you and your partner decide to call medical control to discuss a strategy for transporting this patient because of the refractory hypoxia. Based on the ABG results and the clinical diagnosis of ARDS with an underlying COVID-19 condition, the recommended strategy is to follow the ARDS Network's protocol. The first adjustment to consider is the target tidal volume and the measured plateau pressure. The patient is 73 inches (185 cm) tall and male, so the PBW is calculated as 176 pounds (80 kg). Following the ARDS Network's protocol, you could try using the 6 mL/kg of PBW for a tidal volume of 480 mL, titrating it lower if needed. Another strategy to address the hypoxia condition is to raise the PEEP to inflate the alveoli for better oxygenation. This increase in PEEP should be done in small increments and monitored for the desired results.

After consulting with medical control, the hospital's ED physician, and the respiratory therapist, it was decided to make some changes to the ventilator settings. The adjusted settings are assist/control rate, 18 breaths/min; tidal volume, 480 mL; PEEP, 12 cm H_2O; and FIO_2, 1.0. The dexmedetomidine dosage was increased because the patient was overbreathing at the ventilator's set rate. The monitored values from the new settings are PIP, 30 cm H_2O; plateau, 27; total respiratory rate, 19 breaths/min; exhaled tidal volume, 469 mL; PEEP, 12 cm H_2O; and minute volume, 9.1 L/min. An ABG was drawn an hour after the changes were made and the following results obtained: pH, 7.29; $PaCO_2$, 55 mm Hg; PaO_2, 121 mm Hg; HCO_3^-, 22 mEq/L; and calculated saturation, 91%.

A major goal in any patient who is being mechanically ventilated is to keep plateau pressures at less than 30 cm H_2O. Another goal is to keep driving pressures (plateau – PEEP) at less than 15 cm H_2O. In this case, the driving pressure is 15 cm H_2O (plateau 27 – PEEP 12 = 15).

To be on the safe side during transport, lowering the tidal volume to 450 mL might be beneficial as part of the lung-protective strategy.

Another consideration is oxygen consumption. The patient is on an FIO_2 of 1.0 with a set minute volume of 9 L/min that can change with spontaneous patient breaths. Some ventilators may calculate oxygen consumption along with the bias flow provided on exhalation.

Another potential strategy for ventilating this particular patient would be APRV. Transport ventilator manufacturers are adding this mode to the menu to match the hospital ventilator modes and help transport patients with complicated respiratory conditions.

Analysis

The patient was managed appropriately on admission to the ED. Attempting to correct the hypoxic presentation and respiratory distress with supplemental oxygen, HFNC therapy, and noninvasive ventilation was an appropriate first-line strategy to address the respiratory issues. Self-proning was attempted but not tolerated well by the patient. The ED team decided to intubate the patient and begin mechanical ventilation before respiratory failure became apparent. The initial diagnosis leaned toward COVID-19 pneumonia with ARDS.

The ET tube may have been small for someone this size, adding some airway resistance, and was inadvertently placed too deeply initially. The initial ventilator settings were aggressive and were based on the patient's actual weight, not the PBW. The plateau pressure was high, at 34 cm H_2O, and the tidal volume should have been corrected prior to the ICU admission. The feedback from the ventilator following the patient's initial intubation contains valuable information that should give the clinician an indication of how the lungs are responding to the positive-pressure breaths delivered by the ventilator.

This patient did not appear to be adequately sedated, as the total breath rate was initially 25 breaths/min. The driving pressure was 29 cm H_2O initially, almost double the target driving pressure of 15 cm H_2O. The other major concern was the lack of PEEP in the presence of hypoxia on an FIO_2 of 1.0. The ARDS Network's protocol could have been instituted earlier in the course of this patient's treatment. The backup plan would have been to use APRV mode to recruit more alveoli if possible. The next option might have been ECMO.

PREP KIT

Ready for Review

- Mechanical ventilation entails the use of a machine to provide ventilatory support. Indications for mechanical ventilation include managing the work of breathing, improving distribution of inhaled gases, protecting the airway, and managing conditions such as apnea and ventilatory or respiratory failure.
- The CCTP must understand common respiratory terminology, including dead space ventilation, alveolar-to-arterial oxygen (A-a) gradient, ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, and minute volume.
- All ventilators have several characteristics in common, including the use of a power source, cycling, breath delivery, parameters, circuitry and interface, and alarms. Not all ventilators have the same parameters available for adjustment, nor do all ventilators have the same range of features. Specifically, not all transport ventilators compensate for altitude changes.
- Normal ventilation is negative-pressure ventilation. Negative pressure pulls the diaphragm down, causing the lungs to fill. When the pressure is released, the diaphragm relaxes and the lungs empty.
- In positive-pressure ventilation, air is pushed into the respiratory tract. Positive-pressure ventilators are often described in terms of which variable terminates the inspiratory phase of the breath, such as pressure ventilators, volume ventilators, flow-cycled ventilators, and time-cycled ventilators.
- It is important to understand the changes that occur when a positive-pressure system is applied to a negative-pressure system.
- Conventional ventilation requires invasive ventilation by placing an artificial airway, chiefly the endotracheal tube.

- Noninvasive ventilation is any form of mechanical ventilation without an artificial airway, but includes other devices such as continuous positive airway pressure and bilevel positive airway pressure, which use nasal or full-face masks to deliver a certain pressure to the lungs during spontaneous breathing.
- When caring for the acutely hypoxic patient, it is common practice to place the patient on supplemental oxygen via a nasal cannula with liter flows ranging from 1 to 6 L/min, referred to as a low-flow nasal cannula. A high-flow nasal cannula enables more comfortable delivery and a more precise fraction of inspired oxygen (F_{IO_2}) target. The high flows required to support this modality present a challenge during transport, requiring careful pretransport planning by the CCTP.
- Volume and pressure are flow targets that are set for the ventilator to end the inspiratory cycle.
- Ventilator modes describe which types of breaths are being delivered to the patient—that is, whether the breath is a mandatory or machine breath or a spontaneous breath. Ventilator parameters refer to the other settings that may be adjusted and should be monitored continuously by the clinician.
    - Modes include control (or continuous) manual ventilation, assist/control ventilation, synchronized intermittent mandatory ventilation, pressure control ventilation, pressure-regulated volume control ventilation, inverse-ratio ventilation, pressure support, continuous positive airway pressure, bilevel positive airway pressure, airway pressure release ventilation, and adaptive support ventilation.
    - Parameters include tidal volume, respiratory rate, fraction of inspired oxygen, peak flow, inspiratory time, peak inspiratory pressure, driving pressure, inspiratory plateau pressure, percentage of minute volume, low-pressure alarm, high-pressure alarm, and low-battery alarm.
- Positive end-expiratory pressure (PEEP) occurs at the end of a mandatory machine breath. Instead of exhaling back to ambient

pressure, the ventilator stops the exhalation at a prescribed pressure, which results in an increase in the air in the alveoli, thereby increasing the functional residual capacity, facilitating gas exchange, and improving oxygenation. PEEP may also improve lung compliance when the clinician finds the optimal ventilator setting for the patient's particular lung disease.

- Inhaled gases with which the CCTP must be familiar include nitric oxide, epoprostenol, and heliox.
- The CCTP must recognize and guard against the progression from respiratory distress to respiratory failure. Respiratory distress is a medical emergency that demands immediate treatment. Signs and symptoms include tachypnea, tachycardia, increased anxiety, increased work of breathing, and pallor. Respiratory failure is a medical emergency that may present initially as respiratory distress, but signs and symptoms worsen into cyanosis, hypercapnia, hypoxia, bradycardia, fatigue, shallow breathing, and loss of consciousness.
- During patient transport, few ventilator changes generally need to be made, except for adjustments of F_{IO_2} to accommodate changes in oxygenation. The CCTP is responsible for ensuring proper ventilator function and keeping the patient's ventilatory status stable.
- The CCTP must understand the difference between volume-delivered breaths and pressure-delivered breaths. In volume-delivered breaths, the flow available to the patient is limited to the set (dialed-in) tidal volume and the inspiratory time, although some minor adjustments can be made to increase the flow. In pressure-delivered breaths, the pressure is set and the flow available to the patient is unlimited—at least up to the ventilator's maximum flow capabilities.
- The approaches to mechanical ventilation vary by the lung disease or condition being treated. Common conditions for which mechanical ventilation may be used include acute respiratory distress syndrome, chronic obstructive pulmonary disease,

pneumonia, pulmonary fibrosis, asthma, and congestive heart failure.

- The CCTP's goal is to transport the patient from one place to another in the safest manner possible while doing no harm. During transport, it is crucial to monitor the patient's measured values on the ventilator, including peak inspiratory pressure, respiratory rate, exhaled tidal volume, and I:E ratio.
- Heat moisture exchangers and bacterial/viral filters will help ensure the patient's airway remains warm and humidified during transport, but can become dangerous to the patient if allowed to fill with secretions. The CCTP must understand how these devices work and how to keep them working properly.
- Ventilators in the ICU display various waveforms in the form of scalars and loops; these displays represent a great point-of-care tool for the clinician who has the formal education to interpret the information.
- The CCTP should be able to troubleshoot ventilator function, and a bag-mask device should accompany every patient who is transported while on a ventilator.

Vital Vocabulary

anatomic dead space Space in airway structures such as the trachea, bronchi, and bronchioles that does not participate in gas exchange. It is defined physiologically as ventilation without perfusion.

arterial blood gas (ABG) Analysis of the following characteristics of blood: pH, partial pressure of carbon dioxide (in arterial blood), partial pressure of oxygen (in arterial blood), concentration of bicarbonate ion, base excess (indicating whether the patient is acidotic or alkalotic), and oxygen saturation of the hemoglobin molecule.

auto-PEEP The nonintended increase in end alveolar pressure due to air trapping.

barotrauma Injury to the chest or lungs as a result of increased intrathoracic pressure.

bilevel positive airway pressure (BPAP) The use of inspiratory positive airway pressure and expiratory positive airway pressure to raise the breathing baseline above the ambient pressure. The pressure gradient enhances ventilation, and the reduced expiratory pressure makes exhalation easier and increases patient tolerance.

continuous positive airway pressure (CPAP) A means of raising the breathing baseline above the ambient pressure. The increased pressure across the entire breathing cycle increases the mean airway pressure, stents the airway, and increases the functional residual capacity, thereby improving oxygenation.

flow-cycled ventilator A positive-pressure ventilator that ends inspiration when a predetermined flow rate is achieved.

flow rate The speed of the gas at which the tidal volume is delivered.

fraction of inspired oxygen (FIO_2) Percentage of inhaled oxygen expressed as a decimal. For example, 40% oxygen = FIO_2 of 0.40.

functional residual capacity The amount of air remaining in the lungs after normal expiration; the sum of the residual volume and the expiratory reserve volume.

high-flow nasal cannula (HFNC) therapy A form of noninvasive ventilation used to treat hypoxic respiratory failure by delivering up to 100% humidified and heated oxygen at a flow rate of up to 60 L/min.

hypoxemia An abnormally low oxygen level.

I time The time frame for the delivery of the tidal volume.

inspiratory-to-expiratory (I:E) ratio An expression for comparing the length of expiration to the length of inspiration. The normal ratio is 1:2, which means that expiration is twice as long as inspiration.

inspiration An active process in which gas is taken into the lungs.

invasive ventilation Application of mechanical ventilation through an artificial airway such as a tracheostomy or endotracheal tube.

mean airway pressure (MAP) The amount of positive pressure in the airway, averaged over the inspiratory and expiratory phases of the breathing cycle.

mechanical ventilation The application of a device that provides varying degrees of ventilatory support.

minute volume Total volume of air breathed in and out in 1 minute. It is calculated by multiplying the respiratory rate per minute by the tidal volume.

mode The particular way in which a spontaneous or mechanical breath is delivered.

negative-pressure ventilators Mechanical ventilators that operate using pressure that is less than the ambient (atmospheric) pressure.

noninvasive ventilation Application of mechanical ventilation through a mask, mouthpiece, or other interfaces other than an artificial airway.

peak airway pressure The amount of positive pressure generated by the ventilator to deliver the tidal volume.

peak inspiratory pressure (PIP) The greatest volume of air delivered to the lungs during inhalation.

plateau pressure The average pressure applied to airways and alveoli at the end of inspiration during positive-pressure mechanical ventilation.

positive end-expiratory pressure (PEEP) The amount of pressure above the ambient pressure present in the airway at the end of the respiratory cycle.

positive-pressure ventilators Mechanical ventilators that operate using pressure that is greater than the ambient pressure.

pressure ventilator A type of positive-pressure ventilator that ends the delivery of the tidal volume based on a predetermined pressure; therefore, the volume may vary.

pulse oximetry Measurement of arterial oxygen saturation (SpO_2) and the pulse.

respiratory failure A situation in which the respiratory system fails to meet the body's metabolic needs. If not reversed, it may lead to respiratory or cardiopulmonary arrest.

sensitivity Ventilator control that regulates the amount of negative pressure required by the patient to initiate, or trigger, a breath.

shunt Perfusion without ventilation.

tidal volume The volume of air moved into and out of the lungs with each respiratory cycle.

time-cycled ventilator A type of positive-pressure ventilator in which the ventilator ends inspiration after a selected inspiratory time has been achieved.

ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch A state of inadequate ventilation, perfusion, or both, in which there is inadequate gas exchange.

volume ventilator A type of positive-pressure ventilator in which the breath ends when the predetermined tidal volume is achieved.

volutrauma Trauma caused by excessive lung inflation volumes.

CHAPTER 8

Critical Care Pharmacology

Zlatan Coralic, PharmD, BCPS
Mike McEvoy, PhD, NRP, RN, CCRN

OBJECTIVES

After completing this chapter, you will be able to:

1. Identify reliable resources of medication and pharmacology information (pp 287–288).
2. Outline the principles of medication administration for critical care transport professionals, including patient and medication selection, predicted and desired responses, absorption and elimination principles, side effects or adverse medication reactions, and transport and monitoring considerations (pp 288–289).
3. Discuss the significance of medication pharmacokinetics and pharmacodynamics in the critical care transport setting (pp 289–291).
4. Review principles of medication management, including storage of drugs and maintaining the security of controlled substances (pp 295–296).
5. Discuss the different types and classes of medication used in the critical care arena (pp 296–348).
6. Understand the sequence for medication infusion (p 348).
7. Know how to infuse medication with an infusion pump during transport and through changes in altitude (pp 348–349).

Introduction

Pharmacology is the study of preparation, uses, and actions of medications. Modern health care and modern society are heavily dependent on medications for the management of illness and the alleviation of symptoms. Likewise, medications play an essential role in prehospital and critical care of patients. Critical care transport professionals (CCTPs) need a deep understanding of critical aspects of pharmacology to provide optimal patient care without causing further patient injury or death. Although this chapter includes a brief review of important basics, it assumes a general understanding of the subject of pharmacology. Many specific medications and medication groups are discussed. This list, however, is not comprehensive. As new medications and approaches to treatment of various conditions emerge, it is essential to balance this new information with proven treatment strategies. CCTPs should follow their local regulations, policies, and protocols and consult reliable, current sources when administering any medication.

Pharmacology and Medication Information

CCTPs should stay abreast of newly approved medications and current pharmaceutical research. Up-to-date, reliable medication information may be obtained from a variety of sources, many of which are available in both print and electronic formats **TABLE 8-1**. Medication-related reference materials are published by educational institutions, industry organizations, and independent publishing companies. Formats range from simple listings of medications and doses to complex compilations that include an exhaustive list of interactions, overdose/toxicity treatments, pharmacokinetics, and administration guidelines.

TABLE 8-1 Sources of Drug Information

Source	Description
Lexicomp, Micromedex, Epocrates	Internet-based drug information databases tailored to pharmacists, physicians, dentists, and nurses. Available to subscribers via desktop or mobile applications. Ideal for rapid retrieval of information from personal/company mobile smartphones.
Individual drug package inserts	Printed documents included in the packaging provided by the drug's manufacturer; generally the same information submitted and approved by the FDA. Drug package inserts will usually provide only FDA-approved uses without mention of off-label indications. Package inserts tend to be bulky and formatted in small print, making them difficult to read during patient transport.
Prescriber's Digital Reference (*PDR*)	A compilation of prescribing information from drug package inserts. This information is freely available via the *PDR* website or mobile app. As with individual package inserts, information may be limited. The *PDR* was formerly called the *Physicians' Desk Reference*.

Abbreviation: FDA, Food and Drug Administration

© Jones & Bartlett Learning.

The Internet is a readily accessible source of medication information. Take some time to familiarize yourself with reputable and reliable Internet resources, particularly those that are geared toward professional prescribers and health care providers. Mobile applications, such as Epocrates, are also available for smartphones, tablets, and notebook computers. Regardless of the format used, you must perform careful research to determine the source’s accuracy and ensure reliable information is obtained for clinical practice.

A Practical Approach to Medication Administration

The optimal medication for a particular patient may or may not be immediately available during patient transport. Notably, CCTPs do not routinely carry many specialized medications, such as antidotes, thrombolytics, and antibiotics, as part of their supplies. The expense of medications, storage concerns, and infrequent use of certain drugs also limit the number of drugs carried in the critical care transport (CCT) arena. A sending facility and a transport program’s sponsoring hospital pharmacy are potential resources when a certain medication is needed emergently but is not carried by the transport team. Before leaving a sending facility, transport crews should obtain a sufficient quantity of any needed medication to cover the anticipated transport time, plus an additional amount to provide a safe margin against unanticipated delays. If a desired medication is unavailable, the transport team must decide if there is an acceptable alternative.

The scope of practice and monitoring capabilities of the transport team must also be considered when selecting a medication. For example, many vasoactive medications are best administered with continuous hemodynamic monitoring and require infusion pumps to ensure controlled delivery and precise dosing. The transport team must be adequately trained and equipped to recognize and effectively manage anticipated side effects or adverse reactions associated with a particular medication. Teams who do not perform adequate monitoring or are unable to properly administer a medication place their patients at grave risk.

Other considerations include the patient’s clinical status. If immediate, life-saving interventions are required, it would be best to postpone the administration of scheduled routine medication until the threat has been resolved. Additionally, significant safety or operational priorities related to an aircraft or ambulance may outweigh concerns related to routine medication administration.

CCTPs must consider factors specific to each medication before its administration—specifically, the drug’s indications, contraindications, pharmacodynamics, pharmacokinetics, and potential adverse effects. An **indication** is the specific reason a drug may be used. Indications are based on the US Food and Drug Administration’s (FDA) approval of the medication, which specifies the conditions that the medication is officially authorized to treat. However, some medications are used “off-label” when research supports their use in an indication but the drug’s manufacturer has not sought FDA approval for that specific purpose.

Pharmacokinetics

Pharmacokinetics is the study of the action of medications within the body, with particular emphasis on the time required for absorption, distribution, metabolism (biotransformation), and elimination.

Absorption

Absorption of a medication occurs either immediately or shortly after its administration. The route of administration affects how quickly and how much of the dose is absorbed. CCTPs generally use intravenous (IV), intraosseous (IO), intramuscular (IM), subcutaneous, oral, inhaled (nebulized), transdermal, nasal, and sometimes rectal routes for medication administration. Routes of administration rarely used by CCTPs include ocular, intra-arterial, otic, epidural, and vaginal administration of drugs.

The route of administration affects a medication's **bioavailability**, meaning the amount of an administered medication (fraction or percentage) that reaches the patient's systemic circulation without any alteration. IV medications have 100% bioavailability. By comparison, the bioavailability of medications administered orally ranges from 0% to 100%, depending on the substance. Oral digoxin, for example, has a bioavailability of 60% to 80%. Epinephrine and naloxone, in contrast, have close to 0% bioavailability when given orally. Differences in bioavailability illustrate how a dose of a particular medication may be safe when given orally, yet toxic or lethal when given intravenously. For example, significant differences in bioavailability between oral and IV doses are observed for many drug classes (eg, opioids, beta blockers).

The nasal, sublingual, and rectal routes provide safe, alternative access for some medications when IV access cannot be established. The bioavailability of medications administered by these routes and other non-IV routes depends on numerous factors, including perfusion, skin temperature, membrane pH, and surface area, along with the type of medication, lipophilicity, and its method of preparation.

Distribution

Once absorption has occurred, medication **distribution** within the body may vary. Blood is the primary distribution vehicle. Substances will become distributed within the body based on the molecule’s size, ionization, binding to tissues or plasma proteins, lipid or water solubility, and target tissue penetration. Placental and blood–brain barriers may restrict distribution of certain substances into fetal and brain tissue, respectively. Highly lipid-soluble medications tend to cross these barriers readily, whereas other medications may cross only minimally or not at all. The **first-pass effect** (also called first-pass metabolism) occurs when the concentration of an oral medication is reduced as it passes through the liver before it enters systemic circulation. The first-pass effect is an important determinant of a drug’s bioavailability.

The kidneys and urinary system are the main routes of elimination. Patients with acute or chronic renal disease require careful consideration when medications are administered, because their impaired renal function can result in slower elimination that leads to a potentially toxic buildup of certain agents within the body. Other routes of elimination include the lungs (usually for highly volatile substances or gases), sweat, saliva, stool, and breast milk.

Biotransformation

The liver is the primary site for **biotransformation**, but many body tissues and cells have the ability to support this process as well. Four possible events occur during biotransformation of a medication:

- An active drug may be changed into an inactive metabolite; this new substance causes no new effects and is ultimately eliminated.

- An active drug may be changed into an active metabolite that causes continued or new clinical effects. For example, morphine is transformed into morphine-3 and morphine-6 glucuronide, centrally active metabolites.
- An active medication may be changed into a reactive metabolite that has a greater potential for action/toxicity than its parent substance. For example, acetaminophen is biotransformed into the highly active metabolite *N*-acetyl-*p*-benzoquinone imine.
- A poorly active substance may be changed into an active, potentially toxic substance. For example, codeine is metabolized into morphine through biotransformation.

Active (and reactive) metabolites can complicate the clinical situation and require special consideration when selecting certain medications for use. The presence of active (and reactive) metabolites becomes particularly important when considering the medication’s half-life or monitoring a medication plasma levels.

Enzyme systems in the liver perform biotransformation. The cytochrome P450 system, which is present in the liver and in other tissues, is the main pathway responsible for biotransformation of many medications and chemicals. Genetic polymorphism can affect the cytochrome P450 system. The liver enzymes can also be inhibited or induced by concomitant medications. Commonly used agents such as nicotine, grapefruit juice, and broccoli have a significant impact on the functioning of the cytochrome P450 system; thus, intake of these substances may be prohibited when patients are taking certain drugs. The list of medications that either promote or inhibit the action of liver enzymes is extensive.

Elimination

Drugs are primarily eliminated from the body via the urinary route (kidneys) or the fecal route. Patients with acute or chronic renal disease require careful consideration when medications are dosed and given. Impaired renal function can result in slower drug and metabolite elimination, which may amplify the drug’s effects and lead to toxicity. To a lesser extent, drugs may also be eliminated via the lungs (usually for highly volatile substances or gases), sweat, saliva, and breast milk.

Drug elimination follows one of two possible patterns. If a substance follows **zero-order elimination**, a fixed amount of substance is eliminated over a time period, regardless of the amount of substance present in the plasma. Ethanol, for example, follows zero-order elimination. Regardless of how much ethanol is present, only a relatively fixed amount is excreted each hour. However, most medications follow **first-order elimination**. In this pattern, the amount of substance eliminated over a period of time is proportional to the plasma concentration. Medication half-lives reflect first-order kinetics. A medication **steady state** occurs when the rate of administration of a medication equals the rate of its elimination—a balance that is desirable with antibiotics and anticoagulants.

Factors affecting both biotransformation and elimination include perfusion, liver and kidney status, metabolism, and the manner and extent of absorption. Biotransformation and elimination are also influenced by chronic exposure to a particular medication or chemical.

Pharmacodynamics

Pharmacodynamics is the branch of pharmacology dealing with a drug's **mechanism of action** and its effects. It encompasses the various factors that may alter the intended response and any associated adverse events.

Theories of Drug Action

Medications are chemicals that are administered to cure or treat a disease, symptom, condition, or other anomaly. When these chemicals act upon the body to achieve a particular goal, four basic mechanisms may come into play:

- A medication may bind with a receptor site on a particular cell to either promote or inhibit a specific activity of that cell.
- A medication may affect a physical property of a cell, which in turn alters the functioning of that cell.
- A medication may combine directly with other chemicals within the body to alter or limit the effects of this chemical or allow it to be removed.
- A medication may alter a metabolic pathway to achieve the desired result.

Medications that bind to a receptor site are the most widely used, particularly in the prehospital setting. **Receptor sites** are specialized proteins on a cell that receive chemical mediator messages triggering a particular response. For example, when acetylcholine attaches to receptor sites in the heart, it causes the heart rate to slow. Cellular responses can vary widely, depending on the chemical mediator and the target cells. Generally, a molecule (medication) will have one of two effects when it attaches to a receptor site: (1) It may stimulate the receptor site (ie, act as an **agonist**) or (2) it may block the receptor site from further stimulation (ie, act as an **antagonist**). Some medications act as agonist-antagonists. In trying to bind to its receptor, the drug molecule competes with the endogenous or exogenous chemical mediators. For a medication to work effectively, it must have a higher affinity for the receptor than other mediators have. In addition, more than one medication may compete to bind to the same receptor.

The number of available receptors is inconsistent and can be affected by the actual number of sites present, the number already occupied by another chemical mediator, and the number occupied by another medication. Prolonged binding to receptor sites may result in upregulation or downregulation of available receptor sites and the need for dose adjustments to achieve a desired response.

Drug-Response Relationship

When a medication is administered, the **onset of action** is defined as the amount of time it takes for the concentration of the medication at the target tissue to reach the minimum effective level. The CCTP needs to know how long the medication can be expected to remain above that minimum level and, therefore, exert the intended action (ie, the **duration of action**). The **termination of action** is the amount of time after the concentration level falls below the minimum level to the point at which it is considered eliminated from the body.

The **therapeutic index** is the ratio of a drug's lethal dose for 50% of the population (LD_{50}) to its effective dose for 50% of the population (ED_{50}). In other words, the therapeutic index gives an indication of a medication's margin of safety. The plasma profile also provides information about the medication's biologic **half-life (T½)**—that is, the time it takes the body to eliminate half of the amount of the drug present. Despite the name, a medication is not eliminated in two "half-lives." During the second half-life period, only half of what remained after the first half-life is eliminated. After three half-lives, approximately one-eighth of the medication still remains in the body.

In many instances, the duration of action of a medication is unrelated to its half-life. Aspirin, for example, has a half-life of 15 minutes, yet produces antiplatelet effects that last for 7 days. Typically, a medication has no effect after five to seven half-lives.

Factors Affecting Drug Responses

A number of patient characteristics can affect the action of a drug. Consequently, patients differ with respect to how they react to medications. Age, sex, weight, heredity, and clinical conditions can all influence medication choice, medication response, required dose, and elimination characteristics.

Age

Patients of different ages may have vastly different responses to the same drug. Older adults, for example, tend to be much more sensitive to the effects of drugs and often require smaller doses than younger patients do. Many older patients exhibit declining renal function and decreased muscle mass, both of which interfere with estimating creatinine clearance and predicting optimal dosing. Body fat content and fluid status can also influence dose response. Changes in or a reduction of certain neurotransmitters can further complicate medication dosing in older adults.

A patient’s metabolism may vary significantly at different ages throughout the lifespan. Pediatric patients, for example, generally have an increased metabolic rate compared with adult and older adult patients, often requiring increases in the dosing amount or the frequency of administration. The issue of concern is not solely a matter of dose, however: Some drugs have altogether different effects in different age groups.

For example, sedative-hypnotic agents tend to exhibit a more profound or prolonged effect in older patients. Paradoxical excitement, rather than sedation, is also possible when older adult patients receive certain medications. Barbiturates, for example, act as sedatives in most adults, but may produce excitement or agitation in older patients. Pediatric patients frequently experience paradoxical drug reactions in which sedative agents cause hyperactivity and agitation, further complicating the clinical situation. Diphenhydramine, chloral hydrate, and certain benzodiazepines are frequently the cause of paradoxical medication reactions in children.

Special Populations

Older adult patients require lower doses of medications because of generally diminished renal and liver function. Additionally, extra doses of medications that have a high first-pass metabolism rate through the liver may be necessary to achieve the optimal serum levels in these patients. Consult a specific, reliable reference for each medication that is being given. Online databases usually describe adult, pediatric, and geriatric considerations for each medication.

Weight

Many drug doses are generally intended for adult patients weighing 154 pounds (70 kg). However, the actual drug concentration may be quite different if the same dose is administered to a 106-pound (48-kg) person or a 300-pound (136-kg) person. To account for such differences, body weight must be taken into consideration during dose selection. Specifically, dosages should be calculated in terms of milligrams or micrograms per kilogram of the patient's body weight (mg/kg or µg/kg, respectively).

Depending on the drug's pharmacokinetics and pharmacodynamics, the doses may be based on total (or actual) body weight, ideal body weight, or adjusted body weight. For example, ketamine should be administered according to a patient's ideal body weight, whereas lidocaine should be administered according to a patient's actual body weight. Ideal body weight is calculated as follows:

- Males (kg): 50 ± (2.3 times patient's height in inches over 5 feet)
- Females (kg): 45.5 ± (2.3 times patient's height in inches over 5 feet)

Research is limited on many other weight-based medication dosages; in general, critical care medications are administered and titrated based on effect.

Sex

General differences in body mass between males and females affect their reactions to medications. Some medications can have varying effects in the different sexes. Females, for example, have increased responses to beta blockers compared to males. They also require lower doses of antipsychotic drugs to control symptoms and experience greater analgesic effects from opioid medications compared to males.

Because many medications can carry reproductive risks, a patient’s pregnancy status should always be assessed prior to any medication administration. A good empirical rule is to assume that any woman of childbearing age is pregnant until proven otherwise. You should also use caution when giving medications to breastfeeding women, as many medications are excreted in breast milk.

Environment

The environmental milieu can influence a medication’s reaction because of the psychological and physiologic stresses imposed on the patient. In addition, a particular reaction to an environmental factor, such as seasonal allergies, can alter response to a medication. As many medications are sensitive to temperature and light, extra care should be taken to ensure all medications are stored under the proper conditions once they leave the pharmacy.

Time of Administration

When administering oral medications, the timing may influence absorption. Medications may be absorbed differently based on a recent meal. Some medications are inactivated by certain foods, whereas others require a full stomach to ensure optimal absorption. Timing is also important to ensure medications are not stacked if administered before the next dosing time. For example, if repeat opioid doses are given too frequently, they may cause respiratory depression. Thus, CCTPs must be careful to administer all drugs as instructed. They should keep an accurate medication administration record and clearly communicate the medication status with all health care providers involved in the patient's care, especially during transfers and handoffs.

Condition of the Patient

The patient's overall health also affects the response to many drugs. In patients with renal dysfunction, for example, medications may not be excreted efficiently, and the concentration of a drug may reach toxic levels, possibly requiring urgent dialysis for removal. Liver and kidney failure significantly alter the metabolism and elimination of many medications. *Consult a reliable medication reference or seek medical direction before administering medications to patients with significant liver or kidney dysfunction*.

If the patient is in shock or being resuscitated, it may take an extended time for medications to circulate and have an effect. In a situation such as profound anaphylaxis, it may be necessary to administer medications intravenously that are normally administered intramuscularly or subcutaneously.

Be aware that medications may not be effective in hypothermic patients. IV medications are often withheld if a patient's core temperature has fallen below 80°F (30°C) and are given at greater intervals when hypothermic patients have a core temperature above 80°F (30°C). Chapter 19, *Environmental Emergencies*, provides a more detailed discussion of medication administration for the treatment of hypothermia.

Genetic Factors

A patient's genetic makeup may influence a drug's pharmacokinetics and pharmacodynamics. For example, glucose-6-phosphate dehydrogenase (G6PD) deficiency is a common genetic disorder affecting hundreds of millions of people worldwide. The administration of oxidant medications (eg, antimalarial agents), sulfonamides, nitrofurantoin, or phenazopyridine may cause a potentially life-threatening hemolytic anemia. Other genetic disorders, such as primary pulmonary hypertension and sickle cell disease, raise specific concerns related to pharmacology and hemodynamics. Medications with vasoconstrictor properties will adversely affect lung perfusion in patients with pulmonary hypertension. Any medication that causes hypoxia, vasospasm, or dehydration can precipitate or worsen a sickle cell disease crisis.

Pregnancy

Medication administration in pregnant patients carries special risks. Many medications will pass from the pregnant woman's bloodstream into the placenta and may affect the fetus. During pregnancy, patients also experience altered respiration, hemodilution, and altered hemodynamic parameters. Some evidence suggests that catecholamines, such as norepinephrine and epinephrine, have an adverse impact on placental perfusion, although use of these medications is generally limited to extreme situations, such as profound shock or cardiac arrest. Ephedrine, because of its beta-2 and alpha-1 properties, is the preferred vasopressor for maternal shock.

Psychological Factors

For CCTPs, it is crucial to consider psychological factors when administering medications for analgesia and sedation. Patient positioning, temperature regulation, and proactive communication can optimize the effects of analgesia or sedative medications, possibly decreasing the overall amount of each medication required. Occasionally, patients with severe agitation or delirium may require excessive amounts of sedatives to achieve the desired effect. In such cases, the risk of oversedation should always be assessed and mitigation interventions anticipated. Finally, CCTPs should remember that in some instances medications may cause paradoxical reactions; for example, benzodiazepines may cause agitation in older adults.

Predictable Responses

Clinical research generally identifies the dose-response effects that are expected for a particular drug. In addition, during clinical research and through postmarketing surveillance after a medication is used in the broader population, other unexpected and unwanted drug responses (ie, **side effects**) may be discovered. All medications have side effects, which may be either beneficial or undesirable.

CCTPs need to be able to weigh the risks associated with the use of a medication. If the patient's condition will improve more as a result of the medication's desired effects than its side effects, administering the medication is probably warranted. Conversely, if the risks from side effects outweigh the benefits from drug treatment, it is best to withhold the drug. This concept is known as the **risk-benefit ratio**. The risk-benefit ratio is evaluated separately for each patient and each intervention.

Sometimes a side effect that is insignificant for one group of patients may have life-threatening implications for others. For example, if a medication causes hypotension as a side effect, its use should be avoided in patients with shock. A medication that prolongs the QT interval may be well tolerated by most patients, but could cause deadly arrhythmias in patients with preexisting cardiac disease. The risks associated with medication side effects should not be underestimated in high-risk or critically ill patients.

Iatrogenic Responses

An **iatrogenic response** is an adverse condition inadvertently induced in a patient as a result of treatment. The term *iatrogenic* comes from ancient Greek, meaning "brought forth by the healer." For example, a urinary tract infection may develop after the insertion of an indwelling catheter. In pharmacology, a hemorrhagic stroke caused by administration of a thrombolytic or an extrapyramidal reaction due to chlorpromazine is an example of an iatrogenic response.

Unpredictable Responses

Adverse drug events during treatment are common. While some are avoidable, many are not. The most common unpredictable response encountered in the prehospital setting is an allergic reaction. An allergic reaction occurs when the patient has a hypersensitivity to a medication or one of the ingredients used in its particular form or preparation. Such reactions are unpredictable and may range from an isolated rash to a dangerous systemic immune response, or anaphylaxis. They should be anticipated with any drug. Severe reaction to one penicillin-based antibiotic, for example, may indicate the person has a greater chance of cross-reacting to another penicillin-based antibiotic. An allergy to bananas or avocados is highly suggestive of a latex allergy. Numerous other allergy patterns have been identified among foods, environmental allergens, and medications. When possible, CCTPs should always evaluate a patient's allergies prior to administering any medication.

In rare cases, the patient may experience a completely unique response to a medication. This **idiosyncratic reaction** is unrelated to the pharmacologic action of a medication or the dose administered. For example, in extremely rare cases, patients have developed Stevens-Johnson syndrome after exposure to ibuprofen.

Patients who take a particular medication for an extended period can build up **tolerance** to it. In these cases, the patient will often require higher-than-normal doses to achieve the desired response. Patients may also develop a tolerance to one medication as a result of prolonged administration of another, a condition known as **cross-tolerance**. This phenomenon is often seen in patients who take different opioids. For example, a patient taking higher doses of oxycodone may need higher doses of intravenous morphine to control acute pain.

Tachyphylaxis is a condition in which the patient rapidly becomes tolerant to a medication. With tachyphylaxis, increasingly higher doses of a medication are required to achieve the desired effects. This phenomenon most commonly occurs with prolonged treatment with nitroglycerin.

Keep in mind that toxic thresholds may remain unchanged even when tolerance develops. With prolonged administration of a medication, a patient may also become drug dependent. In this case, the person will have significant symptoms if they stop using the medication.

Frequent dosing of a medication over a relatively short time may lead to a **cumulative effect**, possibly resulting in supratherapeutic or nontherapeutic effects.

Many patients take multiple medications at one time. It is possible for the effects of one medication to alter the patient’s response to another medication, a phenomenon known as a **drug interaction**. For example, a woman on birth control taking rifampin (an antibiotic) may inadvertently become pregnant, as rifampin causes the liver to metabolize the contraceptive at an increased rate. Another example is the administration of epinephrine to a patient taking a monoamine oxidase inhibitor (MAOI). The interaction between these medications can lead to a hypertensive crisis because MAOIs block the breakdown of catecholamines.

If the interaction between two medications causes one drug to enhance the effect of the other, the outcome is known as **potentiation**. For example, acetaminophen and alcohol, both of which may be hepatotoxic, may interact. When patients with chronic alcohol use disorders ingest acetaminophen, it may precipitate liver toxicity even when taken at therapeutic doses, a phenomenon referred to as alcohol-acetaminophen syndrome. Some potentiation effects are known and can be exploited to achieve a desired effect; in other cases, potentiation may occur unexpectedly. A **summation effect** occurs when a patient receives two drugs that have the same effect, thus doubling the overall effect. When the patient receives two drugs that produce a response greater than their sum, the result is known as **synergism**.

A direct biochemical interaction that takes place between two drugs resulting in diminished efficacy is referred to as **interference**. **Inhibition** is the opposite of potentiation, with one medication limiting the effects of another.

Avoiding Medication Errors

Medication errors are the most common errors in medicine. While most produce no harm, others can have devastating effects on the patient, their families, and the health care provider. Medication errors may occur at any point during the medication use process, including the selection, administration, and monitoring phases. As part of ensuring the "rights" of medication administration **TABLE 8-2**, CCTPs must evaluate medication decisions made by the sending facility. It is essential that CCTPs confirm the accuracy of any medication infusion they are continuing during transport. Proper labeling of transport medications and infusions is essential for CCTPs when accepting a patient or turning over patient care. Additionally, line incompatibility should be considered for any patient receiving multiple IV infusions. Some IV solutions may be incompatible when mixed in the same line or bag; such a combination may result in inactivation or precipitation of medications. CCTPs should never infuse drugs that have visible precipitants or unexpected discoloration.

TABLE 8-2 Rights of Medication Administration

Labeling all infusions and cross-checking them with active orders during handoff are key responsibilities of the CCTP. All medication infusions should be labeled both at the distal end of the infusion tubing (proximal to the patient) and on the infusion pump. A CCTP who prepares an infusion should label the bag with, at a minimum, the drug name and concentration, the time and date of preparation, and their initials.

Medication Management

Medication Storage

Some medications may be sensitive to extremes in temperature, exposure to direct sunlight, or excessive humidity. Exposure to such conditions may result in drug inactivation or precipitation. As such, the storage of drugs is a key issue for ensuring safe medication administration during transport.

Each manufacturer provides guidance on the proper medication storage conditions. This information can be found on the drug's package insert or in other drug references. In general, medications should be kept out of direct sunlight and stored at room temperature, as defined in the *United States Pharmacopeia* (ie, 59°F–86°F [15°C–30°C]). During transport, CCTPs and vehicles may be exposed to temperature extremes. It is essential that medications remain within the required temperature ranges. Certain IV medications (eg, diltiazem, lorazepam, succinylcholine) require refrigeration. These medications are stable at room temperature for a limited time and expire quickly. CCTPs should expect transport medications to have different shelf lives, with some remaining stable for years and others expiring in a much shorter time.

Transport vehicles require special consideration in terms of medication storage. CCTPs should monitor the temperature of transport vehicles when they are exposed to extremes of heat or cold. Medications may need to be removed while the vehicle is parked. Smaller electronic devices are now available that can record the temperature of a vehicle and identify periods of deviation from safe medication storage temperatures.

CCTPs should be conscious of these general guidelines, use their best judgment, and ensure medications are stored in areas that are not routinely or constantly exposed to extreme environments. Every department should have a written policy or procedure for all medication, fluid, and diluent storage and handling. In addition, CCTPs should perform monthly audits to identify soon-to-expire medications and restock as appropriate. Finally, it is best practice to double-check the expiration date prior to any drug administration.

Security of Controlled Medications

Most drugs used in the prehospital setting are prescription medications, and many are **controlled substances**. State and federal governments heavily regulate the acquisition, storage, transport, usage, and disposal of controlled medications. State pharmacy boards and the US Drug Enforcement Administration have specific regulations that CCTPs must follow in these situations. Minimum requirements for the storage of controlled substances include housing them in an inconspicuous, securely locked, substantially constructed cabinet. Cabinets constructed of materials that are fragile or allow visualization, such as those with glass or plastic fronts, are inappropriate.

A disposition record must be maintained for all controlled substances, and thorough documentation must be completed for any use of a controlled substance, including the disposal of any leftover waste medication not administered during patient care. Any expired controlled substances must be returned to the agency or departmental officer in charge of maintenance and dispersal of controlled substances and must also be documented in the disposition record(s).

Every agency must have a written protocol and procedure for the use, storage, disposition, and documentation of controlled substances.

Specific Medications Used in Critical Care Transport

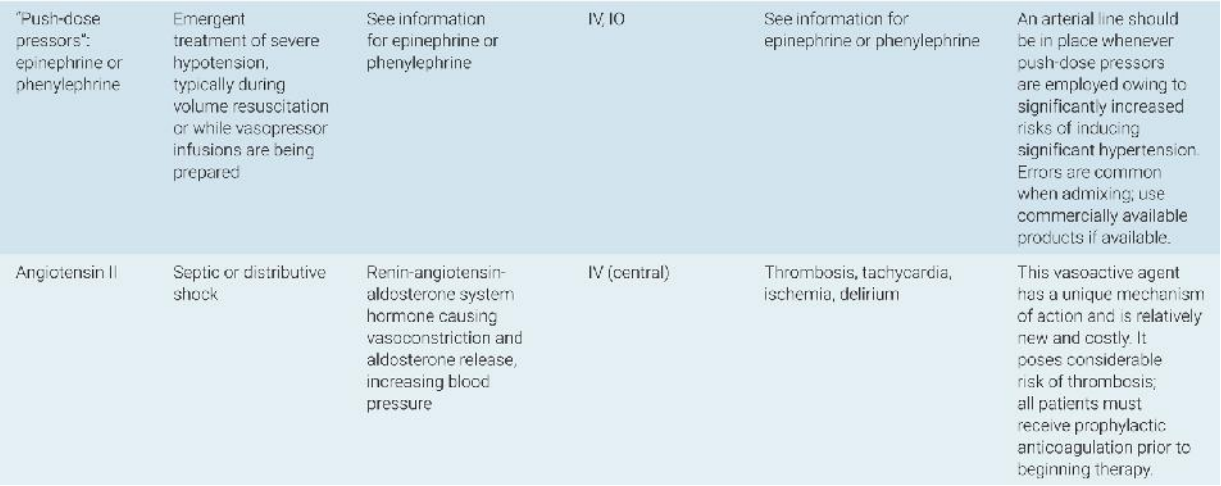
Common medications used by CCTPs are highlighted in this section. CCTPs will encounter additional medications in clinical practice and should develop a strategy for safe administration of any drug that may be needed. Conversely, not every medication or medication class described here may be relevant to providers who perform only CCT of specialty populations (eg, high-risk obstetric or neonatal populations).

Vasopressors

Vasopressor medications induce arterial vasoconstriction, which in turn elevates mean arterial blood pressure. Their mechanism of action usually involves stimulation of the adrenergic receptors involved in vasoconstriction. Some vasopressors may also exhibit inotropic activity (increasing myocardial contractility). Vasopressors are generally indicated for patients in distributive shock states following correction of any fluid volume deficits. Significant side effects of these medications include tissue necrosis from extravasation and ischemia related to vasoconstriction effects (eg, limb ischemia). **TABLE 8-3** profiles selected vasopressors.

TABLE 8-3 Vasopressors

Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Phenylephrine	Hypotension, shock; decongestant (OTC nasal spray)	Pure alpha adrenergic agonist	IV, IO	Peripheral vasoconstriction, hypertension, ischemia, reflex bradycardia, low cardiac output, anxiety, restlessness	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation. Vasopressors may worsen myocardial performance in compromised patients.
Norepinephrine	Hypotension, cardiogenic or septic shock (first-line pressor in adult patients with septic shock)	Stimulates beta-1 and alpha-1 receptors; increases myocardial contractility and heart rate in addition to systemic vasoconstriction; alpha (vasoconstriction) effects are greater than beta (inotropic and chronotropic) effects	IV, IO	Peripheral vasoconstriction, hypertension, ischemia, tachycardia, anxiety, restlessness	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation.
Epinephrine	Anaphylaxis, hypotension, severe asthma unresponsive to inhaled beta agonists, cardiac arrest, bradycardia unresponsive to atropine or pacing, shock unresponsive to adequate fluid volume replacement, low cardiac output	Stimulation of alpha-1, beta-1, and beta-2 adrenergic receptors, resulting in bronchial smooth muscle relaxation, cardiac inotropy (increased contractility), and chronotropy (increased rate)	Nebulized, subcutaneous, IM, IV, IO, endotracheal tube	Arrhythmias (tachycardias, ventricular ectopy, fibrillation), hypertension, increased myocardial oxygen consumption, vasoconstriction, ischemia, hyperglycemia, nausea, vomiting, anxiety, tremors, nervousness, restlessness	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation. Errors with this agent's use are common, requiring careful dosing and administration, especially in pediatric patients.
Vasopressin	Treatment of hypotension refractory to fluids and catecholamines	Direct systemic vasoconstriction with no inotropic or chronotropic effects through V_1 receptor agonism (non–alpha- or beta-mediated mechanism); additionally decreases urine output and acts as an antidiuretic hormone	IV, IO	Hypertension, reflex bradycardia, peripheral vasoconstriction, ischemia, decreased urine output	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation.
Methylene blue	Treatment of drug or chemically induced methemoglobinemia, refractory vasoplegia syndrome following cardiac surgery	Speeds conversion of methemoglobin to hemoglobin; may restore vascular tone by direct inhibition of nitric oxides	IV, IO	Arrhythmias, hypertension, blue skin staining, blue-green fecal discoloration, blue-green urine discoloration, diaphoresis, local ischemia with extravasation	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation.



"Push-dose pressors": epinephrine or phenylephrine	Emergent treatment of severe hypotension, typically during volume resuscitation or while vasopressor infusions are being prepared	See information for epinephrine or phenylephrine	IV, IO	See information for epinephrine or phenylephrine	An arterial line should be in place whenever push-dose pressors are employed owing to significantly increased risks of inducing significant hypertension. Errors are common when admixing; use commercially available products if available.
Angiotensin II	Septic or distributive shock	Renin-angiotensin-aldosterone system hormone causing vasoconstriction and aldosterone release, increasing blood pressure	IV (central)	Thrombosis, tachycardia, ischemia, delirium	This vasoactive agent has a unique mechanism of action and is relatively new and costly. It poses considerable risk of thrombosis; all patients must receive prophylactic anticoagulation prior to beginning therapy.

Abbreviations: cAMP, cyclic adenosine monophosphate; DI, diabetes insipidus; IM, intramuscular; IO, intraosseous; IV, intravenous; OTC, over-the-counter; ROSC, return of spontaneous circulation; SVT, supraventricular tachycardia

Description

Phenylephrine

Phenylephrine is an alpha-1 agonist. This medication binds to and stimulates the alpha-1 receptors, resulting in systemic arterial vasoconstriction. As with any vasopressor, caution must be exercised when this drug is administered to patients with coronary artery disease because it may precipitate or worsen myocardial ischemia. Further, phenylephrine should be avoided in patients with bradycardia because it may further decrease the heart rate (through baroreflex bradycardia due to increased systemic vascular resistance). Phenylephrine is typically given as an infusion at a rate of 40 to 60 µg/min. It may be necessary to rapidly titrate the dose or give a bolus dose to achieve the desired blood pressure response. Phenylephrine is best used in situations where the patient has a loss of vasomotor tone, without simultaneous impairment of myocardial contractility.

Norepinephrine

Norepinephrine is a beta-1 and alpha-1 agonist. It is most commonly used for blood pressure control in patients who are in cardiogenic or septic shock. Norepinephrine is a first-line vasopressor in patients with septic shock who remain hypotensive after an adequate fluid challenge. It is most commonly dosed in units of µg/min; however, certain hospitals may use µg/kg/min, especially in pediatric patients. Norepinephrine's side effects represent a continuation of its mechanism of action; they include arrhythmias, tachycardia, hypertension, and decreased peripheral blood flow. The onset is rapid and the half-life is only 2.5 minutes. As such, infusion interruptions may result in rapid effects on the patient's blood pressure. Norepinephrine infusion ceiling doses are usually in the range of 20 to 40 µg/min; however, in practice larger doses have been reported.

Epinephrine

Epinephrine is an alpha/beta agonist that stimulates alpha-1, beta-1, and beta-2 adrenergic receptors, which in turn leads to relaxation of bronchial smooth muscle, **inotropic** and **chronotropic** cardiac stimulation, and dilation of skeletal muscle vasculature. Low doses cause beta$_2$ vascular receptor stimulation, resulting in vasodilation; in contrast, higher doses constrict skeletal and vascular smooth muscles. When given intravenously, epinephrine's effects are nearly immediate and last for less than 5 minutes.

Infusions of epinephrine for relief of bronchospastic respiratory distress, anaphylaxis, bradycardia, and cardiogenic shock are generally initiated at 0.05 µg/kg/min and titrated every 3 to 5 minutes in increments of 0.02 µg/kg/min, up to a maximum of 1 µg/kg/min. Usual doses range from 0.05 to 0.5 µg/kg/min.

Epinephrine is a potent vasoconstrictor and should be infused through a central access line as soon as one is available. Its adverse effects include tachycardia, anxiety, restlessness, arrhythmias, limb ischemia, diaphoresis, hyperglycemia, and tremor.

Vasopressin

Vasopressin is a naturally occurring antidiuretic hormone that is typically used in critical care to treat refractory distributive (vasodilatory) shock. This agent is frequently used as a second-line pressor in patients with septic shock who remain hypotensive despite adequate fluids and norepinephrine. Vasopressin exhibits direct vasoconstrictor activity without inotropic or chronotropic effects. It stimulates V_1 receptors and increases systemic vascular resistance and mean arterial blood pressure. Dose ranges for vasopressin infusions vary by indication, but typically range between 0.01 unit/min and 0.1 unit/min; dosing in patients with sepsis is usually 0.04 unit/min. Effects of vasopressin are seen in less than 15 minutes and last for less than 15 to 20 minutes when the infusion is discontinued or decreased.

Adverse reactions to vasopressin may include bradycardia, decreased cardiac output, hyponatremia, and tissue and organ ischemia.

Methylene Blue

Methylene blue is an antidote used for treatment of methemoglobinemia. In critical care settings, it is also employed as a treatment for vasopressor-refractory hypotension. In patients with vasoplegia, methylene blue acts as an inhibitor of nitric oxide and blocks the formation of cyclic guanosine monophosphate; both of these effects reduce vasorelaxation.

Dosing strategies for methylene blue vary and are supported primarily by observational studies rather than prospective clinical trials. For cardioplegia associated with cardiac surgery, the methylene blue IV dose is 1.5 to 2 mg/kg given over 20 to 60 minutes. Improvement is usually observed within 1 to 2 hours. Some clinicians follow the loading dose with an infusion of 0.5 to 1 mg/kg/h for several hours.

Methylene blue is a **vesicant**, and any **extravasation** should be treated aggressively. Infusions should be administered through a central line **FIGURE 8-1**. When high doses are given in infants and in patients with G6PD deficiency, methemoglobinemia may occur. Adverse effects include urine discoloration (blue-green color), dysgeusia, limb pain, and interference with pulse oximetry readings.

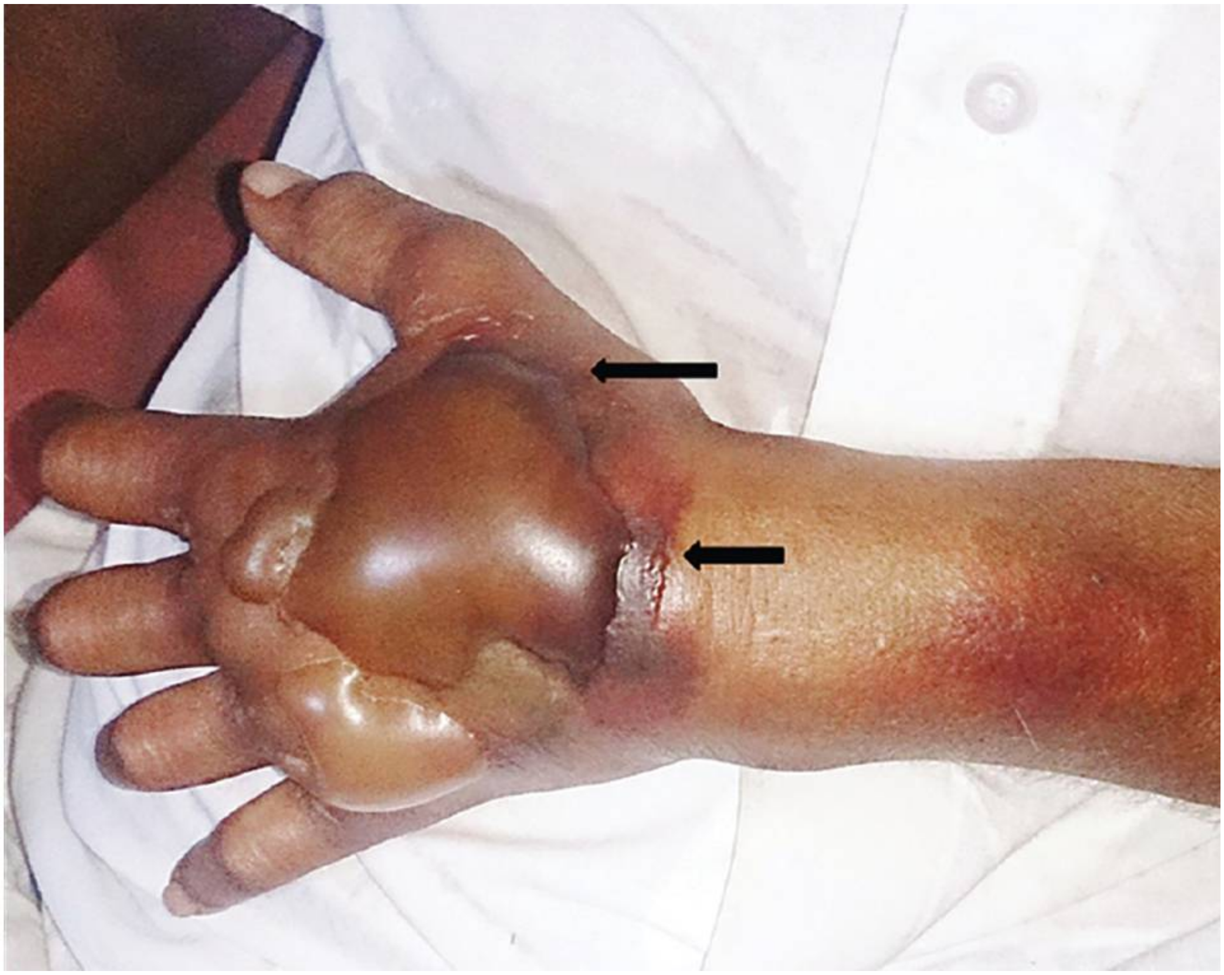

FIGURE 8-1 Extravasation is the leaking of an intravenously administered medication into the surrounding tissues.

Vinod KV, Shravan R, Shrivarthan R, Radhakrishna P, Dutta TK. Acute compartment syndrome of hand resulting from radiographic contrast iohexol extravasation. *J Pharmacol Pharmacother.* 2016;7:44-47, published by Medknow Publications and Media Pvt.

Push-Dose Pressors

Originating in anesthesia, the use of push-dose pressors has become increasingly prevalent over the past decade. Patients may be given small aliquots of appropriately diluted pressors to treat hypotension that is refractory to fluids. These agents are now used in critical care, emergency medicine, and emergency medical services systems. The two medications most often employed as push-dose pressors are dilute concentrations of epinephrine and phenylephrine.

Indications for push-dose pressors include situations where profound hypotension fails to respond to fluid boluses or where vasopressors either are not yet infusing or are not immediately producing an increase in blood pressure. Patients who require such treatment may include those with propofol-induced hypotension, peri- or post-intubation hypotension, hypotension induced by tachyarrhythmias, or profound vasoplegia.

Push-dose epinephrine is usually prepared by adding 0.1 mg of epinephrine to 9 mL of normal saline, with the resulting concentration being 10 μg/mL. Given the onset of action of approximately 1 minute, push-dose pressor doses of 0.5 to 2 mL (5 to 20 μg) would be appropriate to administer every 1 to 5 minutes. Blood pressure, heart rate, and contractility should all increase with the administration of epinephrine.

Unlike epinephrine, phenylephrine has no beta effects and will provide only vasoconstriction with some increase in coronary perfusion. Prepared by either adding 10 mg of phenylephrine to a 100-mL bag of normal saline or adding 10 mg of phenylephrine to a 250-mL bag of saline (the latter is a typical infusion concentration), the resulting concentrations are 100 μg/mL or 40 μg/mL, respectively. With an onset of action of approximately 1 minute, doses consisting of 0.5 to 1 mL of the 100 μg/mL solution (50 to 100 μg) or 1 to 2 mL of the 40 μg/mL solution (40 to 80 μg) would be appropriate to administer every 1 to 5 minutes.

Close patient monitoring is imperative for safety when using push-dose pressors. Ideally, an arterial line should be in place. If not, the patient's blood pressure should be measured at 1-minute intervals. Be careful when preparing push-dose pressors, especially during stressful clinical situations (eg, patients in extremis), as dilution and dosing errors are easy to make and can have devastating consequences. Commercially available products should be considered whenever available.

Angiotensin II

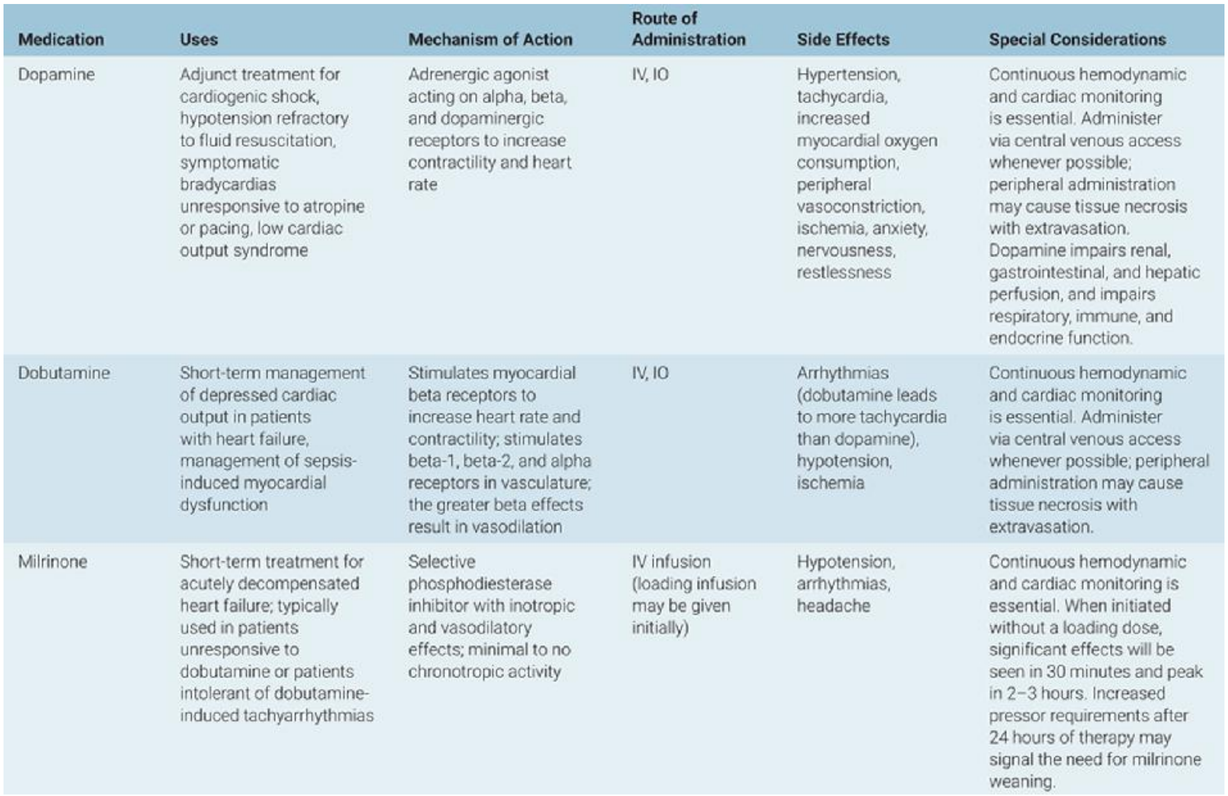
Angiotensin II is a relatively new medication used for blood pressure support in patients with distributive shock. Its mechanism of action differs from the other vasopressors. This agent acts on the renin-angiotensin-aldosterone system, causing vasoconstriction and water retention, both of which increase systemic blood pressure. The usual starting dose is 10 to 20 ng/kg/min, which may be titrated every 5 minutes in increments of 15 ng/kg/min. Once the blood pressure has normalized, angiotensin II can be down-titrated using the same parameters. Maximum doses are usually 80 ng/kg/min during the first 3 hours of treatment and 40 ng/kg/min during maintenance.

During clinical trials, angiotensin II was associated with increased risk of thrombosis, both arterial and venous. To guard against these effects, any patient receiving angiotensin II should be on concomitant venous thromboembolism prophylaxis (eg, heparin, enoxaparin). Due to the significant risk of thrombosis, and its significantly higher cost compared to other vasopressors (ie, $1,800 per vial), few institutions have this drug on their formulary. However, CCTPs may still encounter patients on active infusions of angiotensin II.

Inotropes

Medications may have positive or negative inotropic effects, meaning that they either increase or decrease the force of myocardial contractility, respectively. Inotropic medications increase myocardial contractility and are generally indicated for patients in cardiogenic shock states. Their mechanisms of action vary. Selection typically depends on the diagnosis and provider preference. **TABLE 8-4** profiles selected inotropes.

TABLE 8-4 **Inotropes**



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Dopamine	Adjunct treatment for cardiogenic shock, hypotension refractory to fluid resuscitation, symptomatic bradycardias unresponsive to atropine or pacing, low cardiac output syndrome	Adrenergic agonist acting on alpha, beta, and dopaminergic receptors to increase contractility and heart rate	IV, IO	Hypertension, tachycardia, increased myocardial oxygen consumption, peripheral vasoconstriction, ischemia, anxiety, nervousness, restlessness	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation. Dopamine impairs renal, gastrointestinal, and hepatic perfusion, and impairs respiratory, immune, and endocrine function.
Dobutamine	Short-term management of depressed cardiac output in patients with heart failure, management of sepsis-induced myocardial dysfunction	Stimulates myocardial beta receptors to increase heart rate and contractility; stimulates beta-1, beta-2, and alpha receptors in vasculature; the greater beta effects result in vasodilation	IV, IO	Arrhythmias (dobutamine leads to more tachycardia than dopamine), hypotension, ischemia	Continuous hemodynamic and cardiac monitoring is essential. Administer via central venous access whenever possible; peripheral administration may cause tissue necrosis with extravasation.
Milrinone	Short-term treatment for acutely decompensated heart failure; typically used in patients unresponsive to dobutamine or patients intolerant of dobutamine-induced tachyarrhythmias	Selective phosphodiesterase inhibitor with inotropic and vasodilatory effects; minimal to no chronotropic activity	IV infusion (loading infusion may be given initially)	Hypotension, arrhythmias, headache	Continuous hemodynamic and cardiac monitoring is essential. When initiated without a loading dose, significant effects will be seen in 30 minutes and peak in 2–3 hours. Increased pressor requirements after 24 hours of therapy may signal the need for milrinone weaning.

Abbreviations: AV, atrioventricular; IO, intraosseous; IV, intravenous

Description

Dopamine

Dopamine is an inotrope and is classified as an adrenergic agonist. In its natural endogenous form, it is a precursor to both norepinephrine and epinephrine. The original research that resulted in its popularity in cardiovascular conditions theorized that dopamine had positive inotropic effects by stimulating beta-1 receptors. Additionally, dopamine appeared to stimulate alpha-1 receptors at a higher dose, leading to peripheral vasoconstriction. Dopamine also affects dopaminergic receptors, which are found in the central nervous system (CNS) as well as in the pulmonary arteries and atria of the heart. Stimulation of these receptors increases myocardial contractility and cardiac output.

The wide range of effects found with dopamine allowed for a variety of uses, and clinicians became comfortable with dopamine as a first-line vasopressor in fluid-refractory hypotension. Fear of the ischemic effects of norepinephrine inspired further confidence in the use of dopamine, as clinicians believed its vasopressor and inotropic effects occurred without the renal and gastrointestinal loss of perfusion often seen with other pressors.

Low-dose dopamine, administered at 0.3 to 5 μg/kg/min, was often used and thought to optimize renal perfusion and preserve renal function; this regimen was believed to have minimal effects on cardiac output. More recent studies have challenged the renal and splanchnic (gastrointestinal) protective effects of dopamine and suggested that, in fact, it may do more harm than good in these indications. Significant evidence suggests that dopamine may promote ischemia in the renal medulla, and it may even increase the risk of acute renal failure (ARF) in critically ill patients. The benefits of dopamine in preventing, reversing, or limiting the progression of ARF cannot be substantiated. Norepinephrine, in contrast, has been demonstrated to protect renal blood flow and improve diuresis in patients with shock who have been adequately fluid resuscitated.

Dopamine also creates significant impairment of respiratory function by depressing the carotid body, leading to an impaired response to hypoxemia and hypercapnia. Coupled with regional ventilation-perfusion mismatch, the hypoxemia resulting from dopamine infusions poses significant risks to patients who are not mechanically ventilated or who are weaning from mechanical ventilation. Finally, dopamine significantly depresses endocrine and immunologic function and causes major disturbances in anterior pituitary function. The use of this medication has now fallen out of favor, especially with recent evidence showing norepinephrine to be a superior agent, especially in patients with sepsis.

When used for hemodynamic support, dopamine infusions are titrated from 1 to 20 μg/kg/min in increments of 1 μg/kg/min every 5 to 10 minutes. The drug’s onset of action in adults is 5 minutes, but a steady state of action is not seen for 20 minutes. In children, it may take 1 hour to achieve a steady-state effect. The duration of action of dopamine in adults is 10 minutes.

Dopamine is a vesicant and should be infused into a central line whenever possible. Extravasation should be treated aggressively.

Dobutamine

Dobutamine is an inotrope and is classified as an adrenergic agonist. It is commonly used to treat cardiac decompensation secondary to heart failure. Dobutamine stimulates beta-1 receptors to increase myocardial contractility and heart rate. Its effects on the vasculature (beta-2 effects) also result in vasodilation. The vasodilatory and inotropic effects of dobutamine make it an ideal heart failure drug but limit its utility in patients with hypotension. This agent also results in greater tachycardia than other pressors do, owing to the baroceptor stimulation that occurs secondary to its vasodilatory properties.

As a treatment for heart failure, an infusion of dobutamine is started at 5 μg/kg/min and can be increased every 10 minutes in increments of 2.5 μg/kg/min to a maximum dose of 20 μg/kg/min. Some references suggest starting at lower doses (0.5 to 1 μg/kg/min) to minimize adverse effects such as tachyarrhythmias. Onset of action occurs within 1 to 10 minutes, with peak effects observed in 10 to 20 minutes. The duration of action is short, with the drug having a half-life of only 2 minutes.

Dobutamine does not pose the same risks of tissue damage with extravasation associated with other inotropes and pressors. It may be infused into a peripheral IV line. Patients with home infusions will often have dobutamine running through central IV catheters.

Milrinone

Milrinone is a phosphodiaterase-3 enzyme inhibitor that is used as an inotropic agent for patients in cardiogenic shock or advanced stages of heart failure. Milrinone improves inotropy and results in vasodilation with little effect on heart rate. Typically, this agent is used in patients with heart failure who fail to respond to dobutamine. It may be employed for symptom relief in patients with end-stage heart failure who cannot be discharged from the hospital and are not candidates for heart transplantation or cardiac assist devices. Milrinone also produces a favorable lowering of pulmonary artery pressures and may be used in patients with postoperative pulmonary hypertension.

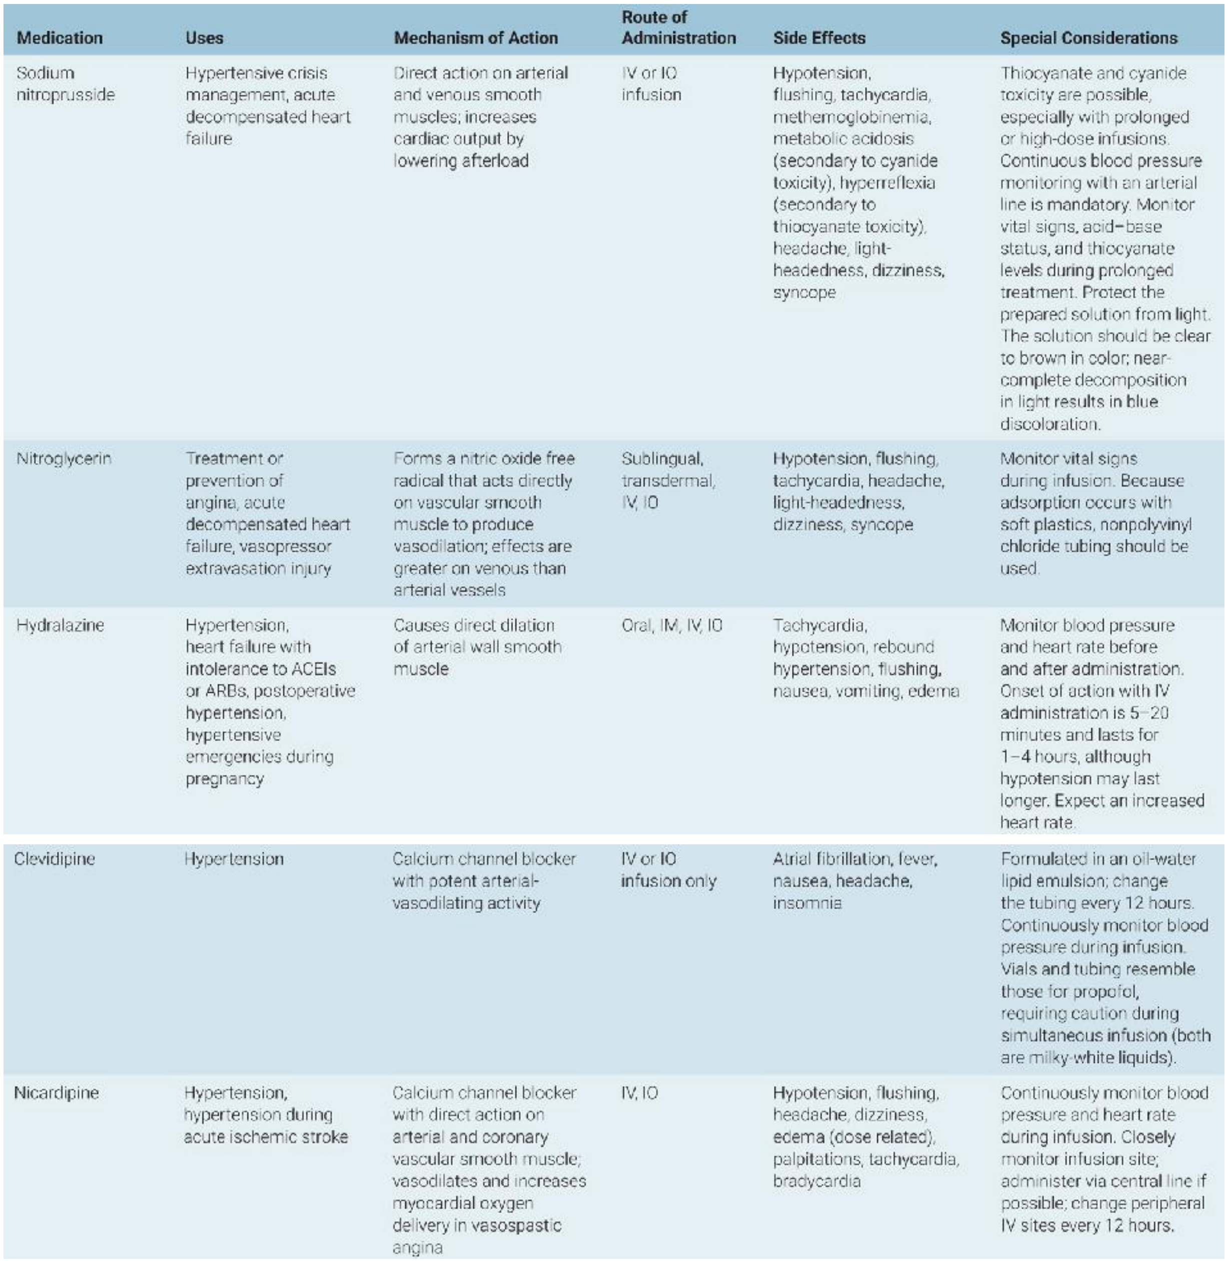
Milrinone infusions are initiated at 0.125 to 0.75 µg/kg/min. Previously, a loading dose of 50 µg/kg administered over 10 minutes was recommended; however, the relatively high incidence of hypotension associated with loading doses has discouraged this practice. While this practice is uncommon, some heart failure specialists may administer milrinone infusions at rates as high as 1.5 µg/kg/min. The onset of action for milrinone is 5 to 15 minutes, and it has a half-life of 2.3 to 2.4 hours. In patients with renal failure, the half-life may be as long as 20 hours.

Major side effects of milrinone include hypotension and arrhythmias (usually ventricular). Hypotension typically responds well to low-dose vasopressors. In patients with new acute decompensated heart failure, recovery over the first 3 to 5 days of milrinone infusion is often associated with increased pressor requirements. Weaning off milrinone will usually decrease the pressor requirements; indeed, with recovery of cardiac function, patients may be completely weaned off milrinone.

Vasodilators and Antihypertensives

Vasodilator medications induce vasodilation, cause preload and/or afterload reduction, and thereby lower mean arterial blood pressure. The mechanism of action for vasodilators is induced relaxation of the smooth muscle in blood vessel walls. Selection of vasodilators depends on the indication for use, patient response, and cost. Hypotension is the most common, and most dangerous, side effect associated with vasodilators. **TABLE 8-5** profiles selected vasodilators.

TABLE 8-5 **Vasodilators and Antihypertensives**



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Sodium nitroprusside	Hypertensive crisis management, acute decompensated heart failure	Direct action on arterial and venous smooth muscles; increases cardiac output by lowering afterload	IV or IO infusion	Hypotension, flushing, tachycardia, methemoglobinemia, metabolic acidosis (secondary to cyanide toxicity), hyperreflexia (secondary to thiocyanate toxicity), headache, light-headedness, dizziness, syncope	Thiocyanate and cyanide toxicity are possible, especially with prolonged or high-dose infusions. Continuous blood pressure monitoring with an arterial line is mandatory. Monitor vital signs, acid–base status, and thiocyanate levels during prolonged treatment. Protect the prepared solution from light. The solution should be clear to brown in color; near-complete decomposition in light results in blue discoloration.
Nitroglycerin	Treatment or prevention of angina, acute decompensated heart failure, vasopressor extravasation injury	Forms a nitric oxide free radical that acts directly on vascular smooth muscle to produce vasodilation; effects are greater on venous than arterial vessels	Sublingual, transdermal, IV, IO	Hypotension, flushing, tachycardia, headache, light-headedness, dizziness, syncope	Monitor vital signs during infusion. Because adsorption occurs with soft plastics, nonpolyvinyl chloride tubing should be used.
Hydralazine	Hypertension, heart failure with intolerance to ACEIs or ARBs, postoperative hypertension, hypertensive emergencies during pregnancy	Causes direct dilation of arterial wall smooth muscle	Oral, IM, IV, IO	Tachycardia, hypotension, rebound hypertension, flushing, nausea, vomiting, edema	Monitor blood pressure and heart rate before and after administration. Onset of action with IV administration is 5–20 minutes and lasts for 1–4 hours, although hypotension may last longer. Expect an increased heart rate.
Clevidipine	Hypertension	Calcium channel blocker with potent arterial-vasodilating activity	IV or IO infusion only	Atrial fibrillation, fever, nausea, headache, insomnia	Formulated in an oil-water lipid emulsion; change the tubing every 12 hours. Continuously monitor blood pressure during infusion. Vials and tubing resemble those for propofol, requiring caution during simultaneous infusion (both are milky-white liquids).
Nicardipine	Hypertension, hypertension during acute ischemic stroke	Calcium channel blocker with direct action on arterial and coronary vascular smooth muscle; vasodilates and increases myocardial oxygen delivery in vasospastic angina	IV, IO	Hypotension, flushing, headache, dizziness, edema (dose related), palpitations, tachycardia, bradycardia	Continuously monitor blood pressure and heart rate during infusion. Closely monitor infusion site; administer via central line if possible; change peripheral IV sites every 12 hours.

Abbreviations: ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; IM, intramuscular; IO, intraosseous; IV, intravenous

Description

Sodium Nitroprusside

Sodium nitroprusside is a potent arterial and venous vasodilator. Its vasodilating effects result from its breakdown to nitric oxide, which acts directly on vascular smooth muscle. Nitroprusside is used to treat acute hypertension and acute decompensated heart failure; its therapeutic effects are seen within 2 minutes. The reduction in total peripheral resistance and venous return produced by this medication decreases both preload and afterload; hence, in patients with severe heart failure, nitroprusside can act to increase cardiac output.

Initial dosing is started at 0.25 to 0.5 μg/kg/min and titrated in increments of 0.5 to 1 μg/kg/min every 3 to 5 minutes. The usual dose range is 0.25 to 3 μg/kg/min to a maximum of 10 μg/kg/min. Some references recommend a maximum rate of 3 to 5 μg/kg/min to avoid cyanide toxicity; such metabolic toxicity occurs when nitroprusside combines with hemoglobin, producing cyanide and cyanmethemoglobin. Normally, cyanide detoxification occurs via conversion of cyanide to thiocyanate, which is then excreted in the urine. However, this process has limited capacity and can become overwhelmed with large cyanide exposures. Nitroprusside's hypotensive effects have a short duration, lasting only 1 to 10 minutes. Common adverse effects with this agent include hypotension, reflex tachyarrhythmias, cyanide toxicity, and methemoglobinemia.

Nitroprusside is relatively unstable. Prepared solutions should be wrapped with aluminum foil to protect them from light, which accelerates their decomposition. Mixtures normally have a clear to brown color; decomposition results in a color change to orange, dark brown, or blue. Blue discoloration indicates almost complete decomposition.

Nitroglycerin

Nitroglycerin is an antianginal agent and vasodilator with primarily venous effects. Its primary action is through the relaxation of vascular smooth muscle. Dilation of post-capillary vessels, including large veins, promotes peripheral pooling of blood, decreasing venous return to the heart and thereby reducing preload. Nitroglycerin also reduces peripheral vascular resistance, thereby reducing afterload. In combination, these effects reduce the heart's workload. In addition, nitroglycerin produces dilation of the coronary vessels themselves, theoretically increasing the supply of oxygenated blood to the myocardium.

Therapeutic doses of nitroglycerin will reduce systolic, diastolic, and mean arterial blood pressure. Effective coronary perfusion pressure is usually maintained, but can be compromised if blood pressure falls excessively, or if the increased heart rate leads to decreased diastolic filling time.

Nitroglycerin infusions, which are typically used to manage ischemic chest pain, are initiated at 10 µg/min and titrated every 3 to 5 minutes in increments of 5 to 10 µg/min. Although the maximum dosing is usually listed as 400 µg/min, most patients are unable to tolerate doses greater than 200 µg/min because of headaches. Other side effects include hypotension, tachycardia, flushing, and nausea. When this medication is used for treatment of acute pulmonary edema, more rapid titration is warranted to doses as high as 100 µg/min to achieve sufficient preload reduction. Prolonged infusions (24 to 48 hours) of nitroglycerin may result in tachyphylaxis.

Because nitroglycerin is absorbed by soft plastic, including polyvinyl chloride–based containers, infusions must be prepared in glass bottles, EXCEL containers, or PAB containers. The drug's manufacturers recommend use of IV tubing sets intended specifically for nitroglycerin.

Hydralazine

Hydralazine is a direct arterial vasodilator that acts on the smooth muscle of the arterioles, yet has little effect on venous vessels. This agent is typically used in hypertensive emergencies and is administered as an IV dose of 10 to 20 mg every 4 to 6 hours. The most common adverse effect with this medication is tachycardia, a phenomenon that leads many clinicians to alternate dosing of hydralazine with a beta blocker such as labetalol.

Clevidipine

Clevidipine is a calcium channel blocker that reduces mean arterial blood pressure by decreasing systemic vascular resistance. It does not reduce cardiac filling pressure (preload), so it is unlikely to lead to myocardial ischemia and decreased cardiac output. This potent antihypertensive agent is used for short-term treatment of hypertension in patients who are unable to take oral medications.

Clevidipine infusions are prepared in a lipid-based, oil-in-water emulsion and should be refrigerated. Bottles of this medication remain stable at room temperature for 2 months when unopened; once opened, however, they are stable for only 12 hours. Bottles and tubing should be changed every 12 hours, as the lipid base increases the risk of bacterial growth.

Clevidipine infusions are started at 1 to 2 mg/h and titrated by doubling the dose every 90 seconds. As blood pressure approaches the target goal, titration increments should be reduced by 1 to 2 mg/h every 3 to 5 minutes. Clevidipine's onset of action is 2 to 4 minutes after the infusion begins, and its duration of action is 5 to 15 minutes.

Because the emulsion contains soybean, egg yolk phospholipids, and glycerin, patients with a history of allergies to soy products or eggs should not receive clevidipine. Adverse effects may include tachycardia, atrial fibrillation, fever, and nausea.

Nicardipine

Nicardipine is a calcium channel blocker used for short-term treatment of hypertension in patients who are unable to take oral medications. Its effects are more selective for vascular smooth muscle than for cardiac muscle. When given intravenously, nicardipine produces significant decreases in systemic vascular resistance, leading to a resultant decrease in blood pressure.

Nicardipine infusions are extremely irritating to peripheral veins, owing to the drug's low pH, and should be administered in a central line or large peripheral vessel. If central access is not available, rotating the peripheral venous administration site every 12 hours may minimize venous irritation.

Nicardipine infusions are initiated at 5 mg/h and titrated every 15 minutes in increments of 2.5 mg/h. If rapid control of blood pressure is desired, titration every 5 minutes is recommended. The maximum recommended dosing is 15 mg/h. The manufacturer recommends that the infusion rate be lowered to 3 mg/h once blood pressure control is achieved, although this dosing may be insufficient to maintain control in many patients.

Other than peripheral access site pain and irritation, side effects of IV nicardipine occur relatively infrequently, but include tachycardia, flushing, pedal edema, and headache. Use of this medication in combination with fentanyl has been reported to exacerbate hypotension.

Sedatives, Anesthetics, Analgesics, Antipsychotics, and Anticonvulsants

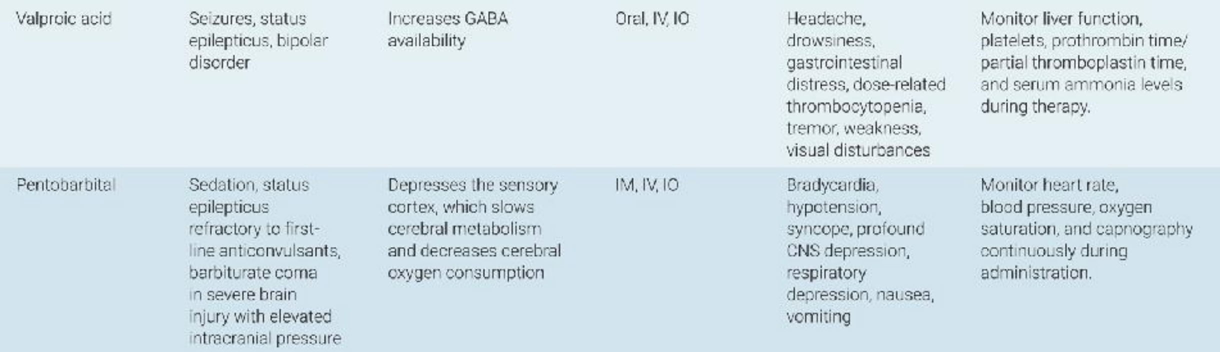
Sedatives, anesthetics, analgesics, and anticonvulsants all act on the nervous system, typically to depress nervous system activity. Sedatives, which include anxiolytics and hypnotics, act as CNS depressants or relaxants. Anesthesia is a state of unconsciousness induced with anesthetics, whereas analgesia is relief of pain. Anticonvulsants act to stop seizure activity. **TABLE 8-6** profiles selected sedatives, anesthetics, analgesics, and anticonvulsants.

TABLE 8-6 **Sedatives, Anesthetics, Analgesics, and Anticonvulsants**

Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Sedatives					
Midazolam	Sedation, anxiety, amnesia (during procedures), for induction of general anesthesia, seizures	Enhances the action of the inhibitory neurotransmitter GABA	Oral, IV, IO, IM, intranasal, buccal	Respiratory depression, hypotension, drowsiness, nausea, vomiting	Due to its low pH of 3, burning is likely to occur with intranasal administration. Higher concentrations (ie, 5 mg/mL) are preferred to reduce the total intranasal volume needed. Monitor respiratory status using capnography as well as blood pressure during administration.
Diazepam	Anxiety, acute alcohol withdrawal, muscle spasm, seizures, sedation	Enhances the action of the inhibitory neurotransmitter GABA	Oral, IV, IO, IM, rectal	Hypotension, drowsiness, respiratory depression, localized phlebitis, pain at injection site	Diazepam is a vesicant; avoid extravasation. Monitor respiratory status using capnography as well as blood pressure during administration.
Lorazepam	Anxiety, amnesia, agitation, premedication to general anesthesia, alcohol withdrawal syndrome, seizures, chemotherapy-associated nausea and vomiting	Enhances the action of the inhibitory neurotransmitter GABA	Oral, SL, IV, IO, IM	Hypotension, sedation, respiratory depression	Unopened vials require refrigeration (contact the manufacturer for room-temperature storage information). The injectable solution requires dilution. Its thickness also makes it difficult to withdraw from vial; use larger-gauge needles. Contains propylene glycol or benzyl alcohol; long-term or high-dose infusions may lead to toxicity. Monitor respiratory status using capnography as well as blood pressure during administration.
Phenobarbital	Seizures, sedation, alcohol and sedative-hypnotic withdrawal, status epilepticus	Depresses the sensory cortex, which slows cerebral metabolism and decreases cerebral oxygen consumption	Oral, IM, IV, IO	Bradycardia, hypotension, syncope, profound CNS depression, respiratory depression	Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration.
Dexmedetomidine	ICU sedation of mechanically ventilated patients, procedural sedation of nonintubated patients	Agonist of alpha-2 adrenergic receptors; exhibits both sedative and anesthetic properties	IV	Sedation, hypotension, bradycardia (risk related to loading doses or higher maintenance doses), agitation/delirium (responds well to benzodiazepines), inhibits salivation	Patients are usually readily aroused with stimulation. Dexmedetomidine is not appropriate for patients who are paralyzed. Monitor heart rate and blood pressure continuously during administration. Use narcotics and benzodiazepines cautiously and in reduced doses; dexmedetomidine enhances their effects.
Anesthetics					
Propofol	Induction of anesthesia, procedural sedation, refractory status epilepticus	Causes global CNS depression through likely agonism of GABA-1 receptors	IV, IO	Hypotension, injection-site burning/pain, apnea, arrhythmias, hypertriglyceridemia with high-dose, long-term infusion (more than 2 days), oversedation, propofol-related infusion syndrome	Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration. Lidocaine may be used to reduce injection-site pain. Requires aseptic handling; the lipid emulsion encourages bacterial growth. Change tubing every 12 hours.

Etomidate	Induction of anesthesia, procedural sedation	Ultra-short-acting benzylimidazole general anesthetic	IV, IO	Pain at injection site, nausea and vomiting on emergence from anesthetic effects, myoclonus (up to 33% of patients), transient skeletal movements, uncontrolled eye movements, hiccups, apnea, impaired cortisol synthesis	Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration. Monitor the infusion site carefully; etomidate is very irritating.
Ketamine	Induction and maintenance of general anesthesia, analgesia, procedural sedation, refractory status epilepticus	Produces a cataleptic-like state (dissociation) most likely by NMDA receptor antagonism	IV, IO, IM, oral	Hypertension and increased heart rate (transient); may cause auditory/visual hallucinations, restlessness, vivid dreams, irrational behavior on emergence; tonic-clonic movements resembling seizure	Laryngeal reflexes and respiratory drive usually remain intact during ketamine administration. Bronchodilation occurs. Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration. Laryngospasm is an extremely rare but dangerous side effect.
Antipsychotics					
Haloperidol	Behavioral disorders, delirium, tranquilization of agitated/aggressive/violent patients	Blocks postsynaptic dopaminergic D_2 receptors; first-generation (typical) antipsychotic	Oral, IM, IV, IO (IV is common but unapproved)	QT prolongation (especially at high IV doses), excessive sedation, hypotension, bradycardia, neuroleptic malignant syndrome, and extrapyramidal symptoms	Avoid large doses. Monitor blood pressure and cardiac rhythm. Baseline 12-lead ECG recommended to follow QTc.
Olanzapine	Treatment of schizophrenia-associated acute agitation, delirium, psychosis or acute agitation, PTSD, Tourette syndrome	Combined antagonism of dopamine and serotonin receptor sites; atypical antipsychotic	IM, oral (ODT available)	Orthostatic hypotension, drowsiness, Parkinson-like syndrome, extrapyramidal syndrome, weight gain (with regular use)	Patients should be monitored closely for excessive sedation.
Quetiapine	Delirium in the critically ill patient, generalized anxiety disorder, bipolar disorder, schizophrenia	Believed to be a combination of dopamine and serotonin receptor antagonism; atypical antipsychotic	Oral	Drowsiness, dry mouth (xerostomia), orthostatic hypotension	Lack of parenteral formulation may be challenging in noncooperative patients.
Analgesics					
Fentanyl	Pain management, adjunct to anesthesia	Binds with opioid receptors in the CNS, preventing painful impulse transmission	Oral, transdermal, IM, IV, IO, intranasal	Respiratory depression, apnea, hypotension, bradycardia, palpitations, flushing, nausea, vomiting, constipation, disorientation, urinary retention	Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration.
Sufentanil	Pain management, adjunct to anesthesia, surgical and postoperative analgesia	Binds with opioid receptors in the CNS, preventing painful impulse transmission	IV, IO, SL	Respiratory depression, apnea, hypotension, bradycardia, palpitations, flushing, nausea	Considerably more potent and shorter acting than fentanyl. Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration.

Morphine	Pain management	Binds with opioid receptors in the CNS, preventing painful impulse transmission	Oral, subcutaneous, IM, IV, IO, intranasal	Respiratory depression, apnea, hypotension, bradycardia, palpitations, flushing, nausea and vomiting (usually related to speed of administration), urinary retention, constipation	Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration. Use with caution in patients with renal dysfunction (may accumulate).
Hydromorphone	Pain management	Binds with opioid receptors in the CNS, preventing painful impulse transmission; produces generalized CNS depression	Oral, subcutaneous, IM, IV, IO, PR	Respiratory depression, apnea, hypotension, bradycardia, palpitations, flushing, nausea, vomiting, abnormal dreams, cognitive dysfunction	Often used in patients who are allergic to or who fail to respond to morphine. Use with caution because of its potency. Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration.
Nalbuphine	Pain management, opioid-induced pruritus (itching)	Agonist and partial antagonist; binds with opioid receptors in the CNS	Subcutaneous, IM, IV, IO	Excessive sedation, respiratory depression, dizziness, nausea, vomiting	Often used for opioid-induced pruritus, especially with epidural opioid infusions. Blood pressure and respiratory monitoring are recommended when nalbuphine is used for analgesia.
Acetaminophen	Temporary relief of minor aches and pains (mild to moderate pain), antipyretic, treatment of moderate to severe pain when combined with an opioid	Believed to activate serotonergic inhibitory pathways; works peripherally to block pain impulses; antipyresis results from inhibition of heat-regulating hypothalamic centers	Oral, PR, IV, IO	Most significant side effect is liver toxicity; maximum daily dose for healthy adults is 4 g; limit to less than 2 g/day for patients with liver disease or EtOH abuse history	Often combined with opioids for treatment of severe pain. Use caution with total daily dose when giving combination products and acetaminophen.
Ketorolac	Short-term (less than 5 days) management of moderate to severe pain, treatment of migraine in adults	Inhibits COX-1 and COX-2 enzymes, decreasing formation of prostaglandin precursors; exhibits antipyretic, analgesic, and anti-inflammatory properties	Oral, IM, IV, IO	Abdominal discomfort, gastritis, headache, renal insufficiency	Use with caution in patients with preexisting renal dysfunction. Ketorolac inhibits platelet function and is contraindicated in patients at high risk of bleeding. Administer IV doses slowly (over more than 15 s).
Anticonvulsants					
Levetiracetam	Seizures, status epilepticus, seizure prophylaxis in patients with subarachnoid hemorrhage	Unknown; believed to have multiple central pharmacologic effects, including calcium channel and facilitation of GABA inhibitory transmission	Oral, IV, IO	Behavioral problems and vomiting in children and adolescents, weakness, CNS depression	Administer IV doses over 15 min or at a rate of 2–5 mg/kg per min.
Phenytoin	Seizures, status epilepticus, prevention of early (within 1 week) seizures following traumatic brain injury	Decreases cellular sodium levels in the motor cortex of the CNS; increases effective refractory period in neural cells; also has antiarrhythmic activity	Oral, IV, IO	Hypotension, CNS depression, nausea, cardiac arrhythmias, venous irritation, skin rash	IV phenytoin should not be infused any faster than 50 mg/min in adults. Slow the infusion rate if hypotension occurs. Monitor IV sites closely for signs of infiltration; phenytoin is a vesicant.
Fosphenytoin	Seizures, status epilepticus	Stabilizes neuronal membranes and influx/efflux of sodium across cell membranes	IM, IV, IO	Hypotension, CNS depression, cardiac arrhythmias, venous irritation; transient and dose-related pruritus, tinnitus, and somnolence	IV fosphenytoin is considered safer for administration than phenytoin. Monitor IV sites closely for signs of infiltration. Continuous respiratory, blood pressure, and ECG monitoring are recommended during loading doses and for 10–20 min after infusion.



Valproic acid	Seizures, status epilepticus, bipolar disorder	Increases GABA availability	Oral, IV, IO	Headache, drowsiness, gastrointestinal distress, dose-related thrombocytopenia, tremor, weakness, visual disturbances	Monitor liver function, platelets, prothrombin time/partial thromboplastin time, and serum ammonia levels during therapy.
Pentobarbital	Sedation, status epilepticus refractory to first-line anticonvulsants, barbiturate coma in severe brain injury with elevated intracranial pressure	Depresses the sensory cortex, which slows cerebral metabolism and decreases cerebral oxygen consumption	IM, IV, IO	Bradycardia, hypotension, syncope, profound CNS depression, respiratory depression, nausea, vomiting	Monitor heart rate, blood pressure, oxygen saturation, and capnography continuously during administration.

Abbreviations: CNS, central nervous system; COX-1, cyclooxygenase 1; COX-2, cyclooxygenase 2; ECG, electrocardiogram; EtOH, ethyl alcohol; GABA, gamma-aminobutyric acid; ICU, intensive care unit; IM, intramuscular; IO, intraosseous; IV, intravenous; NMDA, *N*-methyl-D-aspartate; ODT, oral disintegrating tablets; PR, rectal; PTSD, posttraumatic stress disorder; SL, sublingual

Description

Many medications classified as sedatives, anesthetics, analgesics, or anticonvulsants cross classifications and, depending on the dose and indication, may be considered members of multiple classes. Their mechanisms of action vary widely. While their side effects also vary widely, the most significant and potentially dangerous adverse effect of any CNS depressant is unrecognized respiratory depression. Identification of respiratory depression via continuous monitoring of pulse oximetry, which has long been a standard of care for all critical patients, is significantly delayed; hence, this modality is woefully inadequate as a respiratory depression monitor. Waveform capnography is the standard of care for monitoring when administering anesthetics and sedatives; indeed, it is the only well-validated tool for promptly recognizing respiratory depression. Capnography provides a measure of certainty when administering analgesia and when using anticonvulsants in an actively seizing patient.

Midazolam

Midazolam is a medication often chosen for procedural sedation because of its relatively fast onset (1 to 5 minutes when given intravenously). When used for rapid sequence intubation (RSI), it is usually administered as an adjunct to other sedative-hypnotic agents, rather than as the sole induction agent. Midazolam has a potent amnesic effect, inhibiting the patient's ability to recall the procedure. Because this agent can be stored for a prolonged period at room temperature, it is a popular medication during CCT.

Midazolam is also used for sedation in CCT patients and to terminate **status epilepticus** seizures. It can be administered orally, intravenously/intraosseously by bolus or continuous infusion, intramuscularly, intranasally, or buccally (off-label). Intranasal administration is likely to cause a burning sensation due to the drug's low pH (adjusted pH is 3). Minimizing the volume administered by using a 5 mg/mL concentration reduces irritation, as does the use of a commercial atomizer device such as the MAD Mucosal Atomizer. The maximum recommended volume is 1 mL per nare.

Midazolam dosing is titrated to effect and can vary by indication. Initial IM dosing in adults for sedation is typically 5 mg. IV midazolam is initially given slowly over at least 2 minutes (to avoid profound hypotension) at doses of 0.5 to 2 mg, repeated every 2 to 3 minutes to a usual dose of 2.5 to 5 mg. Continuous infusions of midazolam are usually prepared by adding 100 mg to 100 mL of normal saline (NS) or dextrose 5% in water (D_5W); the infusion is started at 1 to 2 mg/h for adults, and then titrated upward in increments of 2 mg/h. Often, an analgesic infusion such as fentanyl or morphine is used in combination with midazolam, which potentiates the effects of both medications.

The recommended dosing for status epilepticus is 0.2 mg/kg IV, up to a maximum of 10 mg. If given intramuscularly, a single 10-mg dose is recommended in adults. Close cardiorespiratory monitoring is needed when giving larger midazolam doses.

Midazolam is believed to produce its effects by altering the neurotransmitter gamma-aminobutyric acid (GABA). Thus, midazolam acts as a CNS depressant, though it also has hypnotic and anterograde amnesic properties. Patient recovery time depends on both the dose and the duration of administration.

Diazepam

Diazepam is a moderately long-acting benzodiazepine with similar indications as midazolam. Diazepam is also marketed in a gel designed for rectal administration by caregivers in the community to treat status epilepticus seizures. Rectal gel dosing is 0.5 mg/kg for children age 2 to 5 years, 0.3 mg/kg for children age 6 to 11 years, and 0.2 mg/kg for children 12 years and older. Of note, IV diazepam solution (5 mg/mL) is sometimes used for rectal administration in hospital settings. Although diazepam has been used for procedural sedation in adults, its use for this indication has fallen out of favor due to its longer half-life (and its active metabolite).

Diazepam is incompatible with many other drugs. For this reason, it should never be mixed with other solutions or medications.

Lorazepam

Lorazepam remains the preferred benzodiazepine for emergency treatment of status epilepticus. Unfortunately, its physical and chemical properties pose obstacles to field use. Lorazepam requires refrigeration for its storage, although it may remain stable at room temperature for shorter periods, depending on the manufacturer. Injectable lorazepam is a very thick liquid, making it difficult to draw into a syringe, especially if using a smaller-gauge needle. Finally, propylene glycol is typically used to preserve injectable lorazepam; when the drug is administered as a continuous infusion at higher doses, this preservative can result in toxicity. Collectively, these physical and chemical properties explain why midazolam tends to be the benzodiazepine most often carried by field units.

Lorazepam is an anxiolytic and is commonly used to treat acute alcohol withdrawal. In addition, it is often used as an adjunct antiemetic for anticipatory chemotherapy-induced nausea and vomiting.

Flumazenil is a benzodiazepine reversal agent that competitively inhibits benzodiazepine receptor site activity. This medication is rarely used, especially in patients on long-term benzodiazepines, as it may precipitate seizures (highlighted by a black box FDA warning on its label). Many experts recommend symptomatic management of suspected benzodiazepine overdose (ie, assisted ventilation and supportive treatment of hypotension) rather than administering a reversal agent.

Phenobarbital

Phenobarbital is a long-acting barbiturate used in critical care for treatment of status epilepticus, seizures, and alcohol withdrawal. For treatment of status epilepticus, 20 mg/kg of IV phenobarbital is administered initially at 50 to 100 mg/min. A second dose of 5 to 10 mg/kg can be given 10 minutes after completing the initial loading dose if needed. Phenobarbital results in significant sedation and respiratory depression, and hypotension often occurs during the IV loading dose administration. For treatment of status epilepticus, this agent is usually considered only after other first-line therapies (eg, fosphenytoin, levetiracetam) have failed.

Dexmedetomidine

Dexmedetomidine is a selective alpha-2 adrenergic receptor agonist with analgesic and anxiolytic properties. It is used for sedation in mechanically ventilated patients, as a premedication for induction of anesthesia, for procedural sedation, for relief of pain, and to reduce opioid doses following surgery or trauma. Dexmedetomidine may cause hypotension (24% to 56% of patients) and bradycardia (5% to 42%), though these effects tend to be dose and duration dependent.

Loading doses are occasionally used in adult patients, beginning with an infusion of 0.5 to 1 µg/kg/h for 10 minutes; however, such doses are more likely to cause adverse cardiovascular effects (eg, hypertension, hypotension, bradycardia). Most patients are started on maintenance infusion of 0.2 to 0.7 µg/kg/h. Titration is done in increments of 0.1 µg/kg/h. Dexmedetomidine's onset of action varies between 5 and 10 minutes.

There has been considerable discussion regarding the maximum doses and duration of therapy with dexmedetomidine. Doses as high as 2.5 µg/kg/h have been used, although many reference sources note that doses greater than 1.5 µg/kg/h do not offer additional clinical benefits. In practice, the authors typically use doses of up to 2 µg/kg/h. The manufacturer recommends that the duration of dexmedetomidine infusion not exceed 24 hours, although several clinical trials have shown that dexmedetomidine has safety and efficacy comparable to that for lorazepam and midazolam with infusions of up to 5 days.

There is potential for medication errors when administering dexmedetomidine because recommended doses are expressed in micrograms per kilogram per hour (µg/kg/h), an administration unit quite different from that of other sedatives and analgesics used in the ICU.

Hypotension associated with dexmedetomidine can be lessened by eliminating the loading dose and titrating the dose upward no more often than every 30 minutes. Pressors may be needed to manage the hypotension. Bradycardia, especially when it occurs early in the administration of dexmedetomidine, can be treated with atropine. Later in the course of treatment, symptomatic bradycardia may require discontinuation of dexmedetomidine and may take several hours to resolve because of the drug's prolonged clearance time. Patients sedated with dexmedetomidine at sedative doses are usually arousable and alert when stimulated.

Dosing of dexmedetomidine is very individualized and should be titrated to the desired effects. Weaning should be accomplished by downward titration so that the patient becomes more alert slowly. Acute agitation is best managed with small doses of intravenous benzodiazepines such as midazolam. Patients receiving infusions of dexmedetomidine should receive smaller initial doses of sedatives and narcotics, as these agents' effects tend to be increased in the presence of the dexmedetomidine.

Propofol

Propofol is a general anesthetic. In addition to its use in the operating room for induction and maintenance of anesthesia, this agent is employed as a sedative in mechanically ventilated patients. It provides both anesthetic and amnesic effects that begin, on average, 30 seconds following bolus administration (range, 9 to 51 seconds), with these effects then lasting from 3 to 10 minutes depending on dosing. This very short duration of action is one of the primary advantages of propofol over other sedatives, as it allows for rapid awakening and assessment of the patient.

For sedation in the mechanically ventilated critical care patient, usual propofol doses range from 5 to 50 µg/kg/min to a maximum of 100 µg/kg/min at some institutions. Titration upward and downward is usually done every 5 minutes in increments of 5 to 10 µg/kg/min. When higher doses are required, an additional infusion of a narcotic analgesic may significantly lower the propofol requirements. Bolus dosing, when permitted and necessary for acute agitation, is usually given in 25- to 50-mg increments in a typical adult.

Propofol is formulated in a 1% fat emulsion (10 mg/mL). The lipid base increases the potential for microorganism growth in the solution. Tubing should be changed at 12-hour intervals to lessen this risk, and propofol should not be infused with blood or plasma. Propofol may cause pain on injection into peripheral vessels. Injection-site pain can be lessened by using larger veins of the upper arm or antecubital fossa or by pretreatment with 1 mL of a 1% lidocaine solution.

Close and careful cardiopulmonary monitoring is necessary when using propofol. The most significant cardiac effect of propofol is hypotension, which can be more pronounced in patients who are hypovolemic. Hypotension is also dose related and occurs more frequently with bolus dosing and in patients who are receiving other sedatives or narcotics. Dosing should be titrated to individual effect, with continuous monitoring of the level of sedation. Abrupt discontinuation can result in rapid awakening and acute agitation; to avoid this outcome, the infusion should be titrated to allow for slow awakening. Propofol effects may be more pronounced in patients who are frail or elderly.

Propofol is generally intended for short-term use (less than 48 hours). Both prolonged and high-dose infusions have been associated with **propofol-related infusion syndrome (PRIS)**, a constellation of symptoms including arrhythmias (bradycardia), metabolic acidosis, hyperkalemia, rhabdomyolysis or creatine phosphokinase elevations, and progressive renal and cardiac failure. Mortality from PRIS is high, with estimates of 33% to 66%. When propofol is used for more than

48 hours, especially at doses exceeding 50 µg/kg/min, serum triglyceride levels should be monitored every 3 to 7 days.

Etomidate

Etomidate is an ultra-short-acting general anesthetic used for procedural sedation, induction of general anesthesia, and intubation. Its ultra-short duration of action and favorable side-effect profile make it a popular choice for rapid sequence and emergent intubations. Compared to other induction agents, etomidate results in considerably lower incidence of hypotension. This medication depresses the reticular activating system by stimulating GABA receptors. It decreases oxygen consumption and cerebral blood flow, which may be useful in patients with increased intracranial pressure (ICP).

Administered intravenously at a dose of 0.3 mg/kg (range, 0.2 to 0.6 mg/kg) over 30 to 60 seconds, etomidate reaches its peak effect in 1 minute and provides dose-dependent anesthesia for approximately 4 to 10 minutes. This agent is highly irritating and should not be administered in smaller blood vessels. Pretreatment with lidocaine may be considered.

Other than an allergy to etomidate, there are no absolute contraindications to this medication's use in RSI. Etomidate has been associated with a high incidence of uncomfortable myoclonic muscle movements, an effect that is most apparent when this agent is used as monotherapy for procedural sedation. During RSI, myoclonus is masked by rapid administration of paralytics. Some studies had suggested etomidate was associated with adrenal suppression, leading some to reconsider its use in critically ill patients. More recent data suggest that a single etomidate dose blocks the stress-induced rise in adrenal cortisol production for 6 to 8 hours and potentially up to 24 hours in debilitated or older adult patients, but this effect has not been associated with increased mortality. In patients receiving repeated doses of etomidate who are under severe stress, corticosteroid replacement may be indicated.

Ketamine

Ketamine, a phencyclidine (PCP) derivative, is a general anesthetic that is increasingly being used on an off-label basis in the prehospital arena to provide procedural sedation and analgesia. Ketamine's pharmacodynamics make it particularly attractive for critical care and emergency situations. This agent has a rapid onset of action, produces a dose-dependent profound anesthetic or dissociative state, results in bronchodilation, causes little to no respiratory depression or loss of gag reflex, and tends to increase (rather than lower) blood pressure. In addition to its utility for analgesia and procedural sedation of entrapped patients, ketamine has recently shown promise in rapid sedation of patients exhibiting signs and symptoms of excited delirium syndrome (ExDS). Anesthesia providers may use ketamine in concert with propofol, which at low doses may also allow sedation without intubation. The mixture of ketamine and propofol, nicknamed "ketofol," is commonly prepared in a syringe or given sequentially. See Chapter 25, *Bariatric, Psychiatric, and Special Situations*, for further discussion of ExDS.

Induction of general anesthesia is achieved with 1 to 4.5 mg/kg of ketamine when given intravenously or with 6.5 to 13 mg/kg when given intramuscularly. For procedural sedation (pacing, extrication, cardioversion, ExDS, fracture management), 0.2 to 0.8 mg/kg is the recommended IV or IO dose, or 2 to 4 mg/kg intramuscularly. IV or IO doses should be administered over at least 60 seconds, as rapid administration tends to be associated with respiratory depression, apnea, and unusually high spikes in blood pressure. Some references suggest administration of IV ketamine over 2 to 3 minutes. Laryngospasm is a rare adverse reaction that has been reported with use of this medication.

Anesthetic doses of ketamine given intravenously take effect within 30 seconds and last for 5 to 10 minutes, with full recovery occurring within 1 to 2 hours. IM administration takes effect in 3 to 4 minutes, with the action lasting 12 to 25 minutes and full recovery occurring in 3 to 4 hours. Despite the significant anesthetic effect, ketamine leaves the patient with near-normal pharyngeal and laryngeal reflexes and normal to slightly enhanced skeletal muscle tone, though it sometimes results in transient respiratory depression or episodic apnea. Enhanced skeletal muscle tone in some patients may appear as tonic-clonic movements and be mistaken for seizures. In reality, these movements do not imply an emergence from anesthesia or a need for additional medications. Nystagmus is a common finding in patients dissociated with ketamine.

Ketamine elevates heart rate and blood pressure starting shortly after injection, but these vital signs typically return to preadministration values within 15 minutes. Systolic and diastolic blood pressure may increase as well. Ketamine also results in bronchodilation, increased cerebral blood flow and metabolism, and increased salivary secretions. Anesthesia providers may premedicate patients with atropine (0.4 to 0.6 mg given intravenously 30 to 60 minutes before induction) to reduce salivary secretions.

Emergence from a ketamine-induced anesthetic state may result in tachycardia, a rise in blood pressure, nystagmus, and attempts at swallowing. Return to consciousness is usually gradual.

When other sedatives or narcotics are coadministered, lower doses of ketamine are needed to achieve the desired effects, and the risk of apnea increases. These risks are particularly concerning for patients who fail to receive sufficient analgesia from multiple doses of narcotics prior to escalating to ketamine.

For analgesia, ketamine doses of 0.1 to 0.3 mg/kg IV are commonly recommended. Intranasal dosing for acute pain management using 0.5 to 1 mg/kg of ketamine, repeated if necessary using 0.25 to 0.5 mg/kg after 10 to 15 minutes, can be used when IV access is not available.

Ketamine’s label carries a warning about emergence reactions, which appear as the patient emerges from the effects of ketamine sedation. Such emergence reactions, which occur in approximately 12% of patients, comprise psychological manifestations that vary from pleasant dreamlike states, to vivid images and hallucinations, to delirium. They may be associated with confusion, excitement, or irrational behavior, and usually last for only a few hours. Rarely, emergence reactions may recur up to 24 hours later. There is a markedly lower incidence of emergence reactions in patients younger than 15 years and in those older than 65 years. Administration of a benzodiazepine, such as midazolam, diazepam, or lorazepam, in conjunction with ketamine also reduces emergence reactions. Acute emergence reactions should be treated with benzodiazepines.

Clinicians experienced in the use of ketamine for procedural sedation suggest that emergence reactions may be directly influenced by the environment. Informing the patient ahead of time about the expected side effects and ensuring a calm, quiet environment may decrease patient agitation and unpleasant side effects. As ketamine may transiently precipitate symptoms resembling schizophrenia (psychosis), it should be used with caution in patients with schizophrenia. It is not recommended for routine use.

Haloperidol

Haloperidol is an antipsychotic medication that is used in the treatment of delirium and agitation in the critical care setting. Administration of this agent via the IV route is common practice, but is considered an off-label route. For critical care patients with delirium and severe agitation (or escalating agitation that is expected to become severe), haloperidol is administered intravenously at doses ranging from 0.5 to 10 mg, with doubling of the initial dose every 15 to 30 minutes until the patient is calm, and then 25% of the bolus dose being administered every 6 hours as maintenance. Some literature suggests maximum doses greater than 40 mg/d offer no added clinical benefits. In practice, many clinicians find that patients who fail to become calm with several doses of haloperidol do respond to a benzodiazepine.

Haloperidol can be given intramuscularly when IV access is not available. In such cases, this agent is often combined with a benzodiazepine such as lorazepam and sometimes with an antihistamine such as diphenhydramine. The combined effects of these therapies are usually significantly sedating. Additionally, diphenhydramine or benztropine may be used as a prophylactic anticholinergic agent to ameliorate extrapyramidal symptoms when coadministered with haloperidol.

Intravenous haloperidol can result in hypotension. QTc prolongation may occur, especially when given IV. Numerous studies in critically ill patients who were given IV haloperidol have demonstrated that, while QTc prolongation does occur, it is rarely associated with ventricular arrhythmias in patients without preexisting cardiac channel disorders.

Olanzapine

Olanzapine is an atypical antipsychotic used to treat delirium and severe agitation in the critical care environment. While available in a short-acting intramuscular injectable form, the preferred form for administration in the CCT environment is an oral disintegrating tablet; this tablet dissolves rapidly in saliva and can be easily swallowed with or without liquids.

The usual IM adult dose of olanzapine is 5 to 10 mg. A repeat dose may be given 2 hours later, if needed, and a third dose given 4 hours after the second, if needed. The maximum daily adult dose is 30 mg. Parenteral olanzapine and benzodiazepines should not be given together, as their coadministration has been linked with increased mortality.

Quetiapine

Quetiapine is an atypical antipsychotic that is used off-label to treat delirium, confusion, and insomnia in patients in the ICU. Initial dosing is 25 to 50 mg given orally two or three times daily. The dose can be adjusted upward daily to a maximum of 400 mg/d. Compared to other antipsychotics, many intensivists find quetiapine to be the most efficacious agent for ICU delirium. Unfortunately, quetiapine is available in oral form only, limiting its use in uncooperative patients.

Fentanyl

Fentanyl is a potent, synthetic opioid analgesic with a rapid onset and short duration of action. This agent is 70 to 100 times more potent than morphine; that is, 10 mg of morphine is equivalent to 100 to 150 µg of fentanyl. Fentanyl is an analgesic that is also used for procedural sedation in intubated critical care patients. Prehospital providers often administer fentanyl intranasally as an analgesic or for procedural sedation.

Typical adult dosing of fentanyl for analgesia or sedation includes a dose of 50 to 100 µg administered intravenously over 1 to 3 minutes, followed by an infusion starting at 25 µg/h. Incremental dose changes are typically made in steps of 8 to 10 µg/h, implemented every 5 minutes. Alternatively, weight-based dosing of 0.7 to 10 µg/kg/h can be used. Usual infusion dose ranges for adults vary between 25 and 125 µg/h, up to a maximum of 200 µg/h, although some studies report employing doses of as high as 700 µg/h. When fentanyl is given at a dose of 0.5 to 2 µg/kg, the patient will experience analgesia within about 90 seconds, with an effective duration lasting approximately 30 minutes.

Rapid administration of fentanyl and single IV doses exceeding 150 µg in adults have (rarely) been associated with rigid chest wall syndrome. This chest wall rigidity interferes with ventilation and necessitates immediate treatment with naloxone or a short-acting neuromuscular-blocking agent; either option will facilitate adequate ventilation. The occurrence of chest wall rigidity does not appear to be a contraindication to later use of fentanyl or other opioids.

Fentanyl has minimal cardiovascular effects, although bradycardia, tachycardia, and arrhythmias have been reported with its use. Hypotension is also possible, especially when sympathetic stimulation from pain is artificially producing an increased blood pressure in the patient. Consequently, it is common for patients' hemodynamic, CNS, and respiratory status to decline when painful stimulation is suddenly eliminated by opioid medications.

Sufentanil

Sufentanil is similar to fentanyl, with significant analgesic effects and minimal cardiovascular effects. Sufentanil, however, is 10 times more potent than fentanyl; that is, 100 µg of fentanyl is equivalent to 10 µg of sufentanil. Sufentanil also has a shorter half-life than fentanyl, which makes it an ideal choice for use in surgical settings. CCTPs may encounter patients receiving sufentanil in postoperative ICU settings.

Sufentanil bolus and infusion doses are based on the anticipated duration of surgery. Doses range from 1 to 8 µg/kg prior to surgery, followed by maintenance doses up to 1.5 μg/kg/h.

As is true for other opioid agonists, patients with compromised respiratory systems should not receive sufentanil unless their airway and ventilations can be supported. The adverse reactions observed with this agent are similar to those seen with fentanyl, including chest wall rigidity, cardiac arrhythmias, and respiratory depression.

Morphine

Morphine is an opioid receptor agonist that acts directly on the CNS to produce analgesia. It is used as an analgesic in the critical care environment.

Usual doses of morphine vary widely, depending on the patient. Notably, IV doses are two to three times more potent than the same doses taken orally. Morphine should be diluted and bolus doses administered over 3 to 5 minutes to reduce side effects of nausea and vomiting, hypotension, and respiratory depression. An initial loading dose of 5 to 10 mg of morphine can be given over 3 to 5 minutes. Infusions are typically mixed as a concentration of 1 mg/mL and initiated in adults at 2 mg/h. Upward titration can be done hourly in increments of 2 mg/h. Additional bolus doses of 2 to 5 mg can be given as needed until the patient is comfortable. Due to the longer half-life and safer opioid infusion alternatives, morphine infusions are most commonly used during palliative care in hospital settings. However, morphine is also used during patient-controlled analgesia infusions.

Patients frequently report flushing or an itchy feeling when they receive morphine, which is sometimes mistaken for an allergic reaction. The actual cause is morphine-induced histamine release, which leads to vasodilation and rather bothersome incidence of pruritus. Treatment options for these side effects are limited. Typically, antihistamines are used to manage the itching, although their use often results in additional sedative effects. Low doses of IV nalbuphine may be used to relieve opioid-induced pruritus. Low-dose and continuous low-dose infusions of naloxone have also been shown to produce positive results, but are less effective than antihistamines and may reverse the opioid effect and precipitate withdrawal. Another option for patients with significant histamine-related effects from morphine is a change to fentanyl, whose use results in considerably less, if any, histamine release.

Hydromorphone

Hydromorphone is an opioid analgesic used in the management of moderate to severe pain. It is used when the patient does not obtain relief from morphine or fentanyl.

Dosing of hydromorphone to achieve relief from pain varies widely among patients. The IV doses are two to four times more potent than equal doses taken orally. Compared to the effects achieved with IV morphine, 1 mg of hydromorphone is equivalent to 7 mg of morphine.

Usual adult dosing of hydromorphone is 0.4 to 0.8 mg given intravenously over 3 to 5 minutes, repeated every 2 to 6 hours as needed. Rarely, hydromorphone infusion may be required, starting at 0.5 mg/h and titrated upward every hour in increments of 0.3 mg/h. Like morphine, hydromorphone is often used in patient-controlled analgesia infusions.

Nalbuphine

Nalbuphine is an opioid agonist-antagonist that is typically given at a dose of 10 mg (IV, IM, or subcutaneous) every 3 to 6 hours. While not commonly used as an analgesic in critical care, its agonist-antagonist properties make nalbuphine useful in relieving opioid-induced pruritus. This off-label use is dosed intravenously at 2.5 to 5 mg IV, repeated as needed.

Acetaminophen

Acetaminophen is an analgesic and antipyretic. It is commonly used and available as an over-the-counter product in oral and rectal forms. Intravenous acetaminophen was approved by the FDA in 2010.

The actual mechanism of action of acetaminophen is poorly understood. This medication remains a common cause of drug-induced liver failure in the United States. Maximum daily doses of acetaminophen should not exceed 4 g in healthy adults, and patients with hepatic insufficiency and those who consume more than three alcoholic drinks daily are susceptible to liver damage at daily intake exceeding 2 g. The CCTP should be aware that combination pain medications may contain acetaminophen.

Adult oral acetaminophen doses range from 325 to 650 mg every 4 to 6 hours. Pills or tablets can be crushed and administered through a feeding tube. The maximum single oral dose is 1,000 mg. Adult rectal doses also range from 325 to 650 mg every 4 to 6 hours.

The cost of IV acetaminophen has led most hospital formulary committees to restrict its use to patients who are unable to receive enteral or rectal doses. When given intravenously, dosing is similar to oral doses.

Ketorolac

Ketorolac is a nonsteroidal anti-inflammatory drug (NSAID) used for pain management. The natural reaction to injury or infection in the body is to promote inflammation in the areas involved, in an effort to build up the body's defenses against the invader and to rebuild cell populations. This inflammation-promotion activity is carried out by prostaglandins, which also play a role in fever and platelet activity. Prostaglandins are created by an enzyme found in the cells called cyclooxygenase (COX). NSAIDs such as ketorolac work by blocking the COX enzymes, thereby decreasing the body's load of inflammation-causing prostaglandins.

In the critical care setting, ketorolac is most often administered intravenously. The usual IV dose for adults is 15 to 30 mg given every 6 hours. In critically ill patients, patients older than 65 years, and patients with renal insufficiency, the IV dose is often reduced or not given at all. IV doses should be administered over a minimum of 15 seconds.

Ketorolac should not be used for more than 5 days, regardless of the route of administration. Multiple concerns have arisen related to this agent's adverse effects. Ketorolac inhibits platelet function, which increases the risk of gastrointestinal bleeding, surgical bleeding, and bleeding from all other causes. It also carries an increased risk of thrombotic cardiovascular events, including stroke and myocardial infarction, as do many other NSAIDs; this risk is both dose and duration dependent. Ketorolac may compromise renal function, especially in patients with volume depletion. In addition, this drug should not be used in patients in labor.

Levetiracetam

Levetiracetam is an anticonvulsant. Following immediate treatment with a short-acting benzodiazepine, this agent may be considered for treatment of status epilepticus. A recent large multicenter trial found that levetiracetam, fosphenytoin, and valproate were similarly efficacious in treatment of established status epilepticus.

For status epilepticus, levetiracetam is given intravenously, with the recommended adult dose range being 1,000 to 4,500 mg, infused at a rate of 2 to 5 mg/kg/min. Pediatric dosing is 20 to 60 mg/kg. Levetiracetam may also be used to prevent seizures following significant brain injury. Dosing for seizure prophylaxis in adults is 1,000 mg given intravenously every 12 hours; for children, it is 15 to 25 mg/kg every 12 hours.

Phenytoin

Phenytoin is an anticonvulsant medication. In the critical care setting, it is used after short-acting benzodiazepines for treatment of status epilepticus. The initial IV dosing is 20 mg/kg, infused at a rate no faster than 50 mg/min. An additional dose of 5 to 10 mg/kg can be administered, if needed, 10 minutes after completion of the initial loading dose.

Phenytoin should not be given to patients with cardiac arrhythmias, including atrioventricular (AV) blocks and bradycardia. This agent can itself cause cardiac arrhythmias, including ventricular fibrillation and AV conduction abnormalities, and can lead to significant hypotension. Often, hypotension is related to the speed of administration. Even with slow administration, however, pressors may be required to counteract the negative cardiac effects.

Of note, phenytoin is compatible with only saline; it will precipitate if mixed with dextrose or other IV solutions. It may also cause significant tissue necrosis if extravasated. Extravasation of IV phenytoin causes “purple glove syndrome,” which has required limb amputation in severe situations.

When possible, phenytoin should be administered through a central line. It should not be administered through smaller peripheral veins of the hands or feet. This agent cannot be given as an intramuscular injection.

Oral phenytoin loading is much safer than administration of IV phenytoin and should be contemplated for conscious, stable, low-risk patients. Oral loading will take approximately 6 hours to reach a therapeutic plasma level. Dosing should be considered carefully when patients who are already taking phenytoin present following a seizure with a subtherapeutic plasma phenytoin level.

Fosphenytoin

Fosphenytoin is a precursor to phenytoin; when metabolized, it yields phenytoin. This agent is designed to be modified by the body (biotransformed) into phenytoin, which makes it a **prodrug** of phenytoin. Because it transforms into phenytoin, the dose is documented as milligrams of phenytoin equivalents (PE). For status epilepticus, the IV dose of fosphenytoin is 20 mg PE/kg, administered at rates of up to 150 mg PE/min. If needed, a second dose of 5 mg PE/kg can be administered 10 minutes after completion of the initial loading dose.

Fosphenytoin is compatible with saline, dextrose, and lactated Ringer solutions and can be administered as an intramuscular injection. Dose volumes of up to 20 mL per injection site have been reported.

Valproic Acid

Valproic acid is an anticonvulsant that is used to treat benzodiazepine-resistant status epilepticus. IV dosing for adults is 20 to 40 mg/kg administered at a rate of 3 to 6 mg/kg/min (typically, over a minimum of 5 minutes). If needed, a second dose of 20 mg/kg can be administered 10 minutes after completing the loading infusion. In studies where more rapid infusion rates were used, they seemed to be well tolerated. The loading doses may be followed by a continuous infusion of 1 to 4 mg/kg/h for 24 hours. Liver enzymes and serum ammonia levels should be monitored during treatment with valproic acid. In addition, valproic acid may prolong bleeding times.

Seizures are not the only indication for valproic acid. Indeed, this drug is prescribed for a wide range of other conditions, including migraine headaches, bipolar disorder, neuropathic pain syndromes, diabetic neuropathy, postherpetic neuralgia, and borderline personality disorder.

Pentobarbital

Pentobarbital is a short-acting hypnotic barbiturate and an anticonvulsant. Prior to the advent of many newer sedatives with more favorable side-effect profiles, it was used as a sedative for acutely agitated patients. Today, pentobarbital is more commonly employed to induce a barbiturate coma in severely brain-injured patients with elevated ICP as well as to treat refractory status epilepticus. Patients should be intubated prior to administration of this treatment for status epilepticus or traumatic brain injury, as IV pentobarbital can induce significant respiratory depression as well as laryngospasm. Hypotension requiring pressor support is also commonly seen with the high doses needed to induce a pentobarbital coma. The onset of action with IV pentobarbital typically occurs within 1 minute of its administration.

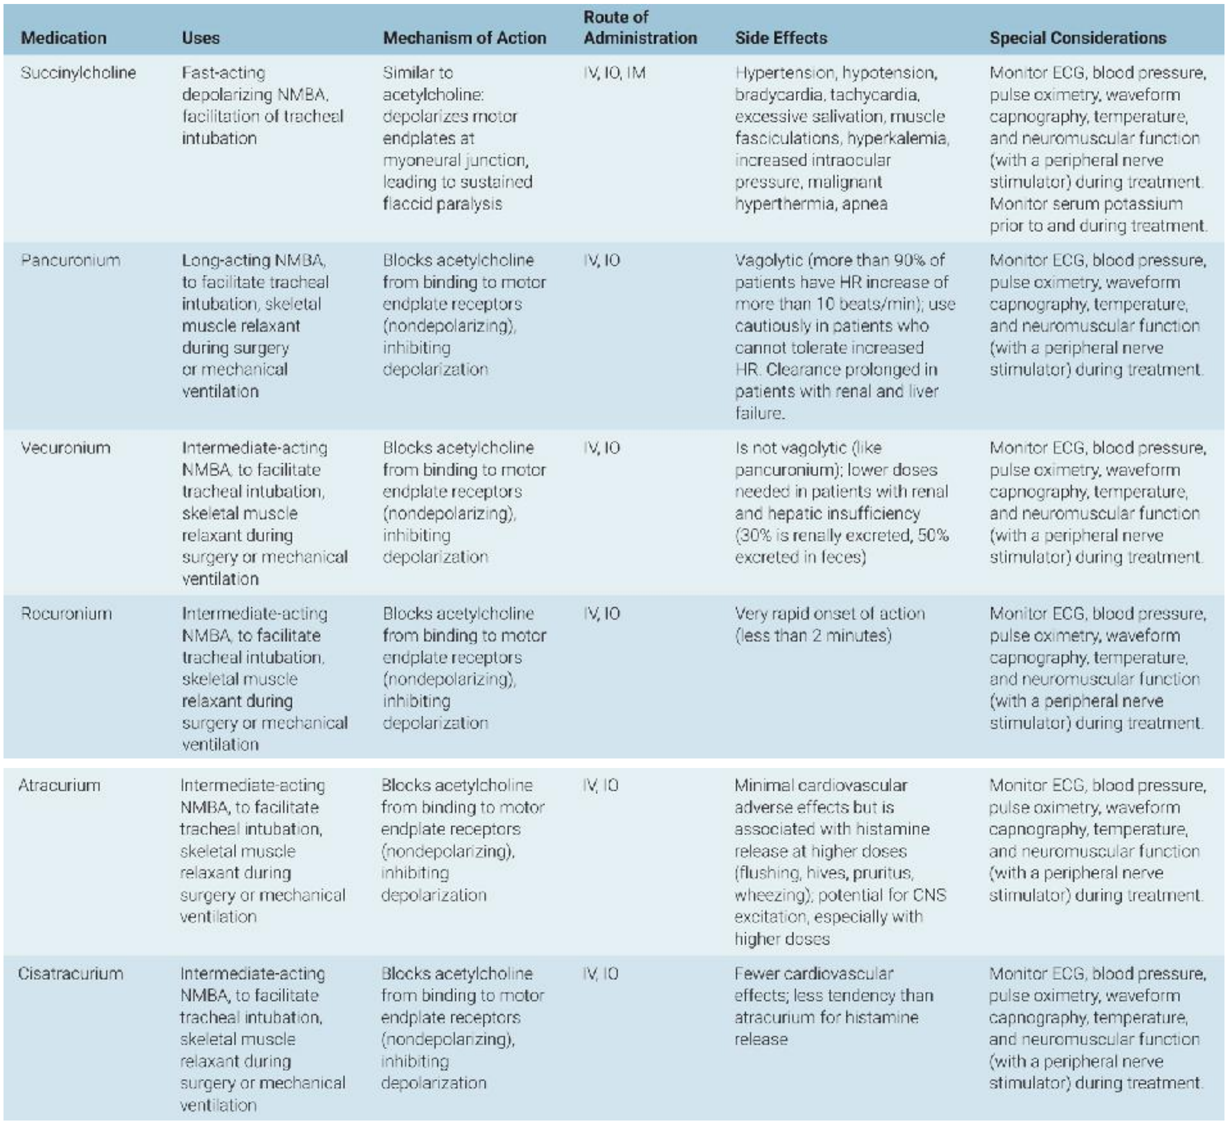
When pentobarbital is used to treat refractory status epilepticus, the loading dose is 5 to 15 mg/kg administered intravenously at a rate no greater than 50 mg/min. This loading dose can be repeated once and is followed by an infusion of 0.5 to 5 mg/kg/h, titrated to electroencephalogram monitoring. Breakthrough seizures are treated with additional boluses of 5 mg/kg and increases in the continuous infusion of 0.5 to 1 mg/kg/h at 12-hour intervals.

As with most barbiturate medications, quick cessation of pentobarbital’s use should be avoided, as it can lead to dangerous withdrawal symptoms—most notably, a return of status epilepticus. Additional withdrawal symptoms may include restlessness, insomnia, nausea, vomiting, diarrhea, diaphoresis, tachycardia, hyperthermia, hallucinations, delirium, and death.

Neuromuscular-Blocking Agents

Neuromuscular-blocking agents (NMBAs) block transmission of neuromuscular signals, resulting in skeletal muscle paralysis. The most common indication in the critical care setting for NMBAs is facilitation of endotracheal intubation. Because NMBAs induce paralysis of respiratory muscles, continuous waveform capnography must be used whenever administering any NMBA. **TABLE 8-7** profiles selected NMBAs.

TABLE 8-7 Neuromuscular-Blocking Agents



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Succinylcholine	Fast-acting depolarizing NMBA, facilitation of tracheal intubation	Similar to acetylcholine: depolarizes motor endplates at myoneural junction, leading to sustained flaccid paralysis	IV, IO, IM	Hypertension, hypotension, bradycardia, tachycardia, excessive salivation, muscle fasciculations, hyperkalemia, increased intraocular pressure, malignant hyperthermia, apnea	Monitor ECG, blood pressure, pulse oximetry, waveform capnography, temperature, and neuromuscular function (with a peripheral nerve stimulator) during treatment. Monitor serum potassium prior to and during treatment.
Pancuronium	Long-acting NMBA, to facilitate tracheal intubation, skeletal muscle relaxant during surgery or mechanical ventilation	Blocks acetylcholine from binding to motor endplate receptors (nondepolarizing), inhibiting depolarization	IV, IO	Vagolytic (more than 90% of patients have HR increase of more than 10 beats/min); use cautiously in patients who cannot tolerate increased HR. Clearance prolonged in patients with renal and liver failure.	Monitor ECG, blood pressure, pulse oximetry, waveform capnography, temperature, and neuromuscular function (with a peripheral nerve stimulator) during treatment.
Vecuronium	Intermediate-acting NMBA, to facilitate tracheal intubation, skeletal muscle relaxant during surgery or mechanical ventilation	Blocks acetylcholine from binding to motor endplate receptors (nondepolarizing), inhibiting depolarization	IV, IO	Is not vagolytic (like pancuronium); lower doses needed in patients with renal and hepatic insufficiency (30% is renally excreted, 50% excreted in feces)	Monitor ECG, blood pressure, pulse oximetry, waveform capnography, temperature, and neuromuscular function (with a peripheral nerve stimulator) during treatment.
Rocuronium	Intermediate-acting NMBA, to facilitate tracheal intubation, skeletal muscle relaxant during surgery or mechanical ventilation	Blocks acetylcholine from binding to motor endplate receptors (nondepolarizing), inhibiting depolarization	IV, IO	Very rapid onset of action (less than 2 minutes)	Monitor ECG, blood pressure, pulse oximetry, waveform capnography, temperature, and neuromuscular function (with a peripheral nerve stimulator) during treatment.
Atracurium	Intermediate-acting NMBA, to facilitate tracheal intubation, skeletal muscle relaxant during surgery or mechanical ventilation	Blocks acetylcholine from binding to motor endplate receptors (nondepolarizing), inhibiting depolarization	IV, IO	Minimal cardiovascular adverse effects but is associated with histamine release at higher doses (flushing, hives, pruritus, wheezing); potential for CNS excitation, especially with higher doses	Monitor ECG, blood pressure, pulse oximetry, waveform capnography, temperature, and neuromuscular function (with a peripheral nerve stimulator) during treatment.
Cisatracurium	Intermediate-acting NMBA, to facilitate tracheal intubation, skeletal muscle relaxant during surgery or mechanical ventilation	Blocks acetylcholine from binding to motor endplate receptors (nondepolarizing), inhibiting depolarization	IV, IO	Fewer cardiovascular effects; less tendency than atracurium for histamine release	Monitor ECG, blood pressure, pulse oximetry, waveform capnography, temperature, and neuromuscular function (with a peripheral nerve stimulator) during treatment.

Abbreviations: CNS, central nervous system; ECG, electrocardiogram; HR, heart rate; IM, intramuscular; IO, intraosseous; IV, intravenous; NMBA, neuromuscular-blocking agent

Description

Long-term chemical paralysis of the patient has serious implications for CCTPs and other health care providers who will care for the patient. Muscle weakness and neuropathies can persist long after the patient has been weaned off paralytic medications. These conditions can impair ventilator weaning, prolong ICU admissions, and further compromise patient recovery. It is essential that patients receive paralytics only for the shortest duration and in the lowest possible dose.

Intensive care providers can use a train-of-four (TOF) measurement, post-tetanic count, or double-burst stimulation to assess for the correct level of neuromuscular blockade in patients receiving NMBAs. Special instruction is required so that CCTPs can perform or interpret these tests. Proper use of NMBAs can help prevent excessive dosing of paralytic medications, which will minimize the risk and severity of long-term complications.

TOF and other paralytic monitoring do not reflect the underlying level of sedation and analgesia in chemically paralyzed patients. For this reason, it is imperative that CCTPs and other health care providers carefully evaluate the level of sedation and analgesia in any patient who is chemically paralyzed. In many patients, but especially those with unstable hemodynamics, assessment of sedation and analgesia using vital signs is unreliable. Conversely, it is common for hypertension and tachycardia to be incorrectly treated with vasoactive medications when the underlying cause is actually undersedation or pain. Unfortunately, inadequate sedation and analgesia in chemically paralyzed patients is commonplace in intensive care and CCT settings. CCTPs must take careful steps to avoid undertreating agitation and pain in any patient whom they transport, especially if the patient is paralyzed. Awareness during paralysis has been linked with poor patient outcomes and posttraumatic stress disorder.

Train-of-Four

Train-of-four (TOF) stimulation delivers an electrical impulse to a relevant nerve, allowing a trained observer to assess the level of muscle contraction and thereby estimate NMBA effects. The TOF monitor is a peripheral nerve stimulator capable of delivering a 0- to 80-mA current to the ulnar, facial, or (least commonly) posterior tibial nerve. With the two electrodes properly placed on the skin, pressing the TOF button sends four serial 0.2-ms pulses, spaced 500 ms apart. The number of twitches observed corresponds to the percentage of muscle receptors under NMBA blockade. No twitches suggests 100% of receptors are blocked; one twitch corresponds to 90% blocked; two twitches, 80% blocked; three twitches, 75% blocked; and four twitches, 0% to 75% blocked. Ulnar stimulation causes twitching of the thumb **FIGURE 8-2**, facial stimulation results in twitching of the eyebrow, and posterior tibial stimulation causes plantar flexion of the great (large) toe.

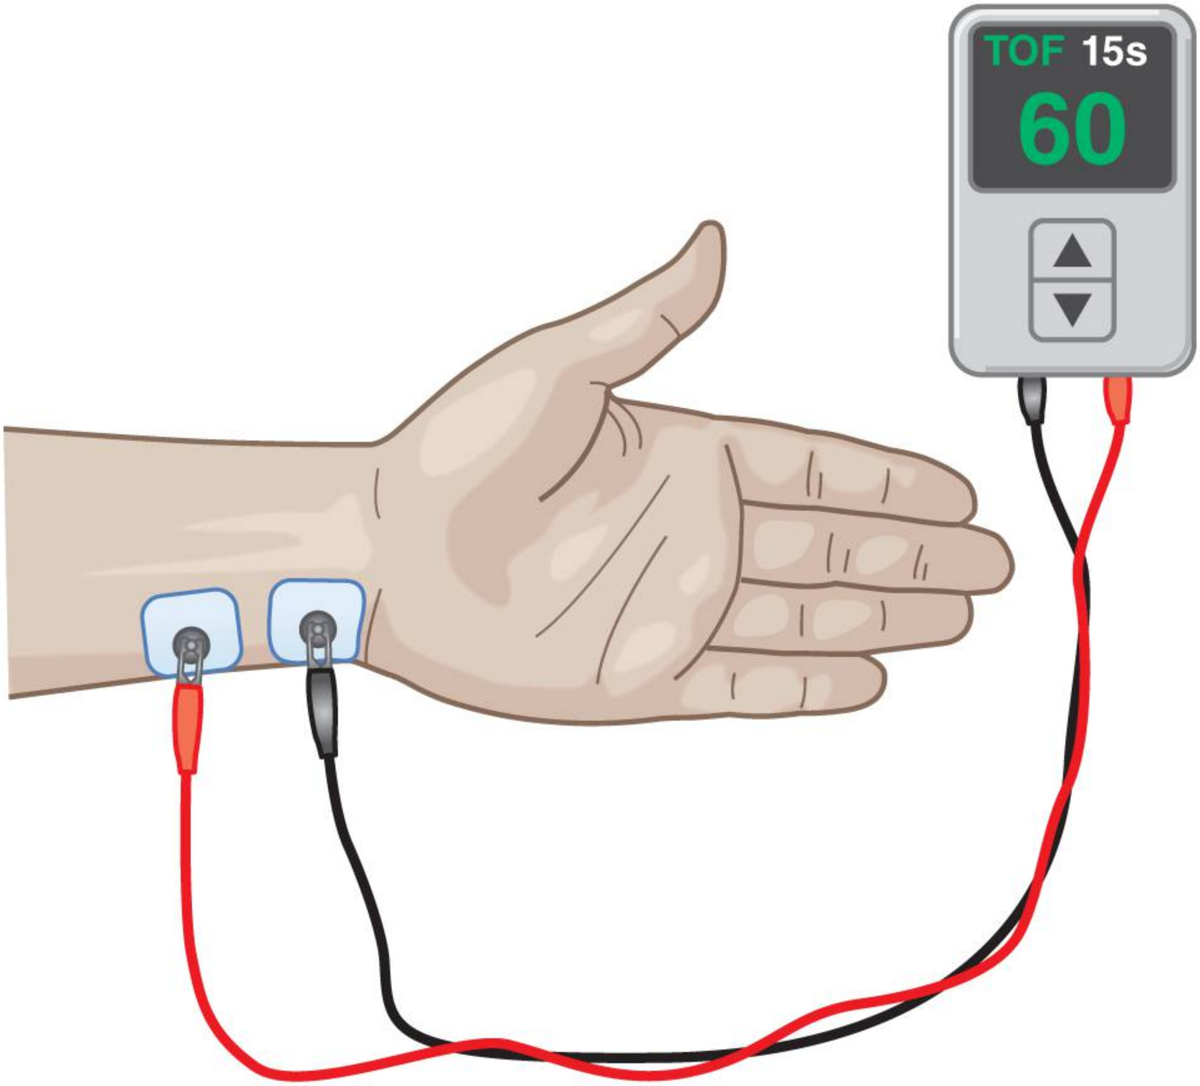

FIGURE 8-2 Train-of-four stimulation of the ulnar nerve causes twitching of the thumb.

Description

Succinylcholine

Succinylcholine is the only **depolarizing paralytic** agent in widespread use. Depolarizing paralytics act as agonists at **nicotinic receptors**, mimicking the activity of acetylcholine. **Acetylcholine**

(ACh) is the neurotransmitter that bridges the synapse at the neuromuscular junction. An influx of calcium in the nerves stimulates the release of ACh, which moves across the synapse and binds with the nicotinic receptors on the muscle cells. When ACh makes that connection, depolarization of the muscle takes place and the intended movement or action occurs. Paralytic medications are grouped into one of two categories depending on how they interact with ACh and the nicotinic receptors: *depolarizing* or *nondepolarizing*. Succinylcholine stimulates muscle depolarization but then remains bound to the receptor, thereby preventing it from repolarizing and being triggered again.

In addition to exhibiting activity at nicotinic receptors, succinylcholine stimulates cardiac muscarinic receptors, leading to bradycardia, especially in children. At a dose of 1 to 1.5 mg/kg, patients will experience muscle relaxation in approximately 30 seconds, with total paralysis occurring in about 45 seconds. This rapid onset time, coupled with its duration of action of 4 to 6 minutes, makes succinylcholine an ideal paralytic agent for medication-assisted airway management.

Succinylcholine may increase serum potassium levels, which can cause significant problems in the presence of chronic or acute conditions in which potassium levels may already be elevated. Acute injuries such as crush injuries and spinal cord injuries should be treated with alternative medications, if available. Patients with chronic conditions associated with hyperkalemia, such as renal failure, should also receive an alternative medication.

Succinylcholine can cause a transient increase in ICP. Although the increased ICP from laryngoscopy is of greater concern, this medication-induced ICP must be considered and accounted for in cases of closed head injury.

The most common side effect of succinylcholine is muscle fasciculations, a twitching activity seen as muscles depolarize. Although the twitching may not appear overly dramatic, care should be taken to ensure the patient does not experience injury or inadvertently dislodge IV lines. Some RSI protocols include a reduced dose of a nondepolarizing muscle relaxer that is administered prior to succinylcholine to reduce these fasciculations.

Succinylcholine can cause malignant hyperthermia and, therefore, is contraindicated in patients who have a personal or family history of this condition. (See Chapter 21, *Toxicologic Emergencies*.) Also, providers should expect succinylcholine to have a much longer than normal duration of action when it is administered to any patient who has been exposed to acetylcholinesterase inhibitors, including those found in chemical nerve agents and pesticides. This extended activity is the result of inhibition of acetylcholinesterase, the enzyme that breaks down ACh. A nondepolarizing muscle relaxer may be preferred in these situations. Malignant hyperthermia is discussed in greater depth in Chapter 21, *Toxicologic Emergencies*.

Pancuronium

Pancuronium is a nondepolarizing neuromuscular-blocking agent. A **nondepolarizing agent** works by competitively antagonizing ACh at the postsynaptic receptors. As a consequence, ACh is unable to cause stimulation at these sites, and muscle depolarization cannot occur. Overall, the major drawback in using nondepolarizing medications is that they tend to have a slower onset of action and longer duration compared to succinylcholine.

Pancuronium is administered as an IV bolus of 0.06 to 0.1 mg/kg, followed by a continuous infusion of 0.8 to 1.7 μg/kg/min (0.048 to 0.102 mg/kg/h). The onset of effect with pancuronium is rapid, occurring within 3 to 5 minutes from administration. While the duration of effect is dose dependent, a typical loading dose will last for about 60 minutes in adults.

Pancuronium must be refrigerated, but is stable at room temperature for as long as 6 months. It can be administered in an undiluted form by rapid IV injection. Its elimination half-life is doubled in patients with renal or hepatic impairment.

Vecuronium

Vecuronium is a nondepolarizing neuromuscular-blocking agent. Initial IV dosing for intubation purposes is 0.08 to 0.1 mg/kg. To maintain paralysis in a critical care setting, a continuous infusion of 0.8 to 1.7 µg/kg/min (0.048 to 0.102 mg/kg/h) is recommended, along with monitoring the depth of neuromuscular blockade every 1 to 2 hours. Usual maintenance infusion doses range from 0.8 to 1.2 µg/kg/min (0.048 to 0.072 mg/kg/h).

Following bolus administration, good intubating conditions occur within 2.5 to 3 minutes. The paralysis lasts for 25 to 40 minutes, with complete recovery occurring approximately 45 to 65 minutes after the initial bolus dose is given.

Vecuronium is manufactured as a powder and must be reconstituted with a compatible diluent prior to use. Vials of powder can be stored at room temperature.

Rocuronium

Rocuronium has the fastest onset time of all the nondepolarizing paralytics, taking effect at 60 to 90 seconds after its administration. It is generally administered at a dose of 0.6 to 1.2 mg/kg, and lasts for as long as 45 minutes with that dose. A higher initial dose (1 mg/kg) permits the shorter onset time needed in RSI procedures. Subsequent maintenance doses can be reduced to 0.5 mg/kg. For maintenance of paralysis, a continuous infusion of 8 to 12 µg/kg/min (0.48 to 0.72 mg/kg/h) is recommended, accompanied by regular monitoring of the depth of neuromuscular blockade.

Rocuronium can be administered in an undiluted form by rapid IV injection. It should be refrigerated when stored. If kept at room temperature, however, it is stable for 60 days.

Atracurium

Atracurium is a nondepolarizing neuromuscular-blocking agent. Initial IV dosing for intubation purposes is 0.4 to 0.5 mg/kg. To maintain paralysis in a critical care setting, a continuous infusion of 4 to 20 µg/kg/min (0.24 to 1.2 mg/kg/h) is recommended, along with monitoring the depth of neuromuscular blockade every 1 to 2 hours. The onset of action of atracurium is dose dependent but, for intubation, typically takes 2 to 3 minutes. Recovery begins 20 to 35 minutes following the initial bolus dose.

Atracurium can be administered in an undiluted form by rapid IV injection. Vials must be refrigerated.

Cisatracurium

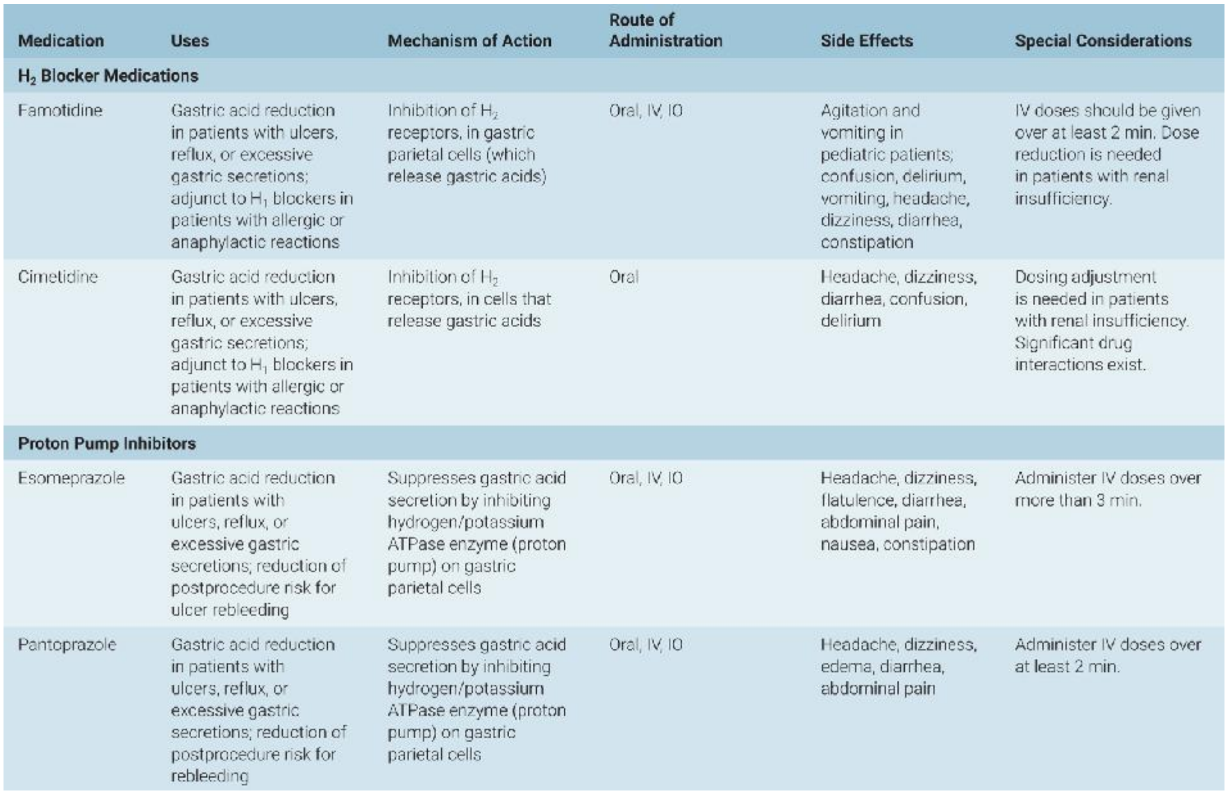
Cisatracurium is a nondepolarizing neuromuscular-blocking agent. Initial IV dosing for intubation purposes is 0.15 to 0.2 mg/kg. To maintain paralysis in a critical care setting, a continuous infusion of 1 to 3 µg/kg/min (0.06 to 0.18 mg/kg/h) is recommended, along with monitoring the depth of neuromuscular blockade every 1 to 2 hours. Usual doses range from 0.5 to 10 µg/kg/min (0.03 to 0.6 mg/kg/h). The onset of action of cisatracurium given for intubation is typically 2 to 3 minutes. Recovery begins 35 to 45 minutes following the initial bolus dose.

Cisatracurium can be administered in an undiluted form as a bolus injection over 5 to 10 seconds. Vials must be refrigerated. At room temperature, they remain stable for 21 days.

Histamine Antagonists and Proton Pump Inhibitors

Stress ulcer prophylaxis is undertaken in critically ill patients with associated risk factors such as coagulopathy, severe sepsis, or mechanical ventilation for more than 48 hours. Histamine antagonists and proton pump inhibitors (PPIs) **TABLE 8-8** are used to reduce the effects of gastric acids on the walls of the stomach and intestines. Once these risk factors are resolved, the stress ulcer prophylaxis should be discontinued.

TABLE 8-8 **Histamine Antagonists and Proton Pump Inhibitors**



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
H_2 Blocker Medications					
Famotidine	Gastric acid reduction in patients with ulcers, reflux, or excessive gastric secretions; adjunct to H_1 blockers in patients with allergic or anaphylactic reactions	Inhibition of H_2 receptors, in gastric parietal cells (which release gastric acids)	Oral, IV, IO	Agitation and vomiting in pediatric patients; confusion, delirium, vomiting, headache, dizziness, diarrhea, constipation	IV doses should be given over at least 2 min. Dose reduction is needed in patients with renal insufficiency.
Cimetidine	Gastric acid reduction in patients with ulcers, reflux, or excessive gastric secretions; adjunct to H_1 blockers in patients with allergic or anaphylactic reactions	Inhibition of H_2 receptors, in cells that release gastric acids	Oral	Headache, dizziness, diarrhea, confusion, delirium	Dosing adjustment is needed in patients with renal insufficiency. Significant drug interactions exist.
Proton Pump Inhibitors					
Esomeprazole	Gastric acid reduction in patients with ulcers, reflux, or excessive gastric secretions; reduction of postprocedure risk for ulcer rebleeding	Suppresses gastric acid secretion by inhibiting hydrogen/potassium ATPase enzyme (proton pump) on gastric parietal cells	Oral, IV, IO	Headache, dizziness, flatulence, diarrhea, abdominal pain, nausea, constipation	Administer IV doses over more than 3 min.
Pantoprazole	Gastric acid reduction in patients with ulcers, reflux, or excessive gastric secretions; reduction of postprocedure risk for rebleeding	Suppresses gastric acid secretion by inhibiting hydrogen/potassium ATPase enzyme (proton pump) on gastric parietal cells	Oral, IV, IO	Headache, dizziness, edema, diarrhea, abdominal pain	Administer IV doses over at least 2 min.

Abbreviations: ATPase, adenosine triphosphatase; H_1, histamine$_1$; H_2, histamine$_2$; IM, intramuscular; IO, intraosseous; IV, intravenous

© Jones & Bartlett Learning.

Description

Acids and enzymes are produced in the stomach by cells in the stomach lining, including the gastric parietal cells. Stimulation of these cells can occur when the histamine$_2$ (H_2) receptors on the cells are stimulated. The medications used to reduce acid production do so by antagonizing the H_2 receptors. These medications are particularly useful because they are very selective for the H_2 receptors, have no effect on histamine$_1$ (H_1) receptors, and have no anticholinergic effects. At the same time, H_2 blockers potentiate the effects of H_1 (common antihistamine) medications, which are used to treat allergic reactions and related symptoms. This additive effect is beneficial when treating anaphylaxis and other significant allergic reactions.

Some guidelines recommend the use of PPIs rather than H_2 antagonists for stress ulcer prophylaxis. PPIs suppress gastric acid secretion by inhibiting the hydrogen/potassium adenosine triphosphatase enzyme system (H^+/K^+ ATPase), also referred to as the gastric proton pump. The greater efficacy of PPIs relative to H_2 blockers has made these drugs among the most widely sold agents in the world. Studies comparing the efficacy of PPIs and H_2 antagonists in patients with active gastrointestinal bleeding have demonstrated consistent and significant reduction in rebleeding with PPIs versus H_2 antagonists.

Famotidine

Famotidine is the preferred H_2 antagonist in many intensive care units. Unlike cimetidine, it has no significant hemodynamic effects, nor does it alter hepatic drug metabolism. This favorable safety profile, combined with its profound inhibitory effect on gastric acid secretion and its dosing schedule, have made this H_2 antagonist exceedingly popular for use as an agent for stress ulcer prophylaxis. For adult patients who are unable to take oral medications or for whom famotidine cannot be given through a gastric tube, the recommended dose is 20 mg IV every 12 hours.

Cimetidine

Cimetidine is an H_2 antagonist. While it was used in the past, H_2 antagonists with safer profiles and fewer drug interactions have become more popular.

Esomeprazole

Esomeprazole is a PPI commonly used for stress ulcer prophylaxis in critically ill patients. It is administered intravenously at doses of 20 to 40 mg once daily. Aside from headache, dizziness, and some occasional gastrointestinal symptoms such as flatulence, abdominal pain, diarrhea, and nausea, esomeprazole is well tolerated.

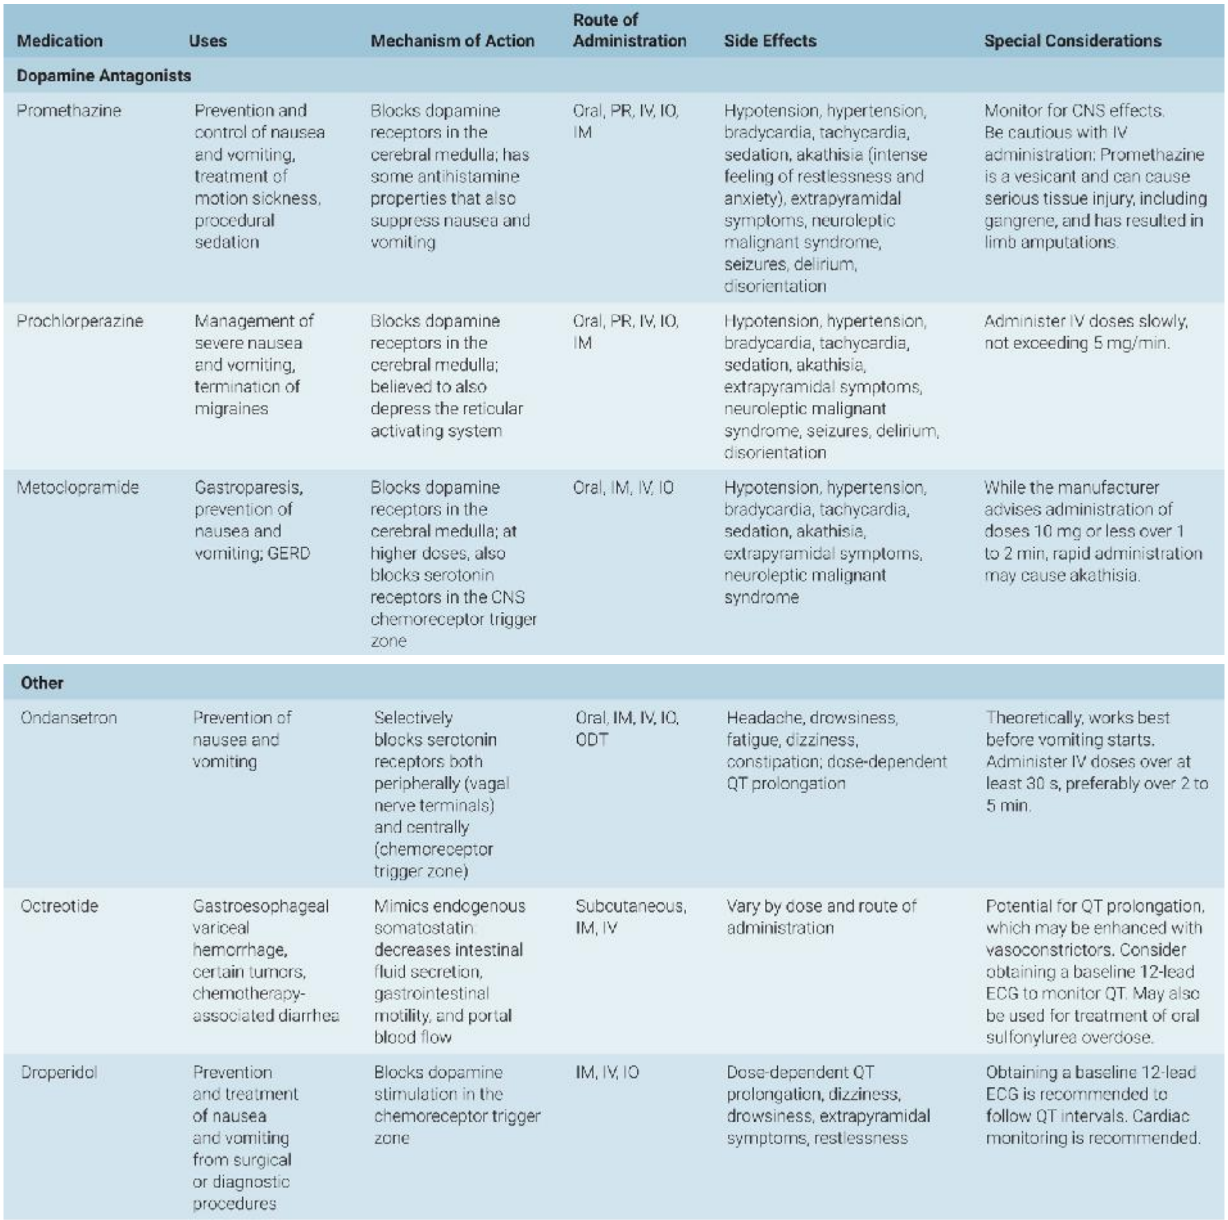
Pantoprazole

Pantoprazole is a PPI most commonly used in the critical care setting to prevent rebleeding in patients with peptic ulcer bleeds. This therapy typically consists of an IV loading dose of 80 mg, followed by a continuous infusion of 8 mg/h for 72 hours. However, recent evidence suggests that intermittent administration via a bolus (eg, 40 mg IV twice daily) is as efficacious as continuous infusion therapy. As with other PPIs, side effects of pantoprazole include headache and gastrointestinal symptoms.

Antiemetic/Gastrointestinal Medications

The general classification of antiemetic medications—that is, those medications intended to treat nausea and vomiting—encompasses several more specific categories. **TABLE 8-9** profiles selected antiemetic and other gastrointestinal medications.

TABLE 8-9 Antiemetic/Gastrointestinal Medications



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Dopamine Antagonists					
Promethazine	Prevention and control of nausea and vomiting, treatment of motion sickness, procedural sedation	Blocks dopamine receptors in the cerebral medulla; has some antihistamine properties that also suppress nausea and vomiting	Oral, PR, IV, IO, IM	Hypotension, hypertension, bradycardia, tachycardia, sedation, akathisia (intense feeling of restlessness and anxiety), extrapyramidal symptoms, neuroleptic malignant syndrome, seizures, delirium, disorientation	Monitor for CNS effects. Be cautious with IV administration: Promethazine is a vesicant and can cause serious tissue injury, including gangrene, and has resulted in limb amputations.
Prochlorperazine	Management of severe nausea and vomiting, termination of migraines	Blocks dopamine receptors in the cerebral medulla; believed to also depress the reticular activating system	Oral, PR, IV, IO, IM	Hypotension, hypertension, bradycardia, tachycardia, sedation, akathisia, extrapyramidal symptoms, neuroleptic malignant syndrome, seizures, delirium, disorientation	Administer IV doses slowly, not exceeding 5 mg/min.
Metoclopramide	Gastroparesis, prevention of nausea and vomiting; GERD	Blocks dopamine receptors in the cerebral medulla; at higher doses, also blocks serotonin receptors in the CNS chemoreceptor trigger zone	Oral, IM, IV, IO	Hypotension, hypertension, bradycardia, tachycardia, sedation, akathisia, extrapyramidal symptoms, neuroleptic malignant syndrome	While the manufacturer advises administration of doses 10 mg or less over 1 to 2 min, rapid administration may cause akathisia.
Other					
Ondansetron	Prevention of nausea and vomiting	Selectively blocks serotonin receptors both peripherally (vagal nerve terminals) and centrally (chemoreceptor trigger zone)	Oral, IM, IV, IO, ODT	Headache, drowsiness, fatigue, dizziness, constipation; dose-dependent QT prolongation	Theoretically, works best before vomiting starts. Administer IV doses over at least 30 s, preferably over 2 to 5 min.
Octreotide	Gastroesophageal variceal hemorrhage, certain tumors, chemotherapy-associated diarrhea	Mimics endogenous somatostatin: decreases intestinal fluid secretion, gastrointestinal motility, and portal blood flow	Subcutaneous, IM, IV	Vary by dose and route of administration	Potential for QT prolongation, which may be enhanced with vasoconstrictors. Consider obtaining a baseline 12-lead ECG to monitor QT. May also be used for treatment of oral sulfonylurea overdose.
Droperidol	Prevention and treatment of nausea and vomiting from surgical or diagnostic procedures	Blocks dopamine stimulation in the chemoreceptor trigger zone	IM, IV, IO	Dose-dependent QT prolongation, dizziness, drowsiness, extrapyramidal symptoms, restlessness	Obtaining a baseline 12-lead ECG is recommended to follow QT intervals. Cardiac monitoring is recommended.

Abbreviations: CNS, central nervous system; ECG, electrocardiogram; GERD, gastroesophageal reflux disease; IM, intramuscular; IO, intraosseous; IV, intravenous; ODT, orally disintegrating tablet; PR, per rectum

Description

Antihistamines and Anticholinergics

Nausea and vomiting are typically triggered in the medulla but can also be triggered by the vestibular system. The vestibular system contains a high concentration of both histamine and ACh. Certain antihistamine medications can inhibit the activity of the histamine in the vestibular system, thereby suppressing the stimulation of the medulla. The same suppression effect can be accomplished by blocking the ACh receptors. Meclizine and dimenhydrinate are examples of antihistamines used as antiemetics; scopolamine is an anticholinergic used to treat nausea and vomiting. Both drug classes are associated with similar adverse reactions—sedation, visual acuity changes, and, most notably, the potential worsening of narrow-angle glaucoma.

Dopamine Antagonists

The vomiting center of the medulla can be triggered by the neurochemical transmitter dopamine when it activates the D_2 dopamine receptor. Medications that antagonize D_2 receptors, therefore, may be useful in reducing nausea and vomiting. Unfortunately, these medications all have major side effects—notably, considerable sedation, orthostatic hypotension, and extrapyramidal effects.

Promethazine

Promethazine is a phenothiazine-type antiemetic that belongs to the dopamine antagonist category. This agent is typically administered intravenously or intramuscularly at a dose of 12.5 to 25 mg, with even smaller doses being given in frail patients or older adults. Intravenous administration of promethazine has been associated with severe reactions, including tissue necrosis and need for amputation. If possible, the IV route of promethazine should be avoided. Promethazine should also be avoided in children; it is contraindicated in patients younger than 2 years.

Prochlorperazine

Prochlorperazine also blocks dopamine at the D_2 receptor in the medulla. The dose is 2.5 to 10 mg every 3 to 4 hours when given intravenously. This medication may cause extrapyramidal symptoms (eg, Parkinson-like syndromes, dystonia, akathisia).

It is imperative that prochlorperazine be administered slowly or by infusion, as rapid injection may cause orthostatic hypotension. Prochlorperazine, like promethazine, has the potential to lower the seizure threshold and may increase the likelihood of seizures in patients already predisposed to them. Use caution when administering these medications in older adults and other at-risk patients. Prochlorperazine is contraindicated in children younger than 2 years of age.

Metoclopramide

Metoclopramide has similar action on the D_2 receptors as prochlorperazine and promethazine do, but has the added benefit of increasing gastrointestinal motility. This is accomplished by enhancing ACh's effects on receptors in the upper gastrointestinal tract. Metoclopramide can cause drowsiness, dizziness, akathisia, and dystonic reactions, similar to other phenothiazine antiemetics.

Metoclopramide is usually given at a dose of 5 to 10 mg IV or IM. Many providers administer diphenhydramine with metoclopramide as prophylaxis against dystonic reactions. Rapid IV infusion can cause a profound dysphoria. The action of metoclopramide begins within 1 to 3 minutes and persists for 1 to 2 hours.

Ondansetron

Ondansetron is an antiemetic belonging to the selective 5-HT_3 receptor antagonist class. This class of antiemetics works by selectively blocking serotonin, both peripherally on the vagal nerve terminals and centrally in the chemoreceptor trigger zone. These drugs have gained popularity owing to their safer adverse-effect profile. The side effects most commonly associated with 5-HT_3 receptor antagonists include headache, fatigue, and general malaise.

Ondansetron is used for prevention of postoperative nausea and vomiting via the IV, IM, or oral route. It comes in an oral disintegrating tablet form that readily dissolves with even small amounts of saliva or a sip of water. For chemotherapy-induced nausea and vomiting, 8 mg or larger doses may be used, although single IV doses exceeding 16 mg create a significant risk of QT prolongation with. IV doses should be administered over at least 30 seconds and preferably over 2 to 5 minutes. Larger doses are safest if infused over at least 15 minutes.

Ondansetron is most effective when used to prevent vomiting. Its effectiveness is considerably lessened once a patient has vomited, although it may help to prevent further vomiting episodes.

Octreotide

Octreotide is an antidiarrheal, somatostatin analog used off-label in critical care for patients with bleeding esophageal varices. Somatostatin is a naturally occurring peptide chain that decreases intestinal fluid secretion, slows gastrointestinal motility, and reduces portal blood flow through vascular smooth muscle vasoconstriction. Unfortunately, the half-life of both naturally occurring and synthetic somatostatin is limited to minutes. Octreotide is a synthetic peptide with actions analogous to somatostatin, but a longer, more clinically useful duration of action.

Octreotide is given as a loading IV dose of 25 to 100 µg over at least 3 minutes (the usual bolus dose is 50 µg), followed by an IV infusion of 25 to 50 µg/h for 2 to 5 days. If bleeding is not controlled, the bolus dose may be repeated in the first hour.

Adverse reactions to octreotide vary by dosage. With IV dosing, sinus bradycardia, chest pain, pruritus (itching), and gastrointestinal distress have been reported.

Octreotide is also used subcutaneously or intramuscularly to treat dumping syndrome (often associated with gastric bypass surgery or esophagectomy), acromegaly, a variety of tumors and malignancies, and other gastrointestinal conditions, in addition to its primary use in critical care as a vasoconstrictor in patients with bleeding esophageal varices. Another use of octreotide is for the treatment of hypoglycemia following an overdose of oral sulfonylurea (a hypoglycemic agent for control of type 2 diabetes).

Droperidol

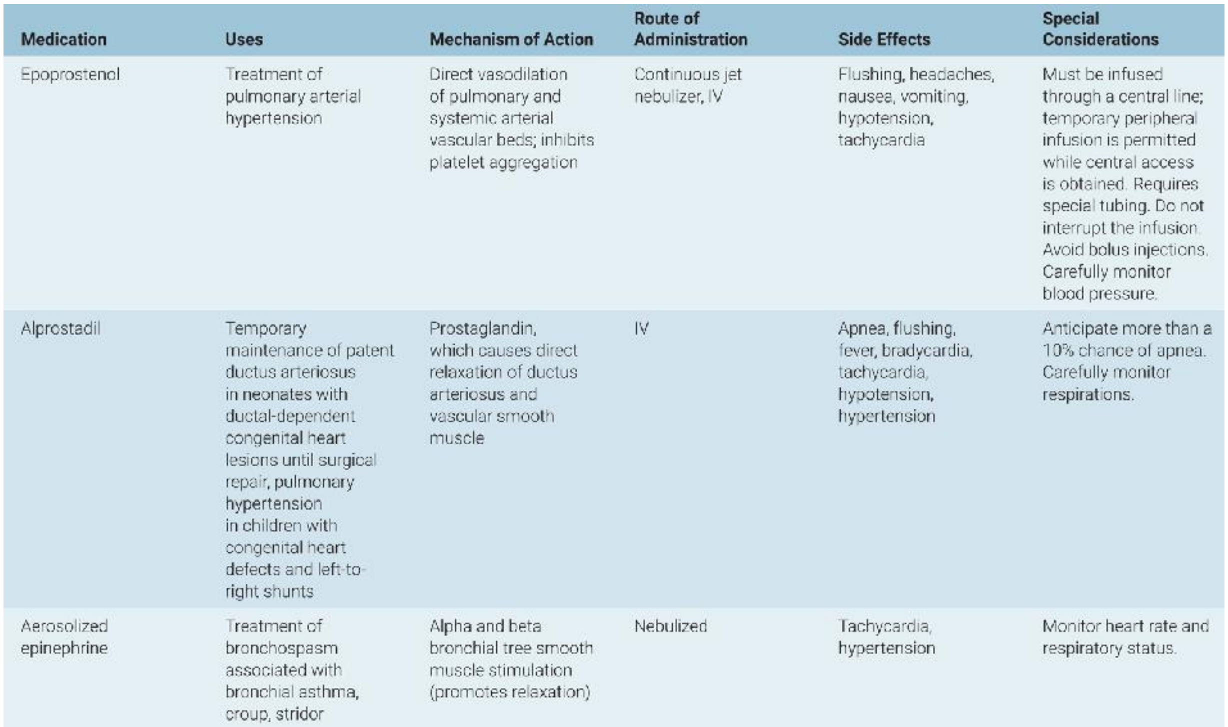
Droperidol is a dopamine-blocking agent that is used in critical care as an antiemetic. Intravenous administration of this drug is used for both treatment and prevention of nausea and vomiting in adults, with doses ranging from 0.625 mg to 1.25 mg given every 6 hours. Such doses should be administered slowly, over 2 to 5 minutes.

Droperidol has QT-prolonging effects and is contraindicated in patients with prolonged QTc intervals (greater than 440 ms in males or greater than 450 ms in females). While considerable debate exists about the clinical significance of droperidol-induced QTc prolongation, the drug has a reasonable safety record with the low doses used to treat nausea and vomiting. Most reported adverse events with droperidol occurred at doses of 2.5 mg and higher—doses that had previously been used for sedation, agitation, and induction of general anesthesia.

Pulmonary Medications

Paramedics are familiar with bronchodilators such as albuterol and anticholinergics such as ipratropium, both of which are used to manage reactive airways. The pulmonary medications listed in this section are typically systemic drugs used in management of life-threating pulmonary conditions such as pulmonary arterial hypertension, refractory hypoxemia, and ductal issues in neonates. **TABLE 8-10** profiles selected medications for pulmonary indications.

TABLE 8-10 **Pulmonary Medications**



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Epoprostenol	Treatment of pulmonary arterial hypertension	Direct vasodilation of pulmonary and systemic arterial vascular beds; inhibits platelet aggregation	Continuous jet nebulizer, IV	Flushing, headaches, nausea, vomiting, hypotension, tachycardia	Must be infused through a central line; temporary peripheral infusion is permitted while central access is obtained. Requires special tubing. Do not interrupt the infusion. Avoid bolus injections. Carefully monitor blood pressure.
Alprostadil	Temporary maintenance of patent ductus arteriosus in neonates with ductal-dependent congenital heart lesions until surgical repair, pulmonary hypertension in children with congenital heart defects and left-to-right shunts	Prostaglandin, which causes direct relaxation of ductus arteriosus and vascular smooth muscle	IV	Apnea, flushing, fever, bradycardia, tachycardia, hypotension, hypertension	Anticipate more than a 10% chance of apnea. Carefully monitor respirations.
Aerosolized epinephrine	Treatment of bronchospasm associated with bronchial asthma, croup, stridor	Alpha and beta bronchial tree smooth muscle stimulation (promotes relaxation)	Nebulized	Tachycardia, hypertension	Monitor heart rate and respiratory status.

Abbreviations: IO, intraosseous; IV, intravenous

Description

Epoprostenol

Epoprostenol is a vasodilator, prostacyclin and prostaglandin, and inhibitor of platelet aggregation used to treat pulmonary arterial hypertension, also known as primary pulmonary hypertension, as well as severe hypoxemia and acute right heart dysfunction. In adults, it has usually been delivered by intravenous infusion; in pediatric patients, it may also be nebulized. In recent years, data showing equal or better efficacy for inhaled epoprostenol compared to inhaled nitric oxide in adults have led to increased use of continuously nebulized epoprostenol in the adult population.

Dosing of IV epoprostenol is initiated at 2 ng/kg/min and increased in increments of 1 to 2 ng/kg/min at intervals of 10 to 15 minutes until the response plateaus or dose-limiting side effects occur. There is no specified maximum dose, but usual doses range from 25 to 40 ng/kg/min, with doses as high as 195 ng/kg/min reported in children. Increased doses should be expected with chronic use; indeed, such doses are usually needed more frequently the first few months after starting the drug. Dose increases should be made in increments of 1 to 2 ng/kg/min. Conversely, when significant symptoms require dose reduction, decreases are made in increments of 2 ng/kg/min.

Continuously nebulized epoprostenol is initiated at 20 to 50 ng/kg/min and titrated upward in increments of 10 ng/kg/min. When this medication is delivered through a ventilator circuit, the ventilator tidal volume may require adjustment due to the increased flow. In addition, the vent filter may need to be changed as often as every 2 hours if a glycine buffer diluent is used with this medication.

Epoprostenol can cause nausea, vomiting, headache, jaw pain, hypotension, and flushing of the skin. Abrupt withdrawal due to sudden interruption in medication delivery can result in rebound hypoxemia and pulmonary hypertension. This risk is of significant concern, as the half-life of epoprostenol is only 6 minutes. Loss of IV access or failure of nebulization equipment should be considered an emergency in patients who are receiving this medication. Whenever transporting patients from home, a backup supply of medications and equipment should be requested and brought to the receiving hospital.

Alprostadil

Alprostadil is a prostaglandin and vasodilator used to maintain the patency of the ductus arteriosus in neonates with ductal-dependent congenital heart disease until surgery can be performed. It has also been used in postoperative heart transplant patients to facilitate weaning from cardiopulmonary bypass in the presence of severe pulmonary hypertension.

For neonates, alprostadil continuous infusion is initiated at 0.05 μg/kg/min, using a large vein or an umbilical artery catheter placed at the ductal opening. The dose is then titrated in increments of 0.05 to 0.1 μg/kg/min until a therapeutic response is achieved (evidenced by increased pH, systemic blood pressure, or increased P_{O_2}—typically seen within 30 minutes). At that point, the dose should be reduced to the lowest effective amount. It is often possible to reduce doses by as much as 50% without losing the therapeutic effect. Usual dose ranges are 0.01 to 0.4 μg/kg/min, with the maximum dose being 0.4 μg/kg/min.

One of the more common side effects of alprostadil is apnea, which may occur in 10% to 12% of infants with congenital heart defects, especially in those weighing less than 4 pounds (2 kg) at birth. Apnea usually occurs in the first hour of alprostadil infusion. Fever, flushing, hypotension, and bradycardia have also been reported and are considered dose-dependent side effects. If apnea occurs, the infusion should be discontinued and cautiously restarted at a lower dose.

Aerosolized Epinephrine

Aerosolized epinephrine, or racemic epinephrine, is an alpha and beta agonist. It works by stimulating the alpha adrenergic receptors in the airway, which leads to resultant tightening of the mucosa (mucosal vasoconstriction) and decreased fluid in the airway (subglottic edema), and by stimulating the beta adrenergic receptors, which causes relaxation of the bronchial smooth muscle. Racemic epinephrine is typically used for relief of respiratory distress due to stridor, bronchiolitis, laryngeal edema, and upper airway obstruction. It has also been effective in treating post-extubation edema and croup.

Racemic epinephrine is given by small-volume nebulizer, using 0.5 mL of a 2.25% solution added to 3 mL of normal saline, repeated every 15 minutes to 4 hours as needed. Effects should be evident within 1 minute.

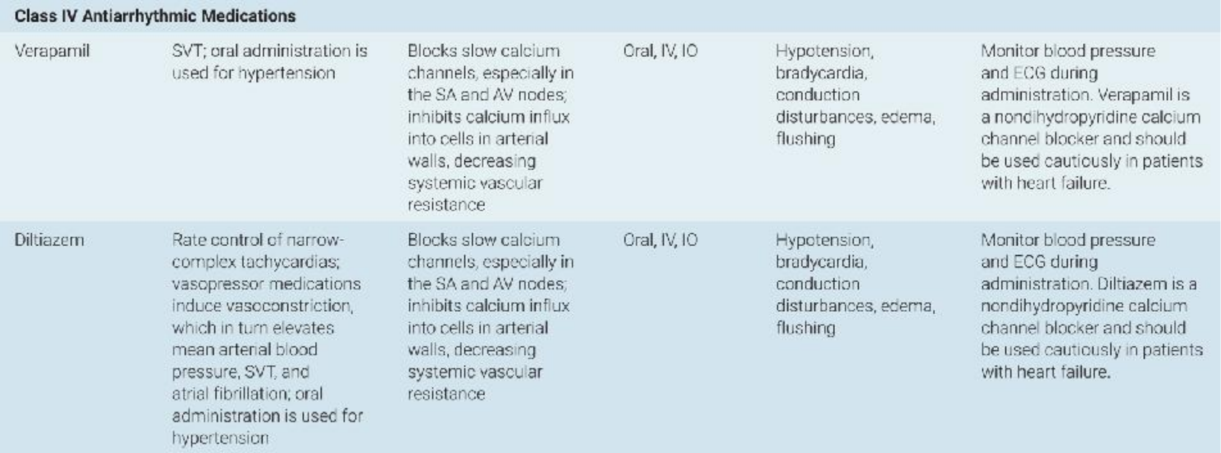
The manufacturer recommends that racemic epinephrine be refrigerated, although it is stable when stored at room temperature. Potential side effects with its use include tremor and tachycardia.

Antiarrhythmics

Antiarrhythmic medications comprise a general, broad-based group of drugs, with subcategories being distinguished based on the medications' mechanisms of action according to the **Vaughan-Williams classification scheme**. This scheme organizes drugs that affect heart rhythms into classes I through IV **TABLE 8-11**. With the advent of newer medications with several simultaneous mechanisms of action (eg, amiodarone), however, the Vaughan-Williams classification system has been found to have significant limitations.

TABLE 8-11 **Antiarrhythmics**

Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Class I Antiarrhythmic Medications					
Procainamide	Treatment of various atrial or ventricular arrhythmias (different class I agents are appropriate for different types of arrhythmias)	Blocks fast sodium channels; inhibits depolarization of neuronal cells; decreases myocardial conduction velocity and automaticity	IV	Hypotension, nausea, vomiting, unwanted conduction disturbances	Monitor ECG, blood pressure, and renal function.
Lidocaine	Treatment of ventricular arrhythmias (different class I agents are appropriate for different types of arrhythmias)	Blocks fast sodium channels; inhibits depolarization of neuronal cells; decreases myocardial conduction velocity and automaticity	IV	Hypotension, nausea, vomiting, seizures, altered mental status	Monitor ECG and CNS status. As with amiodarone, considered a first-line agent in patients with ventricular fibrillation or pulseless ventricular tachycardia.
Flecainide	Treatment/prevention of atrial fibrillation/flutter, PSVT, and ventricular arrhythmias	Slows conduction in cardiac tissue by altering ion transport across cell membranes	PO	Dizziness, visual disturbances, dyspnea	Monitor ECG and blood pressure during administration. Proarrhythmic effects including ventricular fibrillation and tachycardia have been reported with use in patients with atrial fibrillation.
Class II Antiarrhythmic Medications					
Labetalol	Treatment of mild to severe hypertension	Competitively blocks beta receptors in heart, blood vessels; also blocks alpha-1 receptors; may affect other beta receptors at higher doses	Oral, IV	Hypotension, bradycardia, conduction abnormalities, dizziness, hypoglycemia	A loss of beta selectivity occurs following high doses or overdose. May exacerbate bronchospasm in patients with reactive airway disease.
Metoprolol	Treatment of hypertension, rate control in atrial fibrillation, tremors, certain psychological disorders, migraines	Selectively inhibits beta-1 receptors; little to no effect on beta-2 receptors at doses <100 mg/d in adults	Oral, IV	Hypotension, bradycardia, conduction abnormalities, dizziness	Avoid use in patients with cocaine toxicity due to theoretical risk of unopposed alpha stimulation. A loss of beta selectivity occurs following high doses or overdose.
Esmolol	Treatment of SVT and control of ventricular rate in atrial fibrillation/flutter; treatment of tachycardia and hypertension	Competitively blocks beta-1 receptors; little to no effect on beta-2 receptors except at high doses	IV	Hypotension, bradycardia, infusion-site reactions	Use cautiously in heart block greater than first degree. Usually given as an infusion, with an optional bolus prior to start of therapy.
Sotalol	Treatment of life-threatening ventricular arrhythmias; maintenance of sinus rhythm in patients with symptomatic atrial fibrillation/flutter	Both beta blocking and cardiac action potential duration prolonging effects	Oral, IV	Bradycardia, chest pain, palpitations, fatigue; dose-related proarrhythmias such as torsades de pointes	Contraindicated if baseline QTc >450 ms, serum potassium <4 mEq/L, or creatinine clearance <40 mL/min. Monitor QTc during therapy.
Class III Antiarrhythmic Medications					
Amiodarone	Management of life-threatening ventricular arrhythmias, atrial fibrillation in critically ill patients or patients with heart failure, SVT, maintenance of sinus rhythm after conversion of atrial fibrillation	Inhibits alpha and beta stimulation; blocks sodium, potassium, and calcium channels; decreases AV conduction and sinus node function	Oral, IV, IO	QT-interval prolongation, infusion rate–related hypotension, bradycardia, other conduction abnormalities, flushing, edema, hypothyroidism, pulmonary toxicity	Monitor ECG and blood pressure during administration. Central line administration is preferred to decrease the incidence of phlebitis. Long-term effects can be significant, including pulmonary toxicity, hypothyroidism, corneal deposits with visual changes, and abnormal liver function tests. Like lidocaine, considered a first-line agent in patients with ventricular fibrillation or pulseless ventricular tachycardia.



Class IV Antiarrhythmic Medications					
Verapamil	SVT; oral administration is used for hypertension	Blocks slow calcium channels, especially in the SA and AV nodes; inhibits calcium influx into cells in arterial walls, decreasing systemic vascular resistance	Oral, IV, IO	Hypotension, bradycardia, conduction disturbances, edema, flushing	Monitor blood pressure and ECG during administration. Verapamil is a nondihydropyridine calcium channel blocker and should be used cautiously in patients with heart failure.
Diltiazem	Rate control of narrow-complex tachycardias; vasopressor medications induce vasoconstriction, which in turn elevates mean arterial blood pressure, SVT, and atrial fibrillation; oral administration is used for hypertension	Blocks slow calcium channels, especially in the SA and AV nodes; inhibits calcium influx into cells in arterial walls, decreasing systemic vascular resistance	Oral, IV, IO	Hypotension, bradycardia, conduction disturbances, edema, flushing	Monitor blood pressure and ECG during administration. Diltiazem is a nondihydropyridine calcium channel blocker and should be used cautiously in patients with heart failure.

Abbreviations: AV, atrioventricular; CNS, central nervous system; ECG, electrocardiogram; IO, intraosseous; IV, intravenous; PSVT, paroxysmal supraventricular tachycardia; QTc, corrected QT; SA, sinoatrial; SVT, supraventricular tachycardia

© Jones & Bartlett Learning.

Description

Class I Antiarrhythmic Medications

Class I antiarrhythmic medications work by blocking sodium channels. In doing so, the medication reduces the phase 0 slope and the peak of the action potential. Class I drugs are further divided into subclasses IA, IB, and IC based on their strength and degree of phase 0 reduction. Class IA is considered moderate in effect, class IB is weak, and class IC produces a strong reduction. The general principle behind sodium-channel blockade is reduction of the rate and magnitude of depolarization by decreasing conduction velocity in non-nodal tissue. Recall that nodal tissue generates the initial electrical impulse, whereas non-nodal tissue receives stimulation from nodal tissues or neighboring cells to initiate depolarization.

Class IA Medications

Class IA medications have been found to increase the effective refractory period (ERP)—that is, the interval within the cardiac cycle during which cardiac cells (and muscles) are chemically unable to reenergize. During this time, additional action by cardiac tissues is impossible. By increasing the ERP, the medication decreases the cells’ ability to recharge and depolarize as quickly, thereby interrupting reentry mechanisms.

The class IA medications are quinidine, procainamide, and disopyramide. Some significant drawbacks are noted with this class, particularly pertaining to their effects on patients with preexisting infarction or structural heart disease. They also tend to trigger significant adverse reactions, including lupus-like syndromes (inflammation of the heart tissue including the valves and pericardium); such reactions occur in as many as 30% of long-term procainamide users, for example. Oral procainamide is not available in the United States.

Of all the class IA medications, procainamide is the most commonly encountered in the acute setting. Given as an infusion, its typical dose is 20 to 50 mg/min, with a maximum dose of 17 mg/kg. When administering procainamide, the CCTP must be mindful of the clinical endpoints for this therapy: a 50% widening of the QRS complex, suppression of the arrhythmia, or hypotension. Along with the lupus-like syndromes, patients may experience side effects such as widening of the PR and QT intervals, AV blocks, seizures, and CNS depression, which may deteriorate into seizures.

Class IB Medications

Class IB medications carry out their functions by decreasing the ERP and the action potential duration (APD)—that is, the length of the action potential cycle. When the ERP and the APD are decreased, automaticity of the cardiac cells is diminished, which reduces their tendency to depolarize in a disorganized fashion. Class IB medications are indicated for ventricular fibrillation, ventricular tachycardia, and ventricular irritability.

Lidocaine is the prototypical class IB medication. It has a greater impact on ventricular cells with longer action potentials than on atrial cells with shorter action potentials. Given at an initial dose of 1 to 1.5 mg/kg and a repeat dose of 0.5 to 0.75 mg/kg, lidocaine remains a treatment option for patients experiencing cardiac arrhythmias originating in the ventricles.

Lidocaine achieves its peak effect in about 5 minutes but has a highly variable duration of action. Caution should be exercised so as not to exceed the maximum dose of 3 mg/kg.

Class IC Medications

Class IC medications work by suppressing the phase 0 repolarization. These medications differ from class IA and class IB medications in that they have virtually no effect on the action potential. By suppressing repolarization, conductivity is reduced through the heart. Class IC medications are used for life-threatening arrhythmias originating in the ventricles. Interestingly, medications in this class can be proarrhythmic as well. Some studies have indicated a propensity for ST-segment elevation with the use of these medications.

Flecainide is a prototypical class IC medication. This oral medication is not routinely used in CCT.

Class II Antiarrhythmic Medications/Beta Adrenergic Blocking Agents

Class II antiarrhythmics comprise the beta blocking medications. The cardiovascular system is influenced by the sympathetic nervous system, particularly by epinephrine and norepinephrine (**sympathomimetics**) binding to the adrenergic beta-1 and beta-2 receptors. Beta blocking medications work to antagonize the beta receptors by competitively binding to these sites to inhibit stimulation. Earlier beta blocking medications were considered nonselective because they indiscriminately blocked both beta-1 and beta-2 receptors. More recent versions are relatively selective for beta-1 receptors, although some beta-2 binding occurs, particularly with higher doses. These sympathetic nervous system–blocking medications (ie, sympatholytics) have several uses, including the treatment of arrhythmias, hypertension, and heart failure. If the medication causes an excessive blockade, however, the patient may experience bradycardia, heart failure, hypotension, and AV blocks. Especially with the use of nonselective beta blocking medications, bronchoconstriction and hypoglycemia may occur. Propranolol is a commonly used nonselective beta blocking medication.

Labetalol

Labetalol is a medication with both alpha-1 and beta blocking (antagonist) properties. It can be given orally or intravenously for the management of chronic or emergent hypertension, respectively. Health care providers should avoid administering beta blockers, including labetalol, when a patient has a high-degree (greater than first-degree) heart block or sick sinus syndrome. Heart failure, cardiogenic shock, asthma, and obstructive airway disease are other situations in which labetalol should be avoided.

The initial IV dose of labetalol for hypertensive emergency in adults is 10 to 20 mg given over 1 to 2 minutes, followed by subsequent doses of 20 to 80 mg every 10 minutes until the target blood pressure is reached. The manufacturer recommends a cumulative maximum dose of 300 mg, but in practice this maximum dose is sometimes exceeded with careful monitoring. Labetalol can also be administered as a continuous IV infusion of 1 to 2 mg/min. Its effects become evident less than 5 minutes following an IV dose and last up to 4 hours.

Metoprolol

Metoprolol is a selective beta-1 blocking drug that decreases the automaticity of the heart tissue, thereby decreasing cardiac output and systemic blood pressure. For acute rate control, this agent is usually given intravenously at a dose of 5 mg every 2 to 5 minutes for up to three doses. Metoprolol should not be administered to patients with significant heart failure (ejection fraction less than 45%), bradycardia, or cardiogenic shock.

Esmolol

Esmolol is an antihypertensive, beta-1 selective blocker and class II antiarrhythmic. It is used for control of hypertension or tachycardia. Esmolol has an advantage over other antihypertensive and rate control agents in terms of its quick action and very short half-life. Effects are seen within 2 to 10 minutes of starting an infusion of the drug; use of a loading dose can shorten this interval. The duration of action is 10 to 30 minutes following discontinuation of esmolol. With high doses or extended-duration infusions, the duration of action may be longer.

Esmolol infusions are initiated at 50 µg/kg/min and titrated upward in increments of 50 µg/kg/min every 4 minutes to a maximum of 200 µg/kg/min. Some patients with hypertension require higher doses (250 to 300 µg/kg/min). The safety of doses exceeding 300 µg/kg/min has not been studied. At rates greater than 200 µg/kg/min, minimal additional effects on rate control are seen. When immediate control of rate or blood pressure is needed, a bolus of 1 mg/kg can be administered over 1 minute; alternatively, for more gradual lowering, a 0.5-mg/kg bolus can be administered over 1 minute. Both boluses are then followed by an infusion administered at a rate of 50 µg/kg/min.

Esmolol is a vesicant. Thus, although it can be administered through a peripheral IV line, caution should be used to avoid extravasation. Potential side effects include bradycardia, hypotension, heart failure, dizziness, and bronchospasm.

Sotalol

Sotalol is a nonselective beta blocker and class II/III antiarrhythmic. It is indicated for documented sustained ventricular rhythms such as ventricular tachycardia that are judged to be life-threatening as well as for the maintenance of normal sinus rhythm in patients with symptomatic atrial fibrillation or atrial flutter. Sotalol can cause life-threatening ventricular tachycardia associated with significant prolongation of the QT interval (torsades de pointes). Because of this risk, as well as the drug’s very high cost, many US hospitals have chosen not to place IV sotalol on their formularies. Consequently, there is very limited clinical experience with IV sotalol.

When administered intravenously over 5 minutes for ongoing hemodynamically stable ventricular tachycardia, the effects of sotalol are usually seen in 5 to 10 minutes. Recommended dosing is 1.5 mg/kg or 100 mg as a one-time dose.

Class III Antiarrhythmic Medications

The third class of antiarrhythmic medications in the Vaughan-Williams classification is composed of the potassium channel blocker medications. Potassium channels open immediately after cardiac cell depolarization and enable repolarization. Potassium channel–blocking medications block these potassium channels, thereby delaying the phase 3 repolarization of the cardiac cells. In turn, both the duration of the action potential and the effective refractory period increase. Because these medications increase the refractory period, the patient's electrocardiogram (ECG) tends to show a prolonged QT interval. This effect makes potassium channel–blocking medications particularly useful for treating reentry tachycardias and arrhythmias occurring as a result of cellular depolarization due to excessive excitability.

Amiodarone is the most commonly used class III antiarrhythmic medication, even though it also has properties that are consistent with other categories. Like some of the other antiarrhythmic medications, the class III medications can be proarrhythmic as well. Amiodarone can precipitate torsades de pointes, AV blocks, and bradycardia; consequently, it is contraindicated in the presence of bradycardia or AV blocks. Numerous dosing patterns are used for different indications. The onset of action varies, and peak effects may not occur for days or weeks. Because amiodarone carries a high risk for many adverse events and has a variable half-life of 15 to 142 days, careful patient-specific risk-benefit assessment is important before initiating long-term therapy.

Class IV Antiarrhythmic Medications/Calcium Channel–Blocker Medications

The class IV antiarrhythmic medications consist of the calcium channel blockers. Calcium channel–blocking medications bind to the I-type calcium channels in cardiac and vascular smooth muscle cells. These calcium channels play a primary role in cardiac nodal automaticity and phase 0 of the action potential. In other words, the I-type calcium channels influence the impulse-generating and depolarizing activities of the sinoatrial and AV nodes. By blocking the calcium channels, class IV medications cause vasodilation and negative inotropic, negative chronotropic, and negative **dromotropic** (decreased electrical conduction velocity) effects. Although calcium channel–blocking medications decrease the automaticity of aberrant pacemaker sites, their greatest influence comes through their ability to decrease the conduction velocity through the AV node. This action makes class IV antiarrhythmic medications useful for treating tachyarrhythmias originating in the atria.

Currently, only two nondihydropyridine calcium channel–blocking medications are used for treating arrhythmias: verapamil and diltiazem. Neither medication should be given to patients who have preexisting bradycardias, Wolff-Parkinson-White syndrome, or heart failure. Additionally, patients taking a beta blocking medication may experience a potentiation effect.

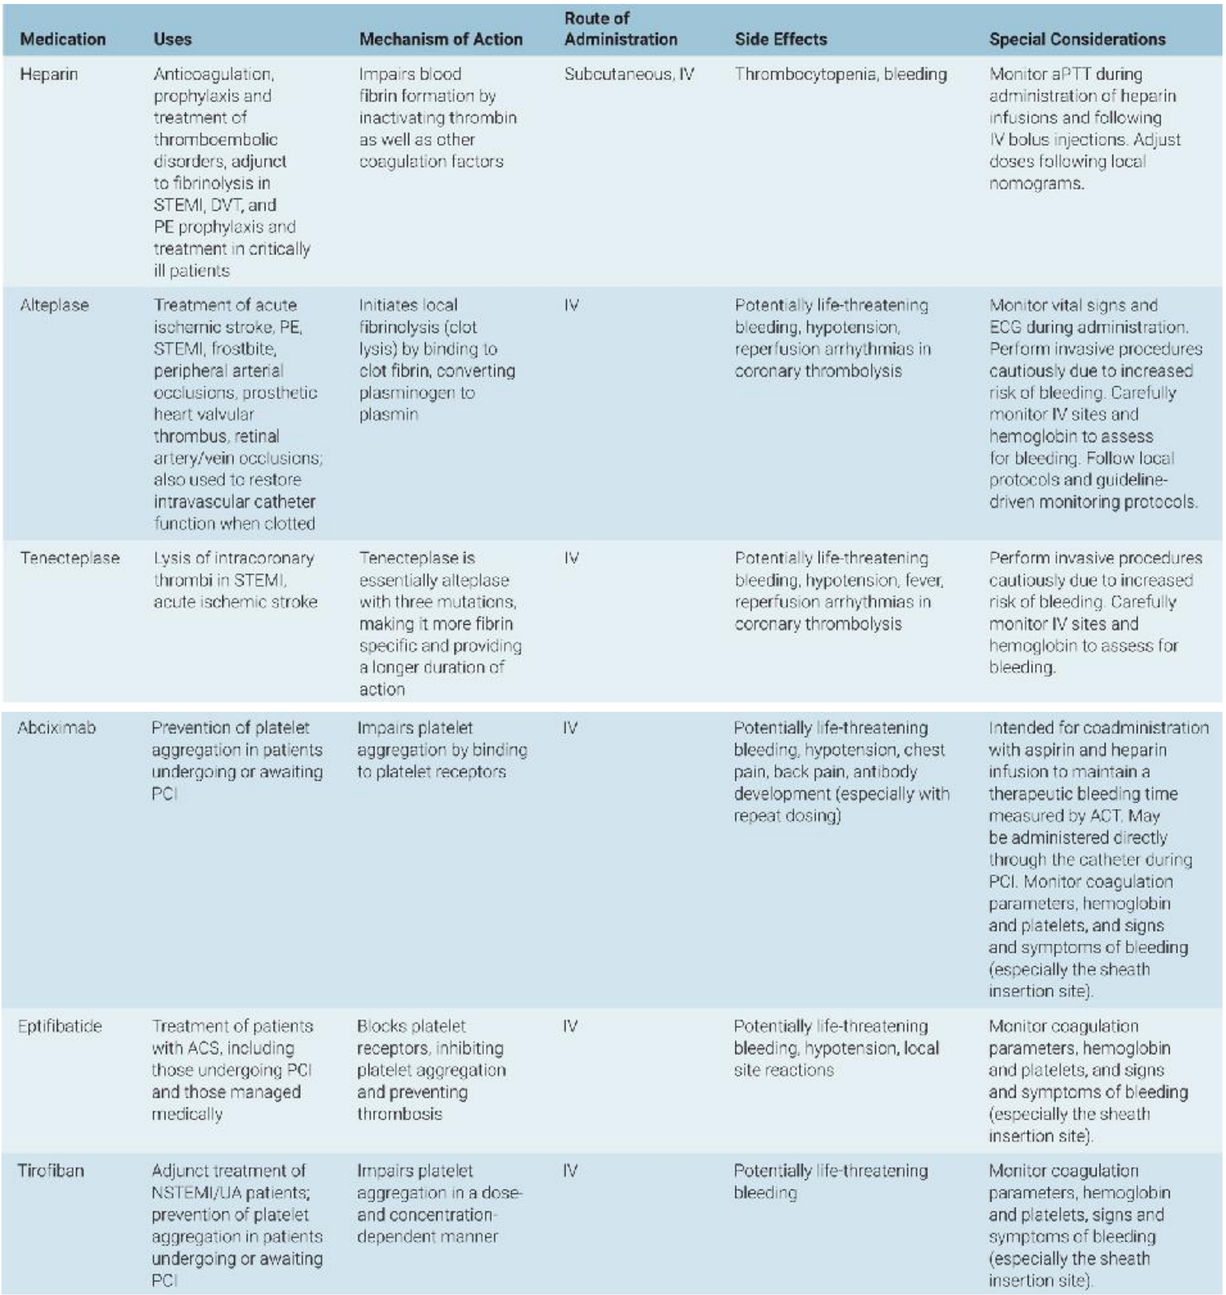
Anticoagulants and Thrombolytics

Anticoagulant medications are used to prevent the formation of blood clots; thrombolytics are used to dissolve existing clots.

The goal of anticoagulation therapy is to prevent thrombosis and thromboembolic events. Critically ill patients represent one of the groups at highest risk for development of thromboembolisms, which often lead to pulmonary emboli. The onerous monitoring requirements and bleeding complications associated with anticoagulant use have led to continued development of newer anticoagulants that directly target the enzyme activity of thrombin and factor Xa. While newer agents have more specific action than the conventional heparins and vitamin K antagonists, their reversal has proved to be challenging.

Thrombolytics are indicated to dissolve clots formed in intravenous catheters and vessels such as the coronary, cerebral, and pulmonary arteries. **TABLE 8-12** profiles selected anticoagulants and thrombolytics.

TABLE 8-12 | Anticoagulants and Thrombolytics



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Heparin	Anticoagulation, prophylaxis and treatment of thromboembolic disorders, adjunct to fibrinolysis in STEMI, DVT, and PE prophylaxis and treatment in critically ill patients	Impairs blood fibrin formation by inactivating thrombin as well as other coagulation factors	Subcutaneous, IV	Thrombocytopenia, bleeding	Monitor aPTT during administration of heparin infusions and following IV bolus injections. Adjust doses following local nomograms.
Alteplase	Treatment of acute ischemic stroke, PE, STEMI, frostbite, peripheral arterial occlusions, prosthetic heart valvular thrombus, retinal artery/vein occlusions; also used to restore intravascular catheter function when clotted	Initiates local fibrinolysis (clot lysis) by binding to clot fibrin, converting plasminogen to plasmin	IV	Potentially life-threatening bleeding, hypotension, reperfusion arrhythmias in coronary thrombolysis	Monitor vital signs and ECG during administration. Perform invasive procedures cautiously due to increased risk of bleeding. Carefully monitor IV sites and hemoglobin to assess for bleeding. Follow local protocols and guideline-driven monitoring protocols.
Tenecteplase	Lysis of intracoronary thrombi in STEMI, acute ischemic stroke	Tenecteplase is essentially alteplase with three mutations, making it more fibrin specific and providing a longer duration of action	IV	Potentially life-threatening bleeding, hypotension, fever, reperfusion arrhythmias in coronary thrombolysis	Perform invasive procedures cautiously due to increased risk of bleeding. Carefully monitor IV sites and hemoglobin to assess for bleeding.
Abciximab	Prevention of platelet aggregation in patients undergoing or awaiting PCI	Impairs platelet aggregation by binding to platelet receptors	IV	Potentially life-threatening bleeding, hypotension, chest pain, back pain, antibody development (especially with repeat dosing)	Intended for coadministration with aspirin and heparin infusion to maintain a therapeutic bleeding time measured by ACT. May be administered directly through the catheter during PCI. Monitor coagulation parameters, hemoglobin and platelets, and signs and symptoms of bleeding (especially the sheath insertion site).
Eptifibatide	Treatment of patients with ACS, including those undergoing PCI and those managed medically	Blocks platelet receptors, inhibiting platelet aggregation and preventing thrombosis	IV	Potentially life-threatening bleeding, hypotension, local site reactions	Monitor coagulation parameters, hemoglobin and platelets, and signs and symptoms of bleeding (especially the sheath insertion site).
Tirofiban	Adjunct treatment of NSTEMI/UA patients; prevention of platelet aggregation in patients undergoing or awaiting PCI	Impairs platelet aggregation in a dose- and concentration-dependent manner	IV	Potentially life-threatening bleeding	Monitor coagulation parameters, hemoglobin and platelets, signs and symptoms of bleeding (especially the sheath insertion site).

Abbreviations: ACS, acute coronary syndrome; ACT, activated clotting time; aPTT, activated partial thromboplastin time; DVT, deep venous thrombosis; ECG, electrocardiogram; IV, intravenous; NSTEMI, non–ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; PE, pulmonary embolism; STEMI, ST-segment elevation myocardial infarction; UA, unstable angina

Description

Heparin

Heparin is an anticoagulant used for acute coronary syndromes, for venous thromboembolism, and in any situation where systemic anticoagulation is desired. Many concentrations of this drug are available, and it can be injected subcutaneously, instilled in a central venous or dialysis catheter to maintain patency, or delivered as a continuous infusion to provide systemic anticoagulation. Heparin inactivates thrombin (as well as several coagulation factors and plasmin) and prevents the conversion of fibrinogen to fibrin. Thus, while heparin is an anticoagulant, it is not a thrombolytic; heparin may prevent the growth of existing thrombi, but will not reduce their size or dissolve them.

Continuous heparin infusion dosing varies by indication. Generally, a loading dose is administered, followed by a continuous, weight-based infusion. Dosing is adjusted to activated partial thromboplastin time (aPTT) levels, which are drawn at 4- to 6-hour intervals, and adjusted to a target of 1.5 to 2 times the upper limit of control (usually 50 to 70 seconds). As an adjunct to fibrinolytics in patients with ST-segment elevation myocardial infarction (STEMI), a heparin bolus of 60 units/kg (maximum 4,000 units) is recommended, followed by a 12 units/kg/h infusion (maximum 1,000 units/h). Heparin dosing and monitoring are most often institution specific and care should be taken to follow local protocols.

Effects of IV heparin are seen immediately, and the medication's duration of action is approximately 20 minutes. Bleeding is the most significant adverse event associated with heparin administration, and patients should be closely monitored for this complication during transport. Most bleeding can be controlled by direct pressure. If serious hemorrhage occurs, heparin should be immediately discontinued and a reversal agent (ie, protamine) considered.

Alteplase

Alteplase is a thrombolytic agent used to treat acute ischemic stroke, acute massive pulmonary embolism, STEMI, acute peripheral artery occlusions, and central catheter clearance. Alteplase triggers local fibrinolysis by binding to the fibrin in a clot (thrombus) and converting plasminogen to plasmin. It begins working immediately once a bolus or infusion is started and continues to exhibit fibrinolytic action for as long as 1 hour after its administration is stopped.

Dosing strategies vary by patient weight and indication, but usually include a loading dose followed by an infusion lasting from 30 minutes to 2 hours. For certain indications, other anticoagulants may be administered simultaneously. However, an important exception is treatment of acute ischemic stroke, as patients should not receive any anticoagulants or antiplatelets for at least 24 hours after treatment.

In patients with STEMI, coronary thrombolysis may result in reperfusion arrhythmias such as accelerated idioventricular rhythms. Bleeding is a risk in all patients and is dose related. Certain conditions increase the risk of bleeding, requiring careful consideration of inclusion/exclusion criteria before administering alteplase. Total alteplase doses should not exceed 90 mg in patients with acute ischemic stroke or 100 mg in patients with acute myocardial infarction or PE. Doses of 150 mg or more are associated with a significantly greater risk of intracranial hemorrhage compared to doses of 100 mg or less. Overall, the bleeding risk with appropriate alteplase therapy is low. If serious hemorrhage occurs, the infusion of alteplase and any other anticoagulants (such as heparin) should be discontinued.

Tenecteplase

Tenecteplase is another thrombolytic agent used in the management of STEMI. Acute ischemic stroke practice guidelines from major medical organizations have recommended alteplase rather than tenecteplase for this indication; however, recent data have shown benefits from tenecteplase in patients with large-vessel occlusion strokes. Additionally, this agent may be associated with better perfusion and potentially fewer bleeding complications.

Tenecteplase promotes fibrinolysis by binding to fibrin and converting plasminogen to plasmin. This medication is essentially alteplase with three mutations that make it more fibrin specific and give it a longer duration of action. The longer half-life (20 to 24 minutes) allows for rapid bolus dosing over 5 seconds, rather than an hour-long infusion as with alteplase.

For STEMI, the total dose of tenecteplase should not exceed 50 mg and is weight based. This agent is administered as a single bolus dose over 5 seconds. Effects are seen immediately and last for 90 to 130 minutes. Adverse effects may include reperfusion arrhythmias and bleeding.

Abciximab

Abciximab is an antiplatelet agent in the glycoprotein IIb/IIIa inhibitor family. It is used during and after percutaneous coronary intervention (PCI) for STEMI and following some carotid stent procedures. It works by blocking the platelet IIb/IIIa receptors, thereby reversibly blocking platelet aggregation and preventing thrombosis.

Abciximab is administered by IV infusion, with a bolus of 0.25 mg/kg given 10 to 60 minutes prior to PCI, followed by an infusion of 0.125 µg/kg/min (maximum 10 µg/min) for 12 hours. In patients with unstable angina and non–ST-segment elevation myocardial infarction (NSTEMI), the infusion may be continued for 18 to 24 hours after PCI. Abciximab is intended for coadministration with aspirin and a continuous heparin infusion.

The most significant adverse effect associated with abciximab is bleeding, which can occur at any site. The precise level of risk depends on multiple variables, including patient susceptibility and concurrent use of other anticoagulating agents. Minor bleeding can be controlled with direct pressure; major bleeding may require discontinuation of abciximab. Consultation with medical control is necessary when discontinuation is contemplated, as a careful risk-benefit assessment is necessary.

Eptifibatide

Eptifibatide is an antiplatelet agent in the glycoprotein IIb/IIIa inhibitor family. It is used for treatment of acute coronary syndrome (ACS) as well as during and after percutaneous coronary intervention. It works by binding to platelet IIb/IIIa receptors, thereby inhibiting platelet aggregation.

Eptifibatide is administered by IV infusion. In patients with ACS, a bolus of 180 µg/kg (maximum 22.6 mg) is administered as soon as possible after diagnosis; the bolus is followed by an infusion of 2 µg/kg/min (maximum 15 mg/h), which is continued until hospital discharge, PCI, or cardiac bypass surgery. In patients undergoing bypass surgery, eptifibatide is discontinued 2 to 4 hours prior to surgery. In patients with PCI, a second bolus is administered 10 minutes after the first, and the infusion is continued for 24 hours post PCI.

The most significant adverse effect associated with eptifibatide is bleeding, which most often occurs at catheter sites. Patients who weigh less than 154 pounds (70 kg) may be at greater risk for bleeding. Minor bleeding can be controlled with direct pressure; major bleeding may require discontinuation of eptifibatide. Consultation with medical control is necessary when discontinuation is contemplated, as a careful risk-benefit assessment is necessary.

Tirofiban

Tirofiban is an antiplatelet agent in the glycoprotein IIb/IIIa inhibitor family. It is used for treatment of ACS as well as during and after PCI. This agent works by binding to platelet IIb/IIIa receptors, thereby inhibiting platelet aggregation. When tirofiban is used as recommended, more than 90% platelet inhibition may be seen within 10 minutes of initiating the infusion, with levels returning to baseline within 4 to 8 hours after discontinuation of the medication.

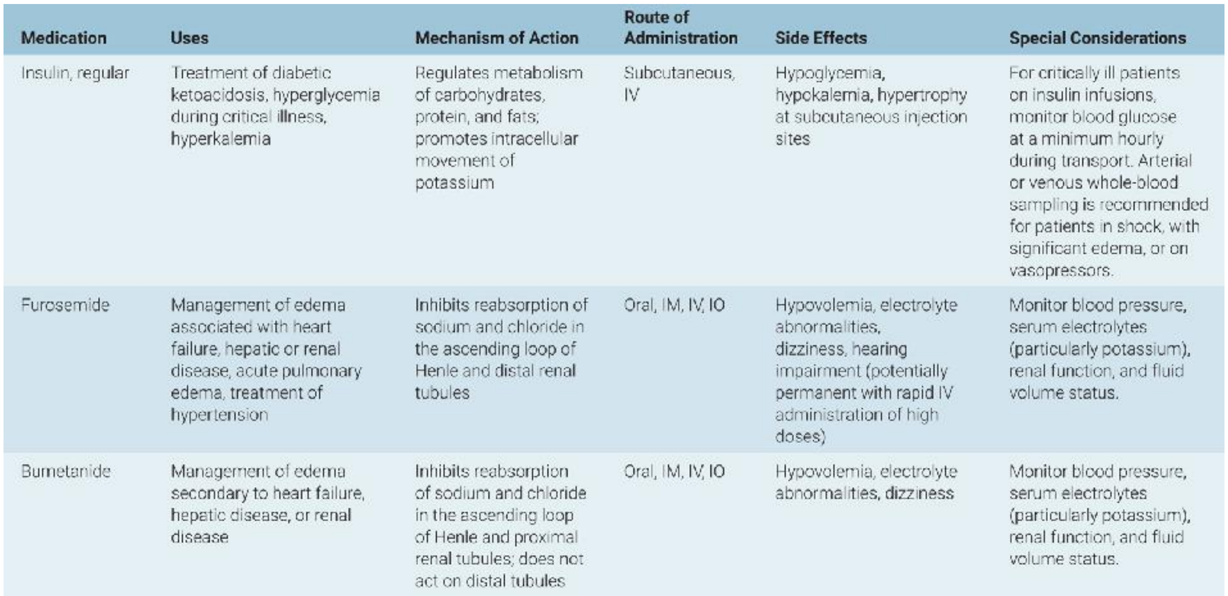
Tirofiban is administered by IV infusion. A loading dose of 25 µg/kg is administered over 5 minutes or less, followed by a maintenance infusion of 0.15 µg/kg/min, which is continued for 18 to 48 hours depending on the indication. Tirofiban is intended to be used in combination with other anticoagulants and antiplatelet agents.

The most common complication of tirofiban is bleeding. Profound thrombocytopenia (reduced platelet counts) has been reported with its use; if this adverse effect is confirmed, it requires discontinuation of the tirofiban and any concurrent heparin infusion. Consultation with medical control is necessary when discontinuation is contemplated, as a careful risk-benefit assessment is necessary.

Miscellaneous Medications

TABLE 8-13 profiles some other medications that CCTPs are likely to use on a routine basis when caring for patients.

TABLE 8-13 Other Medications Used in the Critical Care Transport Setting



Medication	Uses	Mechanism of Action	Route of Administration	Side Effects	Special Considerations
Insulin, regular	Treatment of diabetic ketoacidosis, hyperglycemia during critical illness, hyperkalemia	Regulates metabolism of carbohydrates, protein, and fats; promotes intracellular movement of potassium	Subcutaneous, IV	Hypoglycemia, hypokalemia, hypertrophy at subcutaneous injection sites	For critically ill patients on insulin infusions, monitor blood glucose at a minimum hourly during transport. Arterial or venous whole-blood sampling is recommended for patients in shock, with significant edema, or on vasopressors.
Furosemide	Management of edema associated with heart failure, hepatic or renal disease, acute pulmonary edema, treatment of hypertension	Inhibits reabsorption of sodium and chloride in the ascending loop of Henle and distal renal tubules	Oral, IM, IV, IO	Hypovolemia, electrolyte abnormalities, dizziness, hearing impairment (potentially permanent with rapid IV administration of high doses)	Monitor blood pressure, serum electrolytes (particularly potassium), renal function, and fluid volume status.
Bumetanide	Management of edema secondary to heart failure, hepatic disease, or renal disease	Inhibits reabsorption of sodium and chloride in the ascending loop of Henle and proximal renal tubules; does not act on distal tubules	Oral, IM, IV, IO	Hypovolemia, electrolyte abnormalities, dizziness	Monitor blood pressure, serum electrolytes (particularly potassium), renal function, and fluid volume status.

Abbreviations: IM, intramuscular; IO, intraosseous; IV, intravenous

Description

Insulin

Insulin infusions are used for control of hyperglycemia in patients with diabetic ketoacidosis (DKA). In 2001, insulin infusions became popular across the spectrum of critical care after a study suggested that glycemic control conferred a significant mortality benefit. Since then, it has become abundantly evident that hyperglycemia in critically ill patients is associated with an increase in infection and death. Currently, for most critically ill patients, the American Diabetic Association recommends initiating insulin in patients with a blood glucose of 180 mg/dL or higher, with a goal of maintaining blood glucose between 140 and 180 mg/dL. Likewise, protocols and monitoring need to be designed to avoid hypoglycemia (blood glucose ≤70 mg/dL), which is associated with increased mortality—a risk that increases significantly with even brief episodes of severe hypoglycemia (blood glucose ≤40 mg/dL).

Insulin infusions are usually prepared by adding 100 units of regular insulin (U-100 Humulin-R or Novolin-R) to 100 mL of normal saline. If initiating an infusion in a patient whose blood sugar has triggered the need for glycemic control (ie, blood glucose ≥180 mg/dL), the starting dose is usually 1 to 2 units/h. Incremental dose changes are made hourly according to local protocol or in 0.5 to 1 unit/h steps. The dose needed to maintain a blood glucose level within the target range varies by patient.

For treatment of DKA in adults, fluids are usually the first-line therapy. Once the serum potassium is verified, insulin infusions with or without boluses, depending on institution-specific protocols, are initiated. Of note, in patients with serum potassium less than 3.3 mEq/L, insulin is usually held until potassium is repleted and its level is greater than 3.3 mEq/L. Patients may need continuous potassium repletion while receiving IV insulin. The insulin infusion is usually initiated at 0.1 unit/kg/h, with a goal of reducing the blood glucose by 50 to 75 mg/dL in the first hour. If this outcome is not achieved, the insulin dose should be increased per institutional protocols (eg, doubled each hour until the blood glucose falls by 50 to 75 mg/dL/h). When the serum glucose reaches 250 mg/dL, the insulin dose is usually decreased and dextrose-containing IV fluids are infused to maintain blood glucose between 150 and 250 mg/dL until any acidosis is resolved.

Like nitroglycerin, insulin is absorbed by the plastics used in intravenous tubing. Tubing should be primed with 20 to 25 mL (run through the tubing and wasted) to minimize insulin infusion losses to IV tubing lines.

In any patient receiving an insulin infusion, blood glucose should be checked at least hourly and more often with any titration. When hypoglycemia occurs, the infusion should be stopped and the patient’s blood glucose checked every 15 minutes. Most protocols suggest restarting insulin infusions that have been held for hypoglycemia at 50% of the previous dose. When hypoglycemia is significant or symptomatic, oral or intravenous dextrose should be administered.

Medication Safety Note

One medication safety issue with insulin is how doses are ordered and charted. The abbreviation “u” should never be used in place of “units” because it may be misinterpreted as a number. Also, a decimal point should always be preceded by a zero in values less than 1 (eg, 0.5 unit, not .5 u). Finally, never follow a decimal point with a zero (eg, 5 units, not 5.0 u). These rules are especially important when charting is handwritten.

Furosemide

Furosemide is a loop diuretic. It inhibits reabsorption of sodium and chloride ions in the proximal and distal renal tubules and loop of Henle, resulting in excretion of sodium, potassium, and excess water into the urine. This agent is used to treat edema associated with heart failure and hepatic or renal disease; it is also administered as an adjunct treatment for oliguria (low urine output) in patients with severe renal impairment.

In the CCT setting, furosemide may be administered as a continuous infusion at rates of 10 to 40 mg/h. When the patient’s urine output is less than 1 mL/kg/h, the dose is usually doubled to a maximum of 80 to 160 mg/h. High doses increase the risk of ototoxicity, which can also occur as a result of too-rapid injection of bolus doses (more than 4 mg/min).

The onset of action for IV furosemide is 5 minutes, and its duration of action when given by this route is 2 hours. When furosemide is given orally, its duration of action is 6 hours—hence, the brand name Lasix, which implies the drug lasts 6 hours.

Bumetanide

Bumetanide is a loop diuretic that is significantly more potent than furosemide; in fact, 1 mg of bumetanide is equivalent to 40 mg of furosemide. Bumetanide is often used when patients fail to respond to furosemide.

Like furosemide, bumetanide can be given as a continuous infusion, usually administered at 0.5 to 2 mg/h. The onset of action of IV bumetanide is 2 to 3 minutes, with peak effects usually observed in 15 to 30 minutes. The duration of action is 2 to 3 hours. Boluses of bumetanide should be administered over 1 to 2 minutes.

Medication Infusion Technique

The standard of care for medication infusion during CCT mandates use of infusion pumps for any continuously running infusion. When patients are being transported by aircraft, CCTPs should recognize that actual delivery rates for fluids not infused via pumps will be affected by changes in altitude. Specifically, when altitude increases, IV drip rates will increase; conversely, when altitude decreases, IV drip rates will decrease. Flow rates should not be affected at 1,500 feet to 2,000 feet.

A two-tone alarm from the infusion system indicates that either the infusion is complete or the battery is low. Four quick beeps and a corresponding red light alarm on the screen signal a more serious problem. Silence the alarm and press the *Alarm Channel* key if needed to access alarm information, then press *Start/Stop* to restart fluids.

The sequence for medication infusion is presented in **Skill Drill 8-1** and described here:

1. To set up a medication infusion system, press the *On/Off* key for 1 second, and then prime the tubing system **Step 1**.
2. Pull the white slide clamp on the cassette to the out position, and insert the cassette into the appropriate channel **Step 2**.
3. After placing the tubing collar into the recessed area, select the appropriate channel by pressing *ABC* on the soft pad that corresponds to the pump **Step 3**.
4. Set the rate and volume on the system, and press the *Accept* button **Step 4**.

5. Press *Select* to advance the volume infused; press *Clear* to zero the amount infused **Step 5**.
6. Press the *Standard Display* key, and then press *Start/Stop* to initiate the infusion **Step 6**.

Administration of fluids through a dial-a-flow device is not considered reliable and should be switched to an IV infusion pump.

Summary

Numerous medications are used in critical care medicine, and many of them pose greater risk of harm than the medications used in standard prehospital medicine. It is imperative that CCTPs have an understanding of both the medications used during their transports and the medications they may encounter at sending facilities. Any continuous infusion must be delivered using an infusion pump. Continued review and refamiliarization with medications are necessary to effectively treat critical care patients.

CASE STUDY

You are called to a regional hospital emergency department for a male patient who is experiencing an active STEMI and requires cardiac intervention and emergent air transfer to a tertiary care facility. Transport time by air will be 45 minutes.

On your arrival, the staff reports that the 55-year-old, 269-pound (122-kg) man presented to the emergency department (ED) with chest pain with a rating of 7/10 and mild shortness of breath. He has had chest pain on and off for the past few days and awoke this morning with the current symptoms. His 12-lead ECG revealed an active STEMI.

The patient's medical history and report per the referring registered nurse includes hypertension, coronary artery disease, and hyperlipidemia. This patient's prescription medications include metoprolol, clopidogrel, and aspirin.

In the ED, the patient was placed on the monitor and given oxygen at 2 L/min via nasal cannula to achieve an oxygen saturation of 95%. An 18-gauge angiocatheter was placed in his left forearm, and a 20-gauge angiocatheter was placed in his right hand. Blood samples were obtained. Both IV lines provided 0.9% saline at to-keep-open rates. The patient received three nitroglycerin tablets sublingually, producing total relief of his chest discomfort, and a drip of 10 µg/min was initiated with a concentration of 100 mg/250 mL running at 3 mL/h. Aspirin 325 mg was also given. Serial ECGs revealed ST elevation in the V_3 and V_4 leads, indicative of an anterior infarct. Positive cardiac markers confirmed the ECG findings. A heparin drip of 1,000 units/h was initiated using a concentration of 25,000 units/250 mL running at 10 mL/h. A bolus of 30.5 mg of abciximab was given, and a drip using 9 mg/250 mL was initiated at 10 µg/min, or 16.7 mL/h. The patient also received 5 mg of metoprolol via IV push. His pain is currently a 4/10. His temperature is reported as 98.6°F (37°C). The referring nurse has no further report.

Your assessment reveals the patient is alert and oriented and consents to transfer. He reports chest pain at 4/10, but his shortness of breath feels resolved. Current vital signs at this facility are a blood pressure of 126/86 mm Hg, a pulse rate of 84 beats/min, and normal sinus rhythm on the ECG; respirations of 16 breaths/min and nonlabored; and an oxygen saturation as measured by pulse oximetry (SpO_2) of 96% with 2 L/min oxygen via nasal cannula. The patient feels afebrile to touch. An examination of the patient's head, ears, eyes, nose, and throat reveals equal reactive pupils at 5 mm, a midline trachea, no jugular vein distention, and no audible carotid bruits on auscultation. His chest is symmetric with equal rise and fall, and breath sounds are clear with auscultation. His S_1 and S_2 heart tones are normal on auscultation, and no rubs or gallops are noted. He has a moderately obese abdomen and no organomegaly or pulsatile masses. His extremities are within normal limits, with no trauma, deformity, or other abnormality noted. Pulse quality is normal on palpation. All IV lines are infusing well, and no local redness or swelling is noted. The nitroglycerin is infusing in the right IV line, and the heparin and abciximab are infusing in the left IV line.

You duplicate the flow rates and transfer his IV lines to your pumps. The ECG, blood pressure cuff, and SpO_2 sensors are transferred to your monitors. Oxygen is transferred to your portable cylinder. The patient is transferred to your cot and secured, and IV lines are transferred to the cot. You discharge the patient from the ED, obtain all records, and move to your helicopter. You place the patient in the aircraft, and all oxygen and power needs are transferred to on-board systems. You lift off and transport is begun.

En route, you note no changes in the patient's hemodynamic status, as vital signs remain within the previously described range. The patient continues to report chest pain at 4/10 but has no shortness of breath. He denies having any nausea. Medical control and standing protocols are initiated. You arrive within the 90-minute door-to-balloon time standard at the tertiary care facility, and the patient is moved directly to the catheterization lab and transferred to the facility's staff without incident. You give your report and all paperwork to the charge nurse and retreat to complete your paperwork and prepare your equipment for the next call.

1. Are the medication doses correct?
2. Are any compatibility issues identified?
3. Which further adjustments can be made to current medications to benefit this patient?

Analysis

The case study represents one of the most common scenarios a CCTP will face: The medication dosing is *not* correct. Although all the concentrations are within standards, the dosing for nitroglycerin is not correct. The patient is receiving 20 μg/min with this concentration versus the intended 10 μg/min.

The administration of heparin and abciximab also warrants scrutiny. Although abciximab is not reported as having incompatibility issues when infused via the same IV line in this case, the manufacturer recommends that it be run in a separate IV line. This could be accomplished by placing the nitroglycerin and heparin into the same IV line.

This patient's condition may be better treated by increasing his nitroglycerin dose incrementally and monitoring his responses.

This patient has had, and is receiving, multiple anticoagulant medications. He must be monitored for any bruising or bleeding. If bleeding is suspected, the CCTP should stop the infusions and immediately consult with medical control or follow established protocols. No prescreening information for anticoagulation was readily offered. It is always good practice to ask for this information because it may uncover a contraindication to medication use. Speed is essential in transporting time-sensitive patients, but moving too quickly without paying attention to details is just as detrimental to the patient as moving too slowly.

A standard treatment for STEMI does exist, but treatments and medications vary from region to region because of local preferences, drug availability and cost, and referral patterns related to facilities. CCTPs must be familiar with the protocols used in their region and the common treatment modalities.

The identification of a wrong medication dose is of paramount importance. Although all health care providers strive to provide accurate care, errors can and do occur. The CCTP must ensure a mistake is not repeated. Some of the most common errors involve mistaken concentrations, which result in dosing errors. This risk is increased when IV drips are hand-mixed by the practitioner. The CCTP must ensure concentrations are correct and match the dosing required. All medications administered using IV drips should be checked for flow rate and dosing accuracy. The CCTP must be well versed in many pharmacologic interventions. It is always recommended to consult up-to-date pocket guides or charts to ensure accuracy as well given the large number of medications the CCTP may encounter.

Another issue that the CCTP must consider is compatibility. Although many medications are compatible with each other, many are not. Again, the CCTP is responsible for double-checking all co-infusing medications for compatibility. Adjustments may be required to obtain compatibility in medications administered.

An understanding of pharmacology is a challenging part of CCTP practice. The responsibilities of the CCTP can be as simple as administering an oral medication or as complex as calculating doses, admixing medications, and administering simultaneous infusions. CCTPs are responsible for both maintaining their knowledge of current and emerging pharmacology and performing due diligence in practice.

PREP KIT

Ready for Review

- Pharmacology is defined as the study of the preparation, properties, uses, and actions of medications.
- Current and reliable medication information may be obtained from a variety of print and electronic reference sources.
- Many factors must be considered when selecting the most appropriate medication for a particular condition, including medication availability, the transport team's scope of practice, monitoring capabilities, the patient's clinical status, and medication-specific factors.
- The optimal medication for a particular situation may not be immediately available during patient transport. For example, specialized medications such as antidotes, thrombolytics, and antibiotics are not routinely carried by CCT organizations.
- Pharmacokinetics is the study of the metabolism and action of medications within the body, with particular emphasis on the time required for absorption, distribution in the body, metabolism (biotransformation), and mechanism of excretion.
- The route of administration affects how quickly and how much of an administered dose is absorbed into the patient's body. CCTPs generally use intravenous, intramuscular, subcutaneous, intraosseous, oral, sublingual, transdermal, nasal, and sometimes rectal routes for medication administration.
- The route of medication administration may affect bioavailability—the amount of an administered medication that reaches the patient's systemic circulation without any alteration.
- A medication or other foreign substance in the body undergoes elimination, biotransformation, or both. The kidneys and urinary system are often the primary routes of elimination.

- Biotransformation may lead to any of four outcomes: (1) an active drug may be changed into an inactive metabolite and eliminated; (2) an active drug may be changed into an active metabolite that causes continued or new clinical effects; (3) an active medication may be changed into a reactive metabolite that has a greater potential for action than its parent substance; and (4) an otherwise inactive substance may change into an active, potentially toxic substance.
- Medications work in one of four ways: (1) by binding with a receptor site on a particular cell to either promote or inhibit a specific activity of that cell; (2) by affecting the physical properties of a cell and, thereby, its functioning; (3) by combining directly with other chemicals within the body to either alter or limit the effects of a chemical or allow it to be removed; and (4) by altering a metabolic pathway.
- In downregulation, as the medication molecules bind to their corresponding receptor sites, the number of receptors decreases. In upregulation, the medication increases the number of receptor sites available for binding.
- The drug-response relationship correlates the amount of medication given with the response it causes.
- The onset of action is defined as how long it takes for the concentration of the medication at the target tissue to reach the minimum effective level.
- The duration of action is defined as how long the medication can be expected to remain above that minimum level to provide the intended action.
- The termination of action is the amount of time after the concentration level falls below the minimum level to the point at which it is eliminated from the body.
- The onset of action, duration of action, and termination of action combine to determine the therapeutic index for a medication, which gives an indication of the medication’s margin of safety

(defined as the ratio of a drug's lethal dose for 50% of the population to its effective dose for 50% of the population).

- Patients of different ages may have vastly different responses to the same drug, owing to age-related factors such as renal function, muscle mass, body water/fat content, and metabolic rate.
- Older adult patients often have slower absorption and elimination times, necessitating modification of the doses of many drugs administered to these patients.
- To correct for differences in weight between patients, drugs are sometimes dosed in milligrams or micrograms per kilogram of the patient's body weight.
- Other factors that may affect the dose-response relationship include the patient's sex, environmental factors (eg, stress), time of the medication's administration, the patient's overall state of health, and genetic factors.
- In pregnant patients, medications may pass from the mother's bloodstream into the placenta and ultimately affect the fetus. Medications may also pass into breast milk in breastfeeding women. When contemplating administration of any medication to a pregnant or a breastfeeding patient, evidence of risk and benefits of that medication should be reviewed.
- Every medication has side effects—that is, reactions that can manifest as undesired signs or symptoms but that are nevertheless expected based on how the medication works.
- The transport team must be adequately trained and equipped to recognize and effectively manage anticipated side effects or adverse reactions associated with a particular medication.
- An iatrogenic response is an adverse condition inadvertently induced in a patient by the treatment given. Some of these responses may be devastating and even potentially lethal.
- The most common unpredictable response encountered in the prehospital setting is an allergic reaction.

- The effects of one medication may alter the response of another medication in sometimes unexpected ways, resulting in a drug interaction.
- Medication errors are the most common errors in medicine. While many cause little to no harm, others can have serious, even devastating, consequences for the patient, their family, and caregivers involved in the error.
- The critical care transport environment continually exposes personnel and vehicles to temperature extremes; it is essential that medications remain within their required temperature ranges.
- Minimum requirements for the storage of controlled substances include housing them in a securely locked, substantially constructed cabinet with no sign or any other indication that the cabinet is used for the storage of controlled substances.
- Vasopressors include phenylephrine, norepinephrine, epinephrine, vasopressin, and methylene blue; some may be used as push-dose pressors. Vasopressors are typically administered to improve cardiac output.
- Epinephrine (a sympathomimetic agent) increases blood pressure by increasing vascular tone and cardiac stimulation, and supports respiratory function by opening larger airways. It is the drug of choice for treating patients with anaphylaxis.
- In anesthesia practice, providers may draw a syringe of an available diluted vasopressor drip and administer boluses to treat hypotension that is refractory to fluids (ie, push-dose pressors). The two medications most often employed in these combinations are dilute concentrations of epinephrine and phenylephrine.
- Inotropes include dopamine, dobutamine, and milrinone. Dopamine (a sympathomimetic agent) stimulates alpha-1 receptors when given at a higher dose, thereby producing peripheral vasoconstriction. Stimulation of the dopaminergic receptors may also result in increased myocardial contractility and cardiac output, increased renal output, decreased fluid volume, and increased blood pressure.

- Vasodilators and antihypertensives are used to lower blood pressure; they include sodium nitroprusside, nitroglycerin, hydralazine, clevidipine, and nicardipine.
- The traditional first-line medication for chest pain associated with cardiac ischemia is nitroglycerin. Nitroglycerin may also be used to treat hypertension. Nitroprusside is both an arterial and a venous dilator and is more potent than nitroglycerin; at lower doses, nitroglycerin is only a venous dilating agent.
- Hydralazine is an antihypertensive that is used as an intermittent IV bolus for emergent control of hypertension.
- Benzodiazepines may be used for treatment of anxiety and seizures and to provide sedation. These agents are the initial medications for seizures in prehospital and critical care transport settings.
- Aside from its use in the operating room for induction and maintenance of anesthesia, propofol is used as a sedative in mechanically ventilated patients. It is also commonly used for brief procedures requiring procedural sedation (eg, electric cardioversion).
- Etomidate is an ultra-short-acting general anesthetic used for procedural sedation, induction of general anesthesia, and intubation. Its short duration of action and favorable side-effect profile make it a popular choice for rapid sequence and emergent intubations.
- Ketamine is a general anesthetic that is increasingly being used on an off-label basis in the prehospital arena to provide procedural sedation and analgesia. It has also shown promise in rapid sedation of patients exhibiting signs and symptoms of excited delirium.
- Antipsychotic medications (eg, haloperidol, olanzapine, quetiapine) are often first-line therapies in patients with agitation and psychosis.
- The use of morphine and other opioids is an essential component of patient care during critical care transport. Other analgesic

medications used may include ketamine, acetaminophen, and NSAIDs.

- Anticonvulsants are used in patients with seizures, including status epilepticus, as well as in some other indications. They include levetiracetam, phenytoin, fosphenytoin, and valproic acid.
- Long-term chemical paralysis of the patient has serious implications for CCTPs and other health care providers caring for the patient. Intensive care providers can use a train-of-four measurement, post-tetanic count, or double-burst stimulation to assess for the correct level of neuromuscular-blocking agents in patients receiving long-term paralysis, but CCTPs require special training to interpret these tests.
- Paralytic medications are classified into two categories based on how they interact with acetylcholine (ACH) and the nicotinic receptors: depolarizing and nondepolarizing.
- Succinylcholine, the only depolarizing paralytic, stimulates muscle depolarization but then remains bound to the receptor, thereby preventing repolarization.
- Nondepolarizing agents competitively antagonize ACH at the postsynaptic receptors. They include pancuronium, vecuronium, rocuronium, atracurium, and cisatracurium.
- Stress ulcer prophylaxis is undertaken in critically ill patients with associated risk factors such as coagulopathy, severe sepsis, or mechanical ventilation for more than 48 hours. Histamine antagonists and proton pump inhibitors are used to reduce gastric acid secretion.
- Antihistamine medications, which inhibit the activity of histamine in the vestibular system, and medications that block the ACH receptors are often used to treat nausea and vomiting.
- Medications that antagonize the D_2 receptors, such as the phenothiazine-type antiemetics, are used for treatment of nausea and vomiting.
- The serotonin antagonists exert an antiemetic effect by selectively blocking serotonin receptors in the medulla.

- Octreotide is a synthetic peptide with actions analogous to somatostatin, but a longer, more clinically useful duration of action.
- Epoprostenol is used to treat pulmonary arterial hypertension. Although most commonly given via IV infusion, it may also be nebulized.
- Alprostadil is a vasodilator medication that is used during critical care transport to maintain a patent ductus arteriosus in newborns with certain congenital heart defects.
- Aerosolized epinephrine, which is given by small-volume nebulizer, is typically used for relief of respiratory distress due to stridor, bronchiolitis, laryngeal edema, and upper airway obstruction. It has also been effective in treating postextubation edema and croup.
- The management of cardiac arrhythmias involves several classes of antiarrhythmic medications, many of which are arrhythmogenic.
- Class I antiarrhythmic medications work by blocking sodium channels; they include anticholinergic medications such as quinidine, procainamide, and disopyramide.
- Class II antiarrhythmic medications (beta blockers) work by competitively binding to beta receptor sites to inhibit their stimulation. They are used to treat arrhythmias, hypertension, acute myocardial infarctions, and heart failure.
- Class III antiarrhythmic medications (potassium channel blockers) are particularly useful for treating reentry tachycardias and arrhythmias caused by cellular depolarization as a result of excessive excitability. Their use may produce prolonged QT intervals on the patient's ECG.
- Class IV antiarrhythmic medications (calcium channel blockers) cause vasodilation, negative inotropy, negative chronotropy, and negative dromotropy. Because these medications decrease the conduction velocity through the AV node, they are useful for treating tachyarrhythmias originating in the atria.

- When a patient is taking heparin, the CCTP should review the latest lab values and the partial thromboplastin time prior to transport and monitor the patient closely for bleeding problems.
- Alteplase is a thrombolytic agent used to treat acute ischemic stroke, acute massive pulmonary embolism, ST-segment elevation myocardial infarction (STEMI), and acute peripheral artery occlusions, and to clear clotted central venous catheters. Tenecteplase is an alternative to alteplase in management of STEMI and may be used in the near future for treatment of acute ischemic stroke.
- Glycoprotein IIb/IIIa inhibitors are antiplatelet medications. Abciximab is used during and after percutaneous coronary intervention for STEMI and following some carotid stent procedures; other antiplatelet agents include eptifibatide and tirofiban. All of these agents carry a risk of excessive bleeding.
- For most critically ill patients, interventions to control hyperglycemia should be triggered when the blood glucose level reaches or exceeds 180 mg/dL, with a goal of maintaining this level in the range of 140 to 180 mg/dL. Likewise, protocols and monitoring need to be designed to avoid hypoglycemia (blood glucose ≤70 mg/dL), which is associated with increased mortality.
- Diuretics are widely used by CCTPs for treating patients with fluid volume overload, cerebral edema, hyperkalemia, and rhabdomyolysis. The most commonly administered diuretic is furosemide.
- During air transports, when altitudes increase, IV drip rates will increase; conversely, when altitudes decrease, IV drip rates will decrease.
- Patients should always be placed on infusion pumps to ensure precise medication delivery during critical care transport.

Vital Vocabulary

absorption The process by which molecules are taken up into another medium or tissue.

acetylcholine (ACh) A chemical neurotransmitter of the parasympathetic nervous system.

agonist A molecule (medication) that binds and activates a receptor, producing a biologic response.

antagonist A molecule (medication) that blocks a receptor site from being stimulated by an agonist or other chemical mediators.

bioavailability The amount or percentage of a medication that reaches the systemic circulation without being altered.

biotransformation The process by which the body alters a medication.

chronotropic Altering the heart rate.

controlled substances Drugs whose manufacture, possession, and use are controlled by the government.

cross-tolerance A form of drug tolerance in which patients who take a particular medication for an extended period can build up a tolerance to other medications in the same class.

cumulative effect An effect that occurs when several successive doses of a medication are administered or when absorption of a medication occurs faster than its excretion or metabolism.

depolarizing paralytic A medication that causes neuromuscular blockade by binding and briefly activating receptor sites at the neuromuscular junction, preventing further activation of these sites and causing chemical paralysis.

distribution The process by which molecules move from the body's systemic circulation to specific organs and tissues.

dromotropic Influencing the conduction rate within the heart.

drug interaction The alteration of the action or metabolism of a particular medication when combined with another medication.

duration of action The amount of time a medication concentration can be expected to remain above the minimum level needed to provide the intended action.

extravasation An infusion-related complication in which the drug being administered intravenously leaks outside the vein and enters the surrounding tissues; if that substance is a vesicant, it can cause blisters and tissue damage.

first-order elimination The rate of elimination is proportional to the drug's plasma concentration.

first-pass effect A process by which the dose of an oral medication is reduced as it passes through the liver (and, for some medications, the gut as well as the liver) before it enters systemic circulation; also called first-pass metabolism.

half-life (T½) The time period required to eliminate one-half of the plasma concentration. During the second half-life, an additional 25% of the original plasma concentration is eliminated. After three half-lives, one-eighth of the original plasma concentration remains.

histamine A neurotransmitter that is released by cells in response to injury and in allergic and inflammatory reactions; it causes vasodilation and contraction of smooth muscle tissue.

iatrogenic response An adverse condition inadvertently induced in a patient by the treatment given.

idiosyncratic reaction An abnormal (and usually unexplained) reaction by a person to a medication to which most other people do not react.

indication The reason for using a medication; it may be an official use, approved by the FDA, or an off-label use, for a purpose other than those specifically noted on the medication's label.

inhibition A condition in which the presence of one medication decreases the effect of another medication.

inotropic Affecting the force with which cardiac muscle tissue contracts.

interference A direct biochemical interaction between two drugs.

mechanism of action The way in which a medication produces the intended response.

neuromuscular-blocking agents (NMBAs) Medications that bind to acetylcholine receptors, thereby inhibiting the action of acetylcholine; this effect blocks transmission at the neuromuscular junction and causes paralysis of the muscles.

nicotinic receptors Cholinergic receptors that bind with the neurotransmitter acetylcholine.

nondepolarizing agent A medication designed to cause temporary paralysis by binding in a competitive but nonstimulatory manner to part of the acetylcholine receptor; these medications do not cause fasciculations and have a longer duration of action than succinylcholine does.

onset of action The time needed for the concentration of a medication at the target tissue to reach the minimum effective level.

pharmacodynamics The branch of pharmacology that studies reactions between medications and living structures, including the processes of body responses to pharmacologic, biochemical, physiologic, and therapeutic effects.

pharmacokinetics The study of the metabolism and action of medications, with the particular emphasis on the time required for absorption, duration of action, distribution in the body, and method of excretion.

pharmacology The study of the preparation, properties, uses, and actions of medications.

potentiation The effect of increasing the potency or effectiveness of a drug or other treatment; it may occur when two medications are administered concurrently.

prodrug A medication that, once inside the body, becomes metabolized to a physiologically active form.

propofol-related infusion syndrome (PRIS) A constellation of symptoms, including arrhythmias (bradycardia or tachycardia), metabolic acidosis, hyperkalemia, rhabdomyolysis or creatine phosphokinase elevations, and progressive renal and cardiac failure, associated with use of propofol.

proton pump inhibitors (PPIs) Medications that reduce gastric acid secretion; they are used to treat gastroesophageal reflux disease and peptic ulcers.

receptor sites Specialized proteins on a cell that receive chemical mediator messages.

risk-benefit ratio An evaluation of the therapeutic benefits of a medication versus the risks associated with that medication's side effects.

side effects Reactions that can manifest as signs or symptoms that are not desired but are expected based on how the medication works.

status epilepticus A life-threatening neurologic disorder in which an individual experiences prolonged (more than 5 minutes) seizure or does not recover from such seizures.

steady state A point in drug administration at which the rate of administration (frequency and dose) is equal to the rate of elimination, resulting in a constant plasma medication level.

summation effect The process whereby administration of multiple medications can produce a response that the individual medications alone do not produce.

sympathomimetics Medications that mimic the body's sympathetic nervous system response (fight-or-flight response); include epinephrine and norepinephrine.

synergism An interaction of two or more medications that results in an effect that is greater than the sum of their effects if taken independently.

tachyphylaxis A condition in which the patient rapidly becomes tolerant to a medication.

termination of action The amount of time after the medication's concentration falls below the minimum effective level until the point at which it is eliminated from the body.

therapeutic index The ratio of a drug's lethal dose for 50% (LD_{50}) of the population to its effective dose for 50% (ED_{50}) of the population; a medication's margin of safety.

tolerance Physiologic adaptation to the effects of a drug such that increasingly larger doses of the drug are required to achieve the same effect.

vasopressor A medication that causes constriction of blood vessels, thereby causing blood pressure to rise.

Vaughan-Williams classification scheme A classification system for antiarrhythmic medications.

vesicant A substance that causes tissue injury.

zero-order elimination A process by which medications or chemicals are eliminated from the body at a constant rate, regardless of plasma concentration.

CHAPTER 9

Laboratory Analysis and Diagnostic Studies

Gregory Peters, MD
Christopher J. Hanowitz, MD

OBJECTIVES

After completing this chapter, you will be able to:

1. Understand the overall principles of laboratory analysis (pp 362–364).
2. Understand the difference between sensitivity and specificity (p 363).
3. Discuss the difference between specimen culture and sensitivity (pp 364–365).
4. Understand relevant basic chemistry and biochemistry (pp 365–366).
5. Recognize the most commonly ordered laboratory tests done in the emergency department and in the intensive care unit (pp 366–371).
6. Understand the importance of abnormal laboratory results as they relate to patient condition (p 364).
7. Discuss the causes of abnormal laboratory results (pp 367–369, 371–375, 380–382, 388–393).
8. Explain the proper procedure for collecting blood specimens (pp 382–385).
9. Identify the proper test tubes used for collecting blood specimens (pp 385–386).
10. Recognize which point-of-care testing may be performed during transport (pp 385–386).
11. Describe normal and abnormal values obtained during urinalysis and their implications (pp 387–389).
12. Understand the basics of diagnostic imaging, including standard radiography, computed tomography, magnetic resonance imaging, and ultrasonography (pp 389–396).

Introduction

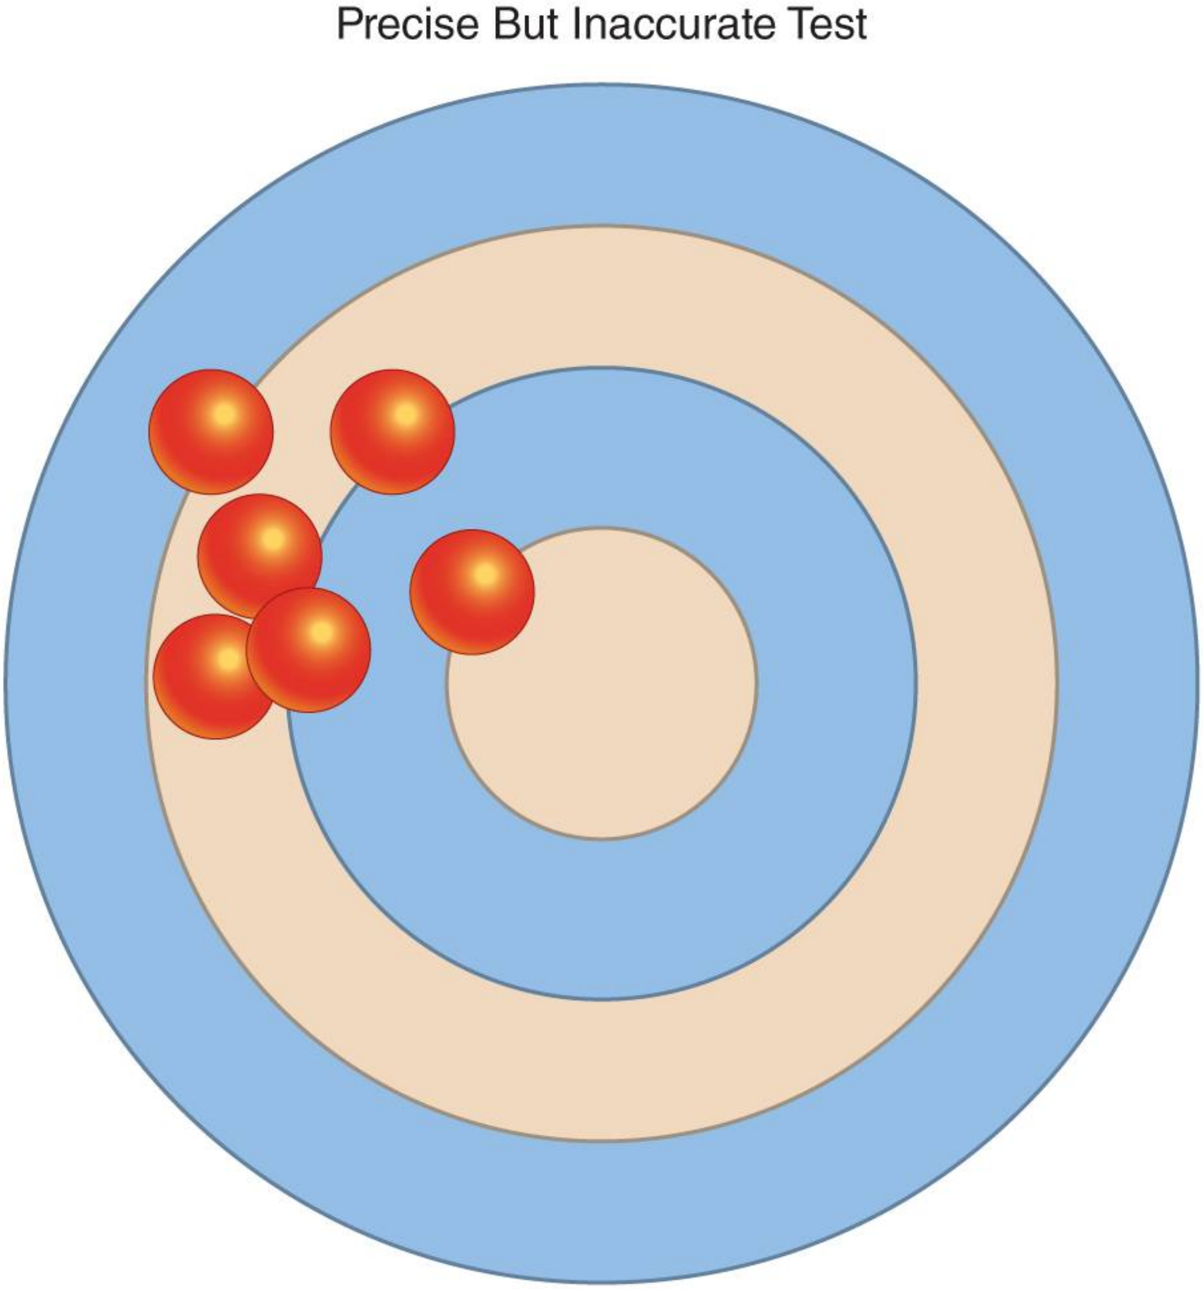
Critical care transport professionals (CCTPs), when performing interfacility transports, are often responsible for patients who have undergone a battery of tests and examinations at the referring institution. Laboratory tests (sometimes called labs) can be very useful in determining the seriousness of the patient’s condition or in preparing for potential problems while en route. Such tests may include laboratory analyses of the patient’s blood, urine, cerebrospinal fluid (CSF), or other body fluids. Similarly, as diagnostic imaging technology continues to advance, the prevalence and relevance of such tests will continue to increase within critical care transport (CCT).

Diagnostic analysis serves many purposes in the CCT environment. A CCTP must know the normal ranges for each lab value, as well as the associated physiologic meaning of each test. These tests are performed to support an evidence-based approach to patient care, in which providers use both well-tested principles and patient-specific knowledge to select and administer treatments. A proper understanding of diagnostic analysis, such as laboratory tests and imaging studies, can be invaluable in preparing for potential incidents, responding to changes in a patient’s clinical status en route, and ensuring optimal transfer of care at both the sending and receiving facilities.

Principles of Analysis

Laboratory analysis should run deeper than simply surmising whether the value is outside the normal range for that test. If the normal value range for creatinine is 0.6 to 1.2 mg/dL, for example, then a creatinine value of 4.5 mg/dL for a specific patient is clearly outside the normal range. But what does that actually mean for the patient? The most important point is to understand how this excess level affects the patient now and how it might affect the patient's condition while the transport team is en route to the receiving facility, including the patient's likely response to different interventions or higher risk of experiencing certain medical emergencies. The underlying principles that guide the analysis of all laboratory values must be ever-present in a CCTP's mind.

An appreciation of a lab test's **precision** and **accuracy** is essential to the proper use of that particular lab test. If the lab test is precise, results of performing it repeatedly on the same sample will be similar. For example, if a patient's serum sodium level is measured five times on the same sample, the values may range from 152 to 155 mEq/L. This test exhibits high precision (tightly packed values), but the results would be inaccurate if the patient's true serum sodium level is 140 mEq/L **FIGURE 9-1**. In contrast, if another test of the same patient's serum sodium was performed five times and yielded results of 135 to 145 mEq/L, this test would be fairly accurate but not precise **FIGURE 9-2**. The scientists who design laboratory tests strive for tests that are both precise and accurate, such that repeated measures will yield results that are both consistent and close to the true value.



Precise But Inaccurate Test

FIGURE 9-1 The sample lab results depicted here are precise (because results cluster together) but inaccurate (because results are out of the normal range [center circle]).

© Jones & Bartlett Learning.

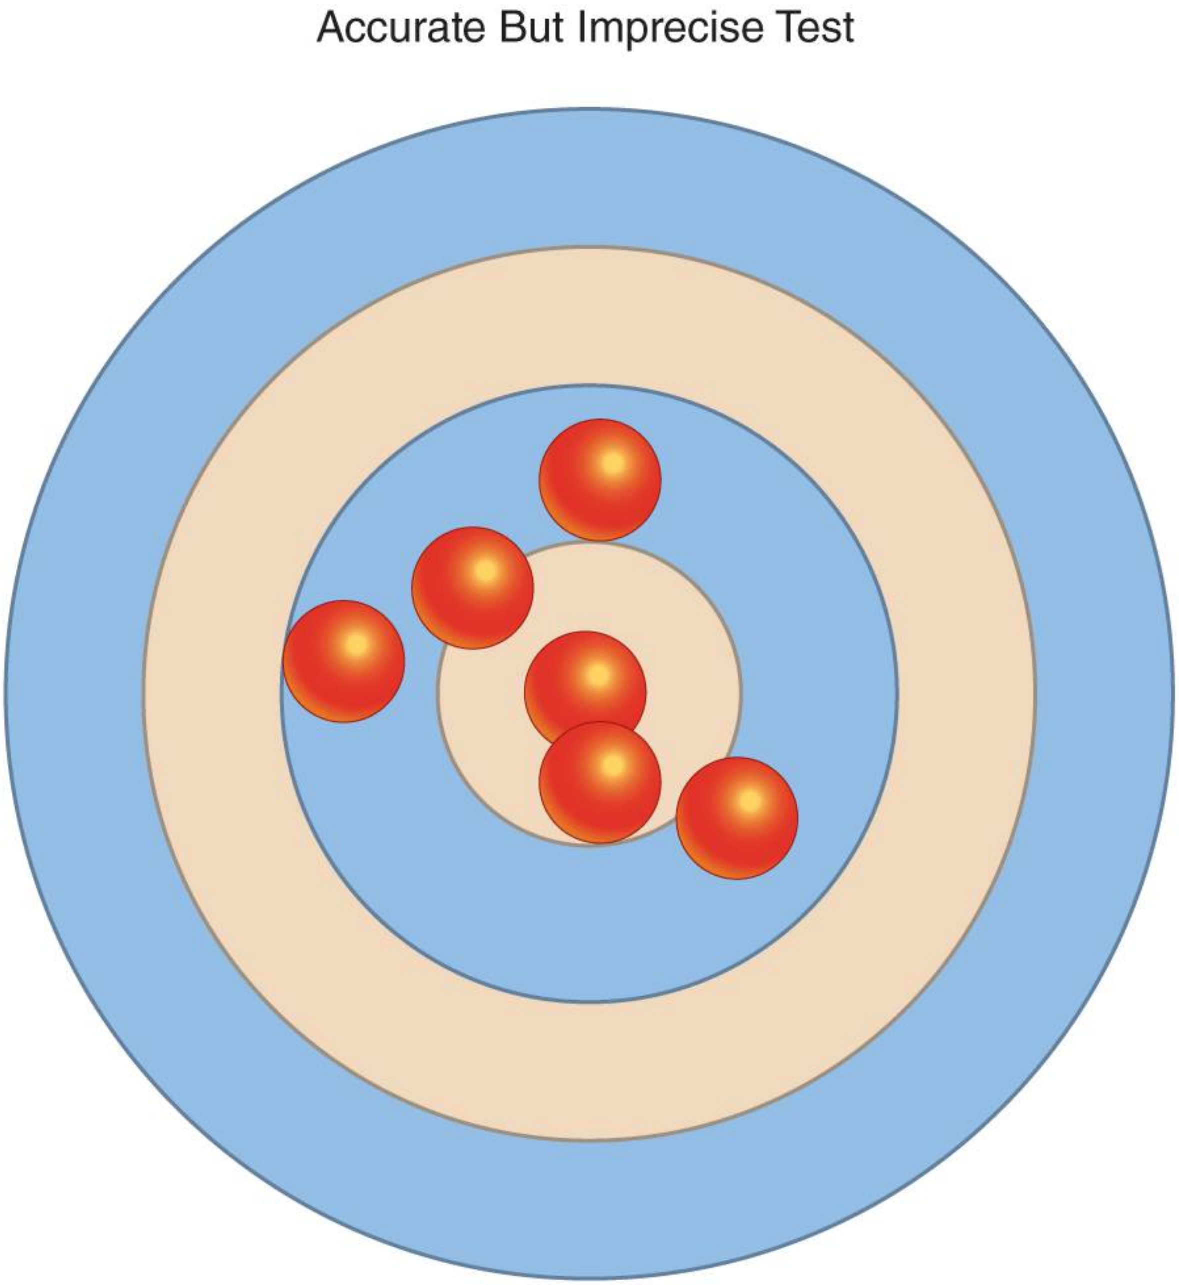


FIGURE 9-2 The sample lab results depicted here are imprecise (because results vary substantially) but accurate.

© Jones & Bartlett Learning.

Laboratory tests also have differing levels of sensitivity and specificity. **Sensitivity** refers to the ability of a test to indicate whether a person does or does not have a certain condition. If a test is highly sensitive, most of the people with a particular condition would have a positive result. If a test has a low sensitivity, many people with the condition would have a negative result. In other words, sensitivity is the proportion of people with the target disorder who have a positive test result. **Specificity**, in contrast, is the proportion of people without the target disorder who have a negative test result **FIGURE 9-3**.

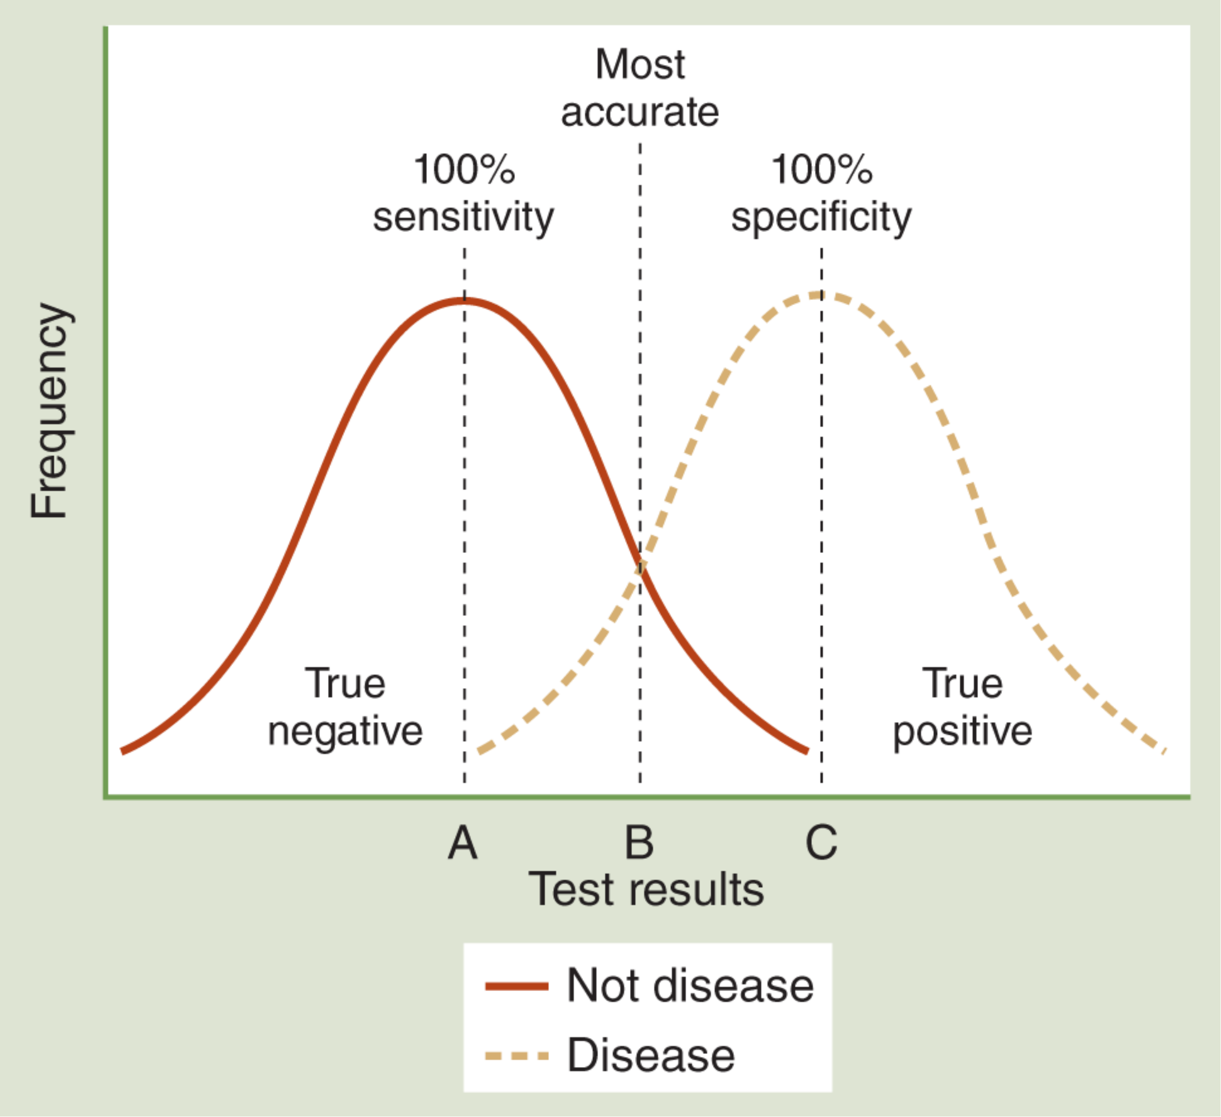

FIGURE 9-3 Graphic representation of the relationship between sensitivity and specificity. **A.** 100% sensitivity. **B.** Most accurate. **C.** 100% specificity.

© Jones & Bartlett Learning.

Description

Let’s consider an example that clarifies these concepts. The **D-dimer test** is a test of hypercoagulability that detects a fragment, D-dimer, from the fibrinolysis process. It is used to help diagnose and monitor diseases and conditions related to inappropriate clotting of the blood. This test provides a good illustration of sensitivity versus specificity. The sensitivity of the D-dimer test for the presence of deep vein thrombosis (DVT) is calculated by dividing the number of patients with a true positive test result by the actual number of patients with the disorder. For example, suppose researchers conduct a study to determine the accuracy of D-dimer tests in diagnosing DVT. If 13 out of the 14 patients included in this study have a true positive test result for DVT, the sensitivity of D-dimer testing would be 93%:

$$13/14 = 0.928, \text{ or } 93\%$$

In other words, the D-dimer test will correctly identify a patient with a DVT 93% of the time; the other 7% of results are false negatives (people with the condition who tested negative).

The specificity of the D-dimer test for the presence of DVT is calculated by dividing the number of patients with a true negative test result by the actual number of patients without the disorder:

$$72/91 = 0.791, \text{ or } 79\%$$

In other words, the D-dimer test will correctly identify a patient without DVT 79% of the time; the other 21% of results are false positives (people without the condition who tested positive).

Therefore, this D-dimer test is more sensitive than specific, meaning that it will be better at ruling out the condition (limiting false negatives) than for definitively diagnosing it (limiting false positives). **TABLE 9-1** presents another example depicting the effectiveness of D-dimer testing, this time illustrating values in patients diagnosed with pulmonary embolism.

TABLE 9-1 Results of D-Dimer Measurement Used in the Diagnosis of Pulmonary Embolism

D-Dimer Test Result	Pulmonary Embolism	No Pulmonary Embolism
D-Dimer ≥500 µg/L	195	278
D-Dimer <500 µg/L	1	197
Total	**196**	**475**
95% confidence interval	Sensitivity = 99.5%, 97.2–100	Specificity = 41.4%, 37.0–45.9

D-dimer testing for suspected pulmonary embolism in outpatients. *Am J Respir Crit Care Med*. 1997;156(2 Pt 1):492-496. The *American Journal of Respiratory and Critical Care Medicine* is an official journal of the American Thoracic Society.

Providers often combine tests with different sensitivity and specificity profiles to optimize these factors and make decisions about how to use resources more efficiently. For example, highly sensitive tests are typically used as screening tests to limit the number of diagnoses missed initially, and individuals with positive results are then subjected to highly specific tests to confirm the diagnosis in those with the target condition, thereby eliminating the initial false positives. It is also important to have an intention to treat prior to ordering or performing any test, so proper assessment of whether a given test is indicated is fundamental to the interpretation of any result. Unnecessary or misused tests can be difficult to interpret and can lead to faulty decision making.

Certain tests lend themselves to certain levels of analysis. For example, a serologic blood test for the presence or absence of the hepatitis B virus will often show a result as positive or negative, respectively. This is a *qualitative* assessment because the result does not identify the specific level of hepatitis B virus within the blood.

If information on the viral load of hepatitis B is desired, a *quantitative* test is performed to indicate the exact amount of the virus within the blood. Sometimes semiquantitative assessments are performed. For example, a urine test looking for blood in the urine may give the result as none, mild, moderate, or severe.

Novices in laboratory analysis can become overly concerned about the notion of normal versus abnormal lab values. One must remember that normal ranges were identified based on findings in healthy people, not the patients being transported by CCTPs. By convention, a **normal range** is empirically derived and represents values that 95% of *healthy* people would have for the particular test. Thus, for every 100 healthy people tested, 5 will not have results that fall in the normal range, even though their particular level is “normal” for them.

When this idea of normality is applied to patients who have acute conditions, one must be careful not to react too impulsively to spuriously high or low values. Not only is the normal range for a particular lab test subjective in the emergency department (ED) or intensive care unit (ICU) context, but an abnormal result may also be the desired effect of a particular treatment or the body’s healthy compensatory response to another condition. Consider the intentional fluid depletion that is implemented with patients who have experienced a traumatic brain injury. Part of the therapy may be to decrease the intravascular volume, which will result in abnormally high serum sodium values. Trying to correct the abnormal serum sodium value would harm the patient in such a case. The message here is simple: Although abnormal lab values cannot be ignored, it is essential to assess them within the context of the patient’s entire clinical picture.

With all tests, it is important to keep in mind that errors in specimen collection, identification, labeling, and laboratory analysis may result in erroneous values being reported. In addition, when evaluating laboratory results, it is critical to recognize that different laboratories have different normal ranges for the same tests. In fact, you may find that many of the normal ranges listed in this text differ from the ranges you are accustomed to using in your local practice. Three different labs may very well have three different sets of normal ranges for each test they perform. Thus, you must pay careful attention to the normal values (which are indicated on report forms) when reviewing a particular patient’s lab reports and always think critically when interpreting the patient’s results.

Specimen Cultures

With a specimen culture, the laboratory technician studies the growth of microorganisms in a biologic sample over a given period of time to learn about suspected infections in the sample's source. Blood, urine, sputum, and other body fluid cultures may all provide information that is used to identify microorganisms and treat specific infections. For example, a sputum culture is obtained when a respiratory infection is suspected. To obtain a sputum sample from a conscious patient, the patient must be well hydrated and able to follow commands to produce sputum from a deep cough. Deep suctioning may be performed to obtain a sputum sample from an unconscious patient. If the sample is not actually sputum, false results on the laboratory report, based on identification of mixed flora, are likely. Such results are not useful.

Bacteremia

Bacteremia can cause a severe systemic inflammatory response called sepsis, which is a medical emergency. Bacteremia is typically treated with empiric broad-spectrum antibiotics. Empiric antibiotic treatment refers to the administration of antibiotic therapy when infection is suspected but the specific pathogen involved is unknown; thus, empiric data are used to treat a patient for the pathogens associated with the suspected source of infection. Antibiotic therapy can then be updated when culture data become available and provide more specific details about the pathogen causing the infection.

Importantly, false-positive cultures can occur when skin flora (microorganisms that normally reside on the skin, such as gram-positive cocci) contaminate the blood sample. This contamination can be caused by inadequate preparation of the skin at the venipuncture site or by breaks in aseptic technique. Taking blood samples from multiple sites can improve the accuracy of blood culture testing, which is why patients will often have two samples in process or completed at the same time.

Blood culture is a common, important type of culture in which the specimen is a blood sample. Blood cultures can test for the growth of various pathogens, such as aerobic bacteria, anaerobic bacteria, or fungi. The most common indication for collecting blood cultures is concern for **bacteremia**, the presence of bacterial infection in the blood.

Sensitivity testing can be done as well. (Culture and sensitivity testing is sometimes called “C and S.”) For bacterial infections, the sensitivity results suggest which antibiotic will most effectively treat the organism causing the infection. A specimen for culture should be obtained before antibiotic therapy is started so that the actions of the antibiotic do not influence the culture result, and so that the proper antibiotic (one to which the microorganism is sensitive) can be selected. Usually, it takes 3 days for a laboratory to complete a culture and sensitivity report; an initial report is generated in approximately 24 hours, but a complete and final report will not be available for 72 hours.

Chemistry Review

Many consider the care of an acute patient to be akin to an advanced experiment in physiology. Physiology is built on the basics of chemistry and cellular biology, the principles of which should be part of the health care provider's educational background. Insightful test interpretation requires a firm grasp of these principles.

Ions

Ions are atoms that have gained or lost electrons. Recall that each electron has a single (−1) negative charge. If electrons are lost, the charge on the atom is less negative; one might also say that the atom is now more positive. The reverse is true if the atom gains electrons. A positively charged ion is referred to as a **cation**; a negatively charged ion is called an **anion**. If one electron is lost from an atom, its charge is +1. If two electrons are lost, its charge is +2. Conversely, if one electron is gained by an atom, its charge is −1. If two electrons are gained, its charge is −2.

Often ions of opposite charge will join together by forming an **ionic bond**. Sodium chloride (NaCl; table salt) is an example of a molecule whose atoms are joined by an ionic bond. When molecules with ionic bonds interact with water (recall that plasma is 90% water), they often dissociate into their basic ionic forms **FIGURE 9-4**. This is why Na^+ and Cl^- exist as separate ions within plasma, rather than as the compound NaCl. The ionic components of plasma are called electrolytes; they include sodium (Na^+), potassium (K^+), chloride (Cl^-), calcium (Ca^{+2}), and magnesium (Mg^{+2}), among others.

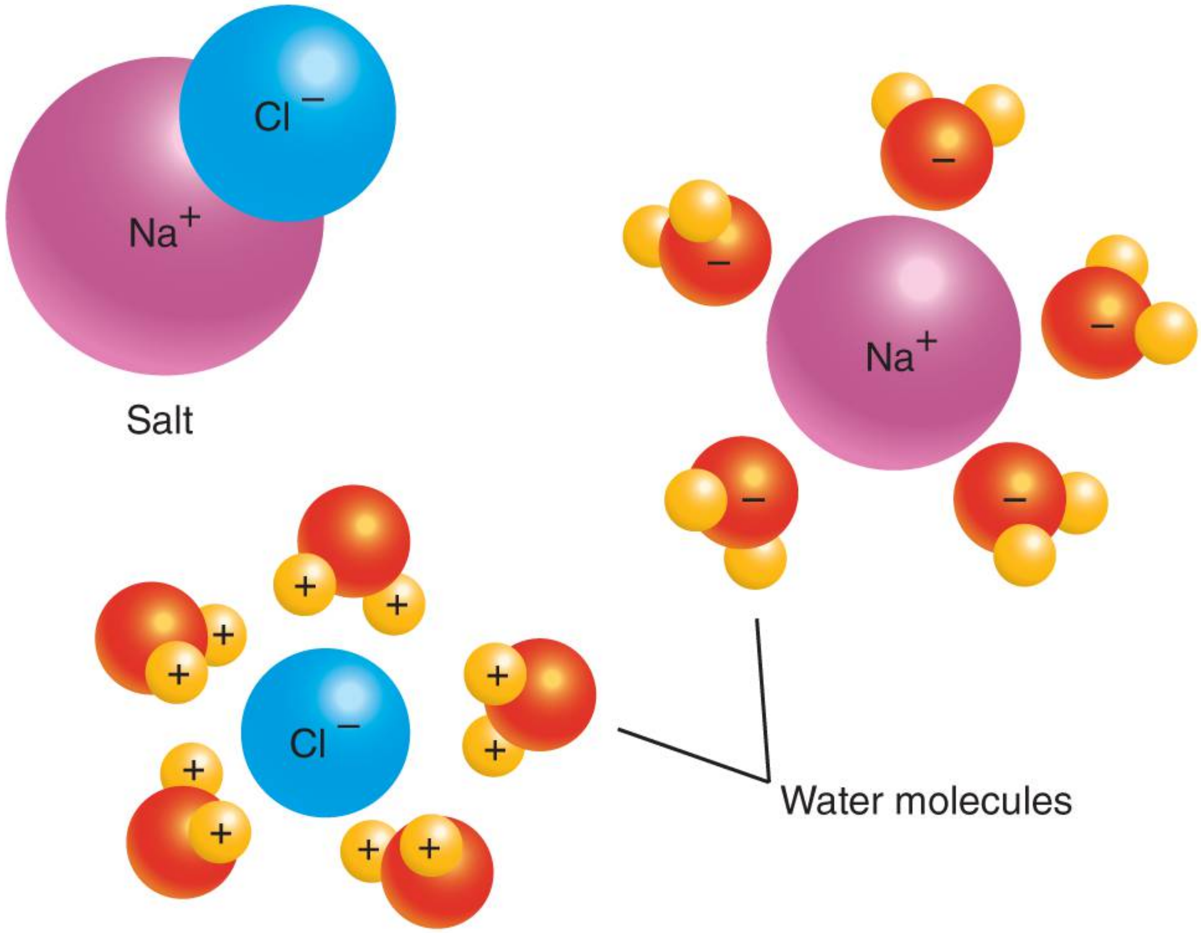

FIGURE 9-4 The ionic bonds of sodium chloride dissociate into their basic ionic forms when they interact with water.

Description

Amounts of ions are expressed in moles or equivalents. A mole is a unit representing 6.02×10^{23} atoms, in much the same way that “a dozen” is used to specify 12 eggs. Equivalents (Eq) are used to measure amounts of charged particles (ie, ions). Essentially, 1 Eq is equal to 1 mole of ionic charges. Given that a single Na^+ atom has one charge, 1 mole of Na^+ atoms has 1 mole of charges (1 Eq). Similarly, calcium (Ca^{+2}) has two charges, so 1 mole of Ca^{+2} has 2 moles of charges (2 Eq). This concept applies only to charged particles; uncharged molecules, such as proteins, are electrically neutral overall.

Osmolarity

Laboratory testing often involves the analysis of certain fluid characteristics. One characteristic of interest to CCTPs is the **osmotic pressure** created by the blood, CSF, or urine sample. Because human cells have semipermeable membranes, **osmosis** (the diffusion of water across membranes) is a major mechanism by which fluid moves between the body's different fluid compartments. In the space divided by the semipermeable membrane, the osmotic pressure is created by differences in concentrations of solutes (dissolved substances) found in the solutions on either side of that membrane.

The osmotic pressure generated by the particles in the fluid is called the osmolarity or osmolality, depending on the method of measurement. Physiologic measurement of osmotic pressure in humans yields information on osmolality (though it is often mislabeled as osmolarity). **Osmolality** measures the amount of dissolved substance in 1 kg of water, where as **osmolarity** measures the amount of dissolved substance in 1 L of water. Because the volume (liter) of a fluid depends on the temperature of the fluid, osmolality is used in lab tests—the weight (kilogram) of fluid used in this method is independent of temperature. The unit of measurement for osmolality is the osmole (Osm), which is the pressure created by 1 mole of particles in solution.

It is important to note a particular chemical property of osmosis: Osmotic pressure depends only on the number of particles present in the fluid, not on the size of those particles. In other words, a single protein or sugar molecule induces the same osmotic pressure as a single ion of sodium (Na^+).

Ultimately, we want to know the amount of a particular ion or protein that is present in the sample. This value is expressed as a **concentration**, which is the amount of the substance present in a given volume of fluid. For example, a patient's Na^+ concentration may be expressed as mmol/dL (millimoles of Na^+ per deciliter of blood). Because Na^+ has a single charge, the Na^+ concentration may also be expressed as mEq/L (milliequivalents of Na^+ per liter of blood). In the physiologic system, most concentrations are incredibly small. As a result, units of 1/1,000 (*milli-*) are often used to describe concentrations, including millimoles (mmol), milliequivalents (mEq), and milliosmoles (mOsm).

Laboratory values are reported in either conventional units (such as milliequivalents per liter) or Système International d'Unités (SI units; such as millimoles per liter). Many laboratories use SI values for some tests and conventional units for others, or they might use only conventional units. When reviewing results for a patient, CCTPs need to be sure that the reported units of measure are the same as the units of measure (ie, both conventional or both SI) used to define the normal range.

Each laboratory has its own normal ranges, which usually are printed on the laboratory report along with the patient-specific values. Note that the normal ranges for measurements performed by a certain device may differ from one instrument manufacturer to another. CCTPs should be familiar with the normal ranges for tests often used in the CCT setting, and they should be alert to the normal ranges listed for the tests performed for a specific patient, especially when comparing results from different facilities.

Biochemistry Review

Examining the basic ions and fluid properties provides only part of the story. To ascertain how well an organ (such as the liver) is functioning, it is necessary to look at the levels of various proteins and enzymes in a serum sample. Thousands of different kinds of proteins are found in the human body, and specific laboratory tests examine the amounts of the various types of proteins present in a sample.

Enzymes are critically important proteins that act as catalysts for biochemical reactions. The formation of one biologic substance from another may proceed slowly when just the two substances are present; with the addition of the appropriate enzyme to catalyze the reaction, however, the reaction rate may increase many times. Methods of measuring enzyme levels often rely on this basic catalytic principle. The beginning substrate (material) for the reaction is added to the sample, and the amount of product generated in a given time is measured. By knowing the beginning amount of substrate and the amount of product produced and by assuming normal enzyme function, one can then calculate how much enzyme is present. The function of enzymes is measured in units per liter (U/L), which is the amount of enzyme that catalyzes 1 micromole (μmol) of substrate per minute.

Lab Panels

In laboratory testing, groups of related tests can be performed as a single unit, called a **panel** (or profile). The single unit comprising these related tests is often named for the common link among those tests. For example, a liver panel consists of a set of tests that examine liver function, whereas a basic electrolyte and metabolite panel may be called a Chem-7 (referring to a chemistry panel of seven tests). In a patient's hospital chart, these panels are written in the form of a matrix.

Serum Chemistry/Metabolic Panels

Examination of the electrolytes and metabolites in the extracellular fluid is one of the most basic and fundamental assessments done in the ED or ICU. Often this testing takes the form of a standard panel —that is, the basic metabolic panel (Chem-7) **FIGURE 9-5**.

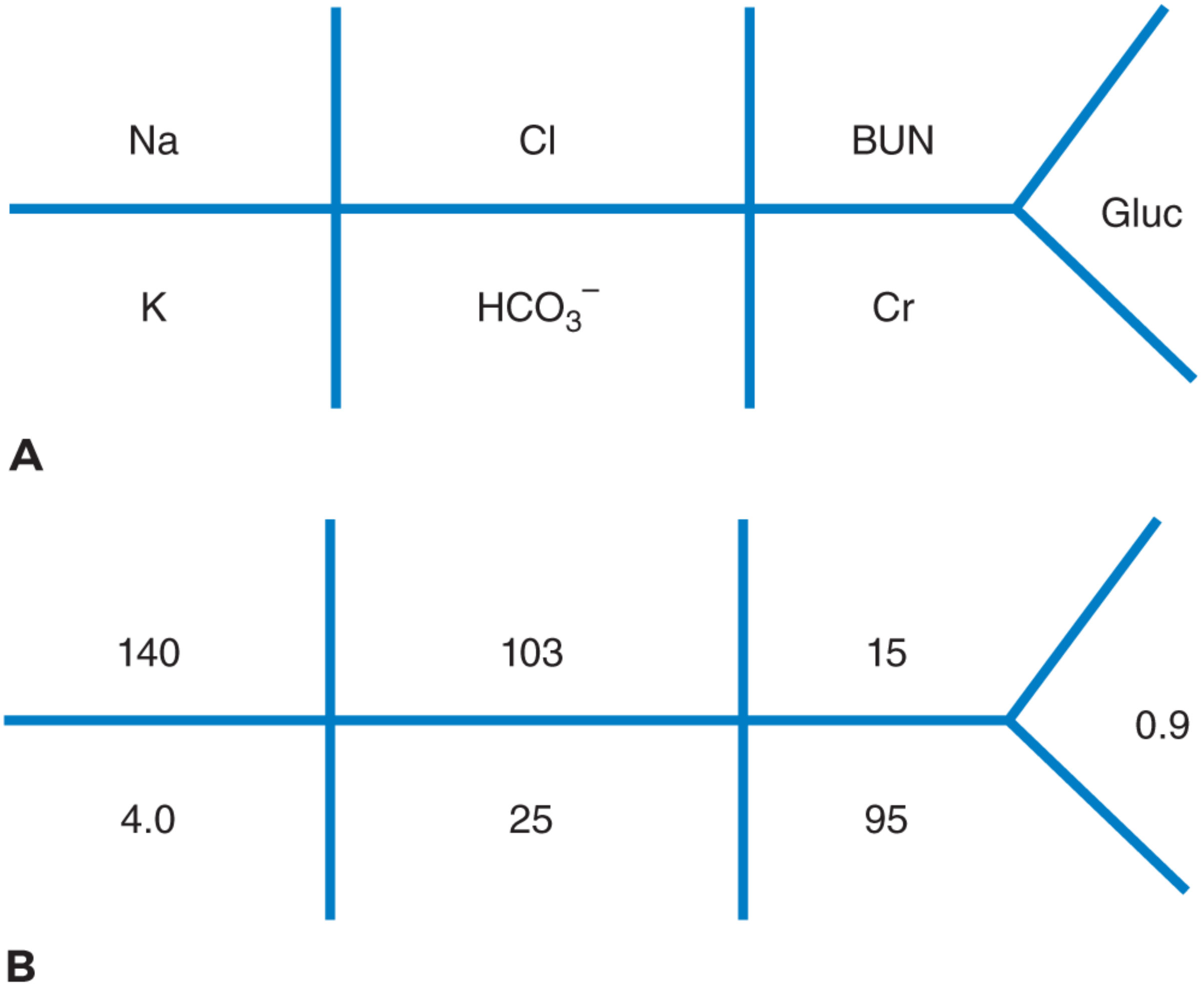

FIGURE 9-5 A. The items measured in a basic metabolic panel, shown in the format in which values are written. **B.** An example of how the values would be written, with each slot representing a particular lab value. These values are for a healthy person.

Description Description

Sodium

Sodium (Na$^+$) is the major extracellular ion; its serum concentration in a healthy person ranges from 136 to 142 mEq/L (mmol/L). In contrast, for intracellular concentrations of Na$^+$, the normal range is only 3 to 20 mEq/L. Dramatic changes in a patient's serum sodium level are possible, primarily due to changes in extracellular water concentrations. As a patient becomes depleted of free (solute-free) water, the serum sodium concentration increases; that is, more sodium ions are present per liter of water in the body. The introduction of excess extracellular water (without additional sodium) will, therefore, decrease serum sodium levels by diluting the concentration.

Serum sodium is a convenient marker for a patient's fluid status and one of the key components of the serum osmolality calculation (explained later in this chapter). Unlike with potassium derangements (discussed later), an abnormal sodium level does not manifest as electrocardiographic (ECG) changes. Instead, most signs and symptoms revolve around neurologic sequelae, which stem from changes in osmolality.

Hypernatremia (elevated sodium levels) is not uncommon in the patients seen in the CCT setting. For example, an elevated sodium level may be observed in a patient with a traumatic brain injury as a consequence of treatment at the referring hospital. Hypertonic saline (HTS), mannitol, and diuretics may all be given to such a patient in an effort to reduce cerebral edema. Serum sodium levels in patients with traumatic brain injury, therefore, are often elevated. While no absolute ceiling has been identified, mortality appears to increase when sodium levels exceed 155 mEq/L.

Hyponatremia (an abnormally low level of sodium in the blood) often results from an excess of free water or excessive sodium depletion. It may be seen in patients with endocrine disorders, congestive heart failure, renal failure, or liver disease and in patients undergoing diuretic therapy. Although some debate exists about how rapidly a hyponatremic state should be corrected, slower appears to be better (4 to 6 mEq/L per 24-hour period), to avoid causing subsequent neurologic problems.

Patients with a sodium imbalance (high or low) need to be monitored for intake and output, including oral and IV input. A sodium level of less than 125 mEq/L can result in behavioral changes, confusion, delirium, increased respiratory rate, muscle twitching, increased intracranial pressure, and cardiac abnormalities. Increased sodium levels can cause fluid retention and cardiac abnormalities.

Potassium

Whereas sodium is the major extracellular cation, potassium (K^+) is the major intracellular cation. The extracellular K^+ concentration (as typically measured in blood) is normally 3.5 to 5.0 mEq/L.

Of primary concern is the effect of an elevated K^+ level on cardiac cells, as cardiac arrhythmias tend to occur with **hyperkalemia** (an abnormally high level of potassium in the blood). If not properly managed, cardiac arrhythmias associated with hyperkalemia pose a high risk of progressing to cardiac arrest and death. Weakness and paralysis are physical findings associated with hyperkalemia. When patients do show ECG changes, the earliest changes, occurring at potassium levels of 5.5 to 6.5 mEq/L, consist of classic peaked T waves and a shortened QT interval. This progresses to lengthening of the PR and QRS intervals, followed by flattened P waves when the potassium level exceeds 7.0 mEq/L. Derangements in other electrolytes (eg, hypocalcemia, hypomagnesemia, and hyponatremia) can exacerbate hyperkalemia. Hyperkalemia can occur in a patient receiving acute care as the result of excessive potassium supplementation, intracellular to extracellular fluid shifts with cellular lysis (seen with crush injuries and tissue necrosis), drug administration (eg, angiotensin-converting enzyme [ACE] inhibitors), metabolic acidosis, and decreased excretion, as might occur in acute renal failure.

CCTPs should be aware that many abnormally high potassium levels seen on lab results are actually erroneous reports. For example, cellular lysis (hemolysis) can cause an elevated potassium level, so if the sample is hemolyzed before its analysis, an incorrect value may be reported. In fact, the most common cause of hyperkalemia diagnosis is lab error, usually involving hemolysis during collection or transportation of the specimen. For this reason, the first consideration when evaluating hyperkalemia is to redraw the specimen, in addition to assessing the patient and checking an ECG for associated changes.

The urgency in correcting hyperkalemia is predicated on the symptoms and cause. Hyperkalemia resulting from massive tissue breakdown (eg, crush injury, tumor lysis syndrome, rhabdomyolysis) can accelerate rapidly and should be treated aggressively. In contrast, chronic hyperkalemia of less than 7.0 mEq/L that is not accompanied by symptoms or ECG changes may not require immediate or aggressive treatment.

Causes of **hypokalemia** (an abnormally low level of potassium in the blood) include cellular shifts (eg, as the result of insulin administration or hypothermia) and increased excretion of potassium (gastrointestinal [GI] tract or renal losses). Although younger patients may have a higher tolerance for decreased levels of potassium, older patients (especially those taking digitalis preparations) are more likely to have arrhythmias and ECG changes with low K^+ levels.

Low K^+ levels result in muscle pain, hyporeflexia, nausea, vomiting, and orthostatic hypotension. High K^+ levels can cause cardiac abnormalities, particularly atrioventricular and intraventricular blocks. Atrial arrest is likely when the K^+ level reaches 9 mEq/L.

For any patient who has a cardiac history, altered renal function, liver disease, or GI disturbances, or who is receiving insulin, a recent K^+ level should be available for review before transport.

Special Populations

Older patients with decreased potassium levels, especially those taking digitalis preparations, will have cardiac changes. Hyperkalemia can exacerbate digitalis toxicity.

Chloride

Chloride (Cl^-) is the major extracellular anion. Its single electrical charge is responsible for offsetting the positive charges of both Na^+ and K^+, thereby maintaining electrical neutrality within the body. Serum concentrations of chloride range from 96 to 106 mEq/L in healthy people.

Chloride is an important means by which the kidney concentrates urine. Patients with **hypochloremia** (an abnormally low level of chloride in the blood) may have impending renal dysfunction. Note, however, that patients receiving diuretic therapy may routinely have abnormally low chloride levels. Strangely, patients who experience excess diuresis can also exhibit **hyperchloremia** (an abnormally high level of chloride in the blood).

In practice, chloride levels mimic sodium levels; that is, when hypernatremia is present, hyperchloremia is often observed as well. Clinically, serum chloride levels help differentiate the various types of metabolic acidosis.

Bicarbonate and Carbon Dioxide

One of the most basic indications of the acid–base status of a patient is the *venous* **bicarbonate (HCO_3^-)** level. Confusing as it may seem, the carbon dioxide level (CO_2) reported on lab results is not a CO_2 level at all; instead, this test indicates the amount of HCO_3^- in the venous sample. CO_2 and HCO_3^- exist in equilibrium according to the following equation:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Thus, the levels of CO_2 and HCO_3^- in the body are related, although they are actually very different substances.

CO_2 is a gas, so when it is measured, the value should be expressed as a partial pressure. HCO_3^- is an ion; thus, as with the other ions mentioned earlier in this chapter, its measured value is expressed as a concentration. A level below the normal range could indicate metabolic acidosis or respiratory alkalosis, whereas an elevated level could indicate metabolic alkalosis or respiratory acidosis. Therefore, this lab value can be helpful when working to understand the balance between a patient’s metabolic and respiratory processes, which produces the current pH of the blood. The normal HCO_3^- value is 21 to 28 mEq/L, and the normal CO_2 value is 22 to 28 mEq/L.

Blood Urea Nitrogen

A product of protein catabolism, urea is related to the amount of protein intake, protein metabolism, and rate of excretion. Urea is considered a useful marker for adequate kidney function because its level in kidney filtrate is often the same as its level in serum. The normal range for **blood urea nitrogen (BUN)**, the test used to measure urea, is 8 to 23 mg/ dL. It is often helpful to interpret BUN values alongside creatinine values, and a BUN to creatinine ratio (BUN:Cr) can sometimes provide helpful indications regarding the cause of acute kidney injury, such as dehydration versus intrarenal disease.

The BUN level tends to increase with age as a consequence of gradually declining renal function; thus, a slightly elevated BUN finding of 28 to 35 mg/dL in older patients is not necessarily a cause for concern. Instead, an elevated BUN level in an older patient should be interpreted in the context of other lab test results and the findings during the patient assessment. Any value of more than 40 mg/dL should be monitored closely.

When patients have high renal output levels, BUN values are a less valid means of assessing kidney health because of the inverse relationship between urine formation and urea reabsorption. Elevated levels of urea occur not only with decreased renal function, but also with consumption of a high-protein diet and in the presence of a high-protein catabolism state (eg, burns, crush injuries).

Occult upper gastrointestinal bleeding may result in an elevated BUN value with a normal creatinine level.

Creatinine

A major storehouse of intramuscular high-energy phosphate, **creatine** is degraded to **creatinine (Cr)**, a chemical waste product that results from muscle metabolism, at a relatively steady rate by the muscles. Within a particular individual, the rate of Cr production typically varies by only 10% at any particular time. Creatinine is filtered from the blood by the kidneys and, unless reabsorption occurs, is excreted in the urine. Because of its steady rate of production, this by-product of metabolism can be used to assess kidney function: Its clearance by the kidneys is the primary variable that determines its serum concentration under typical conditions. If renal function decreases, serum Cr levels will become elevated (normal range, 0.6 to 1.2 mg/dL).

An abnormal serum Cr level does not pinpoint the exact disease or cause at work, but does indicate some level of decreased renal function. Under certain circumstances, a patient may have an increased Cr level with adequate renal function, such as when the patient has experienced a large amount of muscle damage (owing to protein release from trauma, a process called rhabdomyolysis). Care must be taken when a geriatric patient has a Cr level slightly more than the upper normal value (near 1.5 mg/dL): Owing to the proportionately smaller amount of muscle mass and consequent lower Cr production in older people, a small elevation in the Cr level may reflect greater kidney dysfunction in these individuals than would the same level in a younger patient.

Acute elevation in Cr can sometimes indicate a transient condition from which the patient will fully recover. However, if the cause of the elevated Cr level is not identified and corrected, damage to the kidneys will be permanent. Patients who experience such damage may require dialysis for the rest of their lives or need kidney transplantation.

Creatinine clearance is the most accurate measure of the glomerular filtration rate. The results of a Cr clearance test can be used to determine the most appropriate long-term management of patients with chronic disorders of renal function and to calculate the necessary fluid and electrolyte replacement therapy. Creatinine clearance is calculated by multiplying the concentration of measured urine Cr by the volume of urine during a set time and then dividing this product by the serum concentration of Cr. A single test result does not give a great deal of information, but serial results can be very useful in directing a patient’s course of therapy.

Special Populations

Geriatric patients with creatinine levels approaching 1.5 mg/dL warrant careful attention. They may have more kidney dysfunction than might otherwise be suspected, owing to the relatively lower level of creatinine production from the smaller amount of muscle mass present.

Glomerular Filtration Rate

The glomerular filtration rate (GFR) is a measurement of the overall filtration efficiency of all the functioning nephrons. While the exact rate depends on age, sex, and body size, the normal GFR is 90 to 120 mL/min per 1.73 m^2 for both men and women.

Changes in GFR can suggest improvement or decline in kidney function. (But note that GFR declines progressively with age, even in the absence of chronic kidney disease.) Actual measurement of GFR is not possible, however, and its estimation is extremely complex; it is commonly done using blood serum markers in a laboratory analysis. A GFR less than 60 mL/min in any patient suggests renal impairment. Some labs estimate GFRs only when the value is less than 60 mL/min, reporting higher values as simply >60 mL/min.

Glucose

Glucose is the most important carbohydrate in the body, and its quantification is the lab measurement with which CCTPs may be most familiar. Glucose is commonly assessed in the field with a point-of-care testing device, and prehospital care providers often measure the blood glucose level of patients with altered mental status. Concentrations of glucose are normally in the range of 70 to 110 mg/dL (3.9 to 6.1 mmol/L). Maintaining a normal glucose level is an extremely important consideration for CCTPs, because patients may be receiving insulin infusions during transport and may have chronic or acute renal failure, which will affect their blood glucose levels. If a patient is receiving an insulin infusion, a point-of-care glucose test should be done at least hourly, and more often if the patient demonstrates altered mental status or when the CCTP is withholding the infusion for low glucose levels.

Glucose levels that are high (hyperglycemia) or low (hypoglycemia) can lead to coma and death if not properly treated. Hypoglycemia is generally easier to recognize early because of the associated symptoms, such as blurred vision, dizziness, nausea, vomiting, and shakiness. Hypoglycemia can also lead to syncope (loss of consciousness) or seizures, which can result in injuries secondary to falling.

Total Calcium

Calcium is one of the most essential electrolytes found in the body. It is responsible for functions ranging from muscle contraction (including the contraction of cardiac myocytes) to intracellular signal transduction (including the messages sent via neurons). Physiologically, calcium is found in the body in three states: free, chelated, and bound. The largest portion of calcium (47%) is found as a free calcium ion dispersed in the body fluids. Another 43% of calcium in the body is bound to proteins, mostly albumin. Naturally, the amount of calcium bound to proteins depends on the ability of the protein to complex with the calcium ion (Ca^{+2}). Protein binding is a function of the shape of the protein, which in turn is heavily dependent on the surrounding pH. In lower pH states, the amount of calcium bound to proteins decreases, which causes the amount of free calcium to increase. Calcium that is chelated (bound) to other molecules, such as citrate, HCO_3^-, lactate, phosphate, and sulfate, represents only 10% of the calcium in the body.

The sum of all calcium in the body is expressed as the total calcium level (Ca^{+2}_{TOT}). The normal range for Ca^{+2}_{TOT} is 8.5 to 10.2 mg/dL. The Ca^{+2}_{TOT} is increased in elevated parathyroid hormone states, such as hyperparathyroidism and parathyroid-secreting tumors. Low levels of Ca^{+2}_{TOT} are seen with renal insufficiency, hypomagnesemia, and hyperphosphatemia, and in patients who have received a massive blood transfusion or have decreased parathyroid hormone levels.

Ionized Calcium

Only the calcium that is not bound or chelated (ie, free calcium) is physiologically active. In patients whose status is characterized by an altered fraction of bound or chelated calcium, free calcium assessment is warranted. Examples of physiologic states that warrant assessment of **ionized calcium** include renal failure and nephrotic syndrome (hypoalbuminemia), acid–base derangements (particularly acidosis), and decreases or elevations in chelating compounds (citrate, Hco_3^-, lactate, phosphate, and sulfate). The normal range for ionized calcium is 8.8 to 10.3 mg/dL, which is equivalent to 2.2 to 2.6 mmol/L and 4.4 to 5.2 mEq/L.

Low levels of ionized calcium can result in decreased cardiac output and hypotension and are sometimes associated with arrhythmias. They are also often seen in patients with prolonged cardiac arrest, although calcium administration has not been shown to offer survival benefits to these patients. Use of calcium may be warranted in patients with hyperkalemia, hypocalcemia, or calcium channel blocker overdose. Patients with these conditions are sometimes transported with a magnesium sulfate drip to mitigate the risk of further cardiac arrhythmias or cardiac arrest.

Magnesium

Magnesium (Mg) levels can be affected by disruptions of several body systems, in particular the GI and endocrine systems. The normal serum magnesium level is 1.3 to 2.1 mEq/L. High Mg levels are rarely encountered. When they do occur, generally the causes are renal defects, severe dehydration, overadministration of Mg, untreated diabetic coma, and aspiration of sea water. Low Mg levels are more commonly seen—for example, in conjunction with GI distress, vomiting and diarrhea, hepatic cirrhosis, and pancreatitis.

Phosphate

Phosphate is an ion in the blood that contains the mineral phosphorus. The blood’s phosphate level is primarily regulated by the parathyroid endocrine system and the kidneys. Phosphate plays an important role in bone and dental health.

Normal serum phosphate levels are typically defined as 2.3 to 4.7 mg/dL. Hyperphosphatemia (high phosphate levels) can be caused by hypoparathyroidism and kidney failure, among other diseases, and can lead to calcium disorders and muscle spasms. Hypophosphatemia (low phosphate levels) can be caused by nutritional disorders and hyperparathyroidism, among other diseases, and can lead to altered mental status, seizures, or osteopenia.

Blood Components

FIGURE 9-6 shows a schematic of the abbreviated notation for a complete blood count (CBC) test. This schematic is intended to be used for quick reference to pertinent values. Classically, the CBC test includes counts of red blood cells (RBCs), white blood cells, and platelets, as well as hematocrit and hemoglobin levels. It may also include other values that lie outside the scope of this text, many of which describe various attributes of RBCs that can be used to determine the cause of anemia (an abnormally low RBC count). If one of these values is abnormal, the CCTP would be expected to consult the patient’s complete medical record for more information on the patient’s condition.

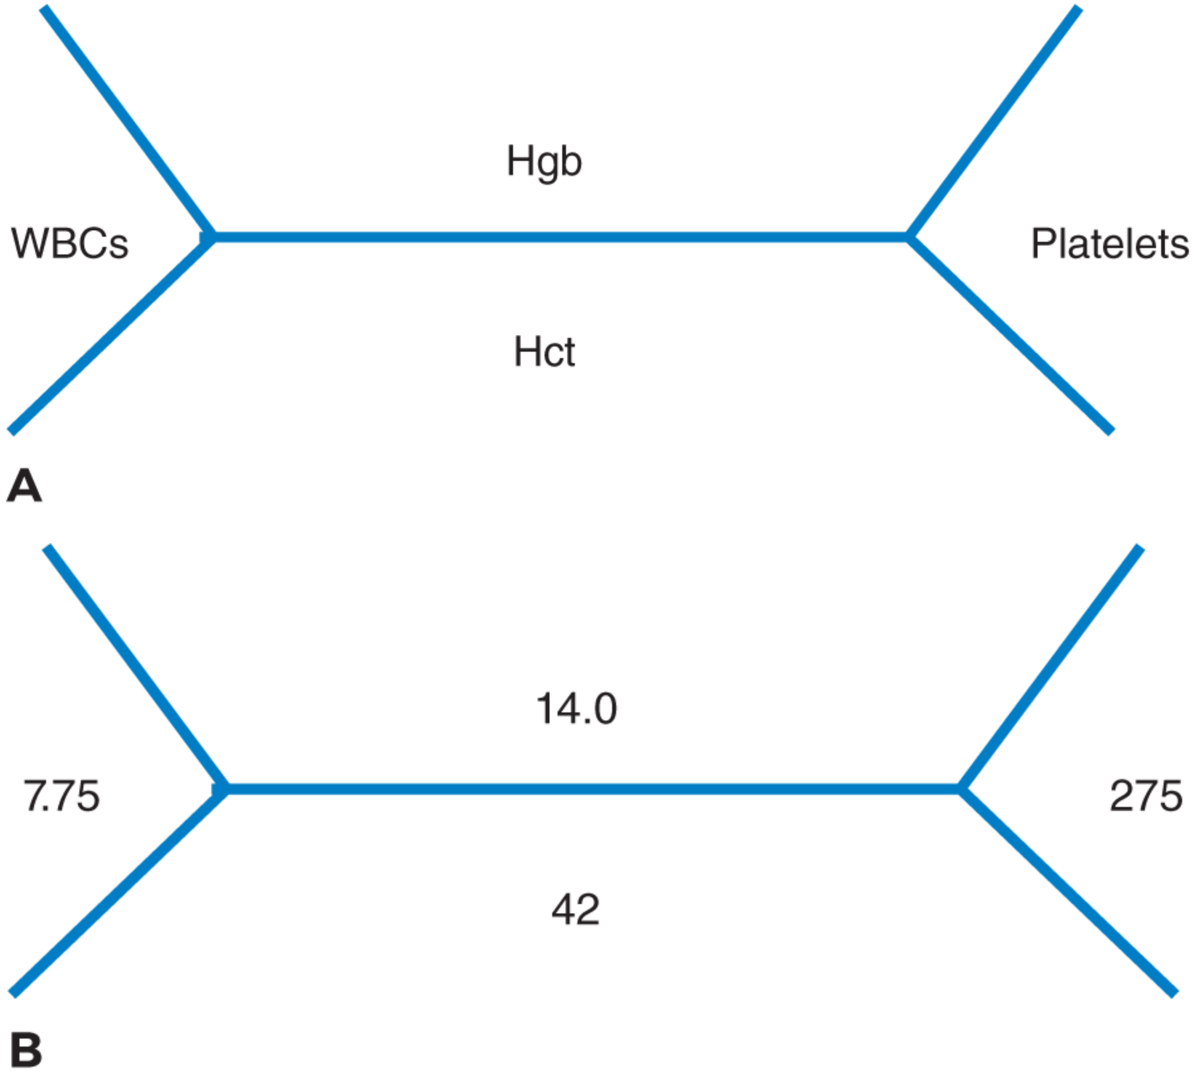

FIGURE 9-6 Complete blood count schematic (abbreviated notation). **A.** The format in which values are written. **B.** An example of values for a healthy person.

Description Description

Hematocrit

Hematocrit, commonly documented using the abbreviation Hct, is the percentage of formed elements (ie, cells) in a venous blood sample. A hematocrit value of 45% indicates that 45% of the sample consists of cells or cellular debris, and the other 55% consists of plasma. The normal range for hematocrit is 41% to 50%.

This test's specificity depends on the nature of the relationship between the blood's formed elements and the plasma. With an acutely ill patient, the health care provider is often concerned with a low hematocrit value. A low level of formed elements (which are predominantly RBCs) can indicate decreased capacity of the blood to deliver oxygen to the tissues. A patient who has an excess amount of plasma (such as from overzealous use of crystalloids) will also have a low hematocrit value. Thus, a patient with a hematocrit value of 22%, for example, could be either exsanguinated or fluid overloaded **FIGURE 9-7**. Therefore, when the hematocrit level is abnormal, further investigation is necessary to identify the precise cause of the abnormality. In acute hemorrhage, hematocrit is not initially relevant but rather serves as a baseline to guide resuscitation.

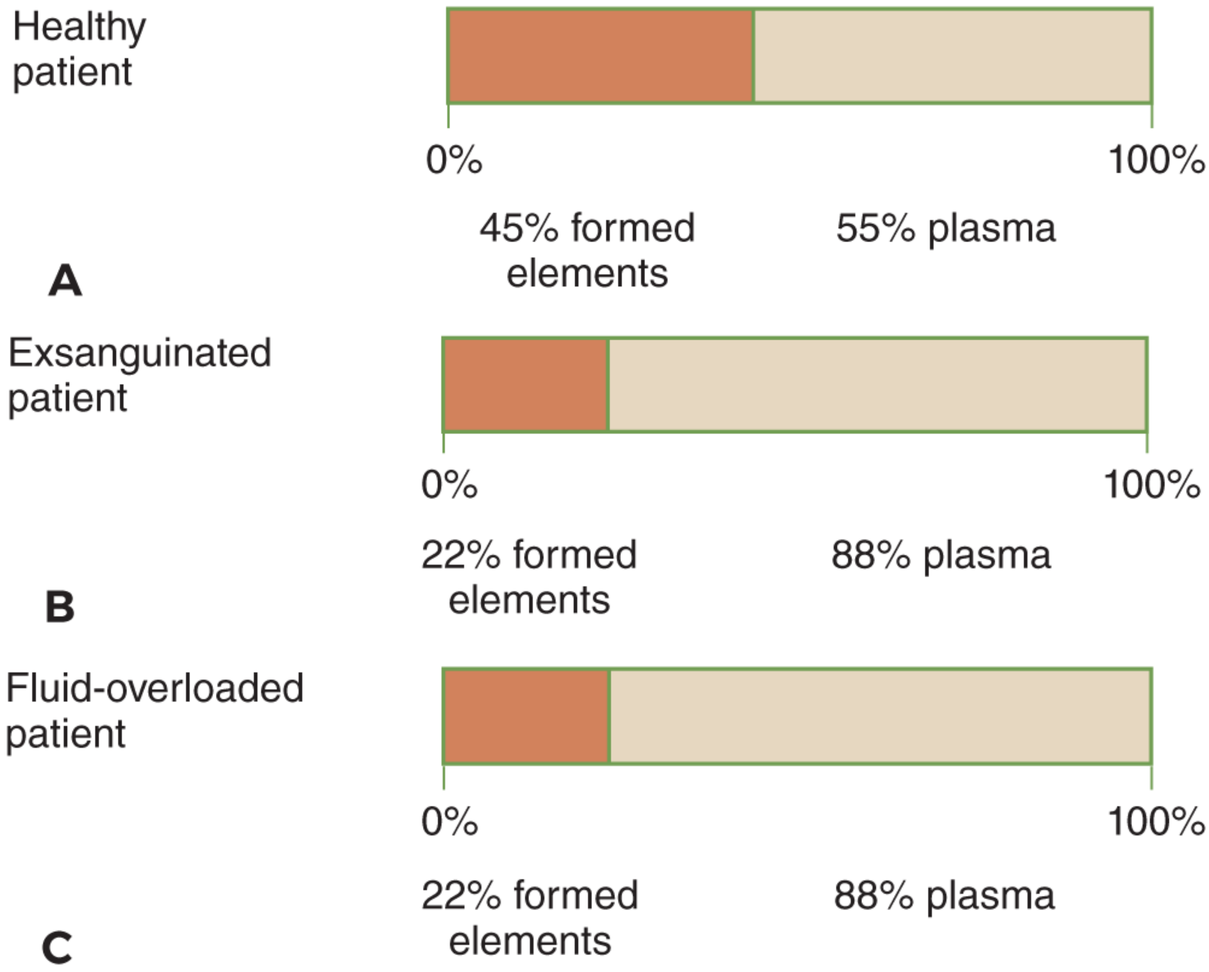

FIGURE 9-7 Examples of hematocrit levels and (B and C) potential causes. **A.** Healthy patient. **B.** Exsanguinated patient. **C.** Fluid-overloaded patient.

Description Description Description

Hemoglobin

Hemoglobin, commonly documented using the abbreviation Hgb (and sometimes Hg or Hb), is the protein responsible for carrying oxygen to the cells and, to a lesser extent, CO_2 back to the lungs. The level of hemoglobin varies by sex, with normal values falling in the range of 135 to 175 g/L (14.0 to 17.5 g/dL) for males and 120 to 160 g/L (12.0 to 16.0 g/dL) for females. Elevated levels are seen in people with **hemoconcentration** (decreased fluid in the blood, which means that concentrations of other blood components increase), which can result from dehydration, burns, or excessive vomiting. Of greater concern are low hemoglobin levels, which are typical of most types of anemia (microcytic, normocytic, and macrocytic). Similar to hematocrit, hemoglobin must be interpreted within the context of a patient's hemodynamic stability in the setting of acute hemorrhage; the hemoglobin level may not drop in the setting of hemorrhagic shock until intravascular volume is expanded, either endogenously or exogenously.

Red Blood Cell Count

The **red blood cell (RBC) count** is the number of erythrocytes (RBCs) per microliter of blood. The normal range for the RBC count is 3.9 to 5.5 × 10^6/μL. Although the presence of an abnormal number of RBCs does not necessarily equate to the presence of disease, the RBC counts can be elevated with hemoconcentration. Patients with elevated white blood cell counts may have an erroneously high RBC count owing to analysis errors. As would be expected, low RBC counts are seen in all types of anemia.

Along with RBC count, a reticulocyte count may be provided on the CBC report. Reticulocytes are immature RBCs. A high reticulocyte count can indicate that erythropoiesis, the process that produces new RBCs, is actively occurring. The RBC and reticulocyte counts have little clinical utility for the CCTP.

White Blood Cell Count

The **white blood cell (WBC) count** is a measure of the total number of leukocytes (WBCs) per microliter of blood. An increased number of WBCs, referred to as **leukocytosis**, can be a healthy response, demonstrating the body's response to a detected threat, such as an infection. An ordinary WBC count does not differentiate among the various types of leukocytes in the sample; a CBC with differential can be performed to provide a detailed summary of the components that contribute to the WBC count (see the following section). The normal range for WBC counts is between 4,500/μL and 11,000/μL.

Low levels of WBCs are seen in patients with certain anemias (eg, aplastic anemia) and vitamin deficiencies, and in patients receiving certain therapies (eg, chemotherapy). Although it might seem counterintuitive, low levels are also seen in sepsis: WBCs are mobilized to fight the infection and are ultimately destroyed at a rate that exceeds their production. Leukocytosis is seen not only with inflammation or infection, but also in certain malignancies (leukemia and lymphoma) and vascular conditions (pulmonary embolism, acute myocardial infarction [AMI], and DVT), with steroid administration, and with the stress of trauma.

White Blood Cell Count Differential

A **CBC with differential**, also called a WBC differential, is an expanded panel of lab tests that includes counts of specific types of WBCs in the blood, such as neutrophils, lymphocytes, monocytes, eosinophils, and basophils. These values may be expressed as absolute counts, percentages of all WBCs, or both. In a healthy immune response, the nature of the stimulus for the leukocytosis can often be indicated by the differential. For example, a leukocytosis predominated by neutrophils is often associated with bacterial—rather than viral—infection, whereas relatively elevated lymphocyte counts are typically associated with viral infection. Other causes of elevated WBC components beyond infection include hematologic malignancy, autoimmune conditions, medication effects, and other inflammatory conditions. For example, corticosteroid therapy can cause elevated neutrophil counts in the absence of any infection or other potential cause.

Neutropenia is an abnormally low neutrophil count. Neutropenia has various causes, with the most common one being chemotherapy or radiation therapy in patients with cancer. Neutrophils are a key aspect of the immune system's defense against bacterial infection, so bacterial infection in a neutropenic patient is considered a life-threatening emergency. (Neutropenic fever refers to a fever in a patient with neutropenia, which is also considered a medical emergency.)

The WBC differential may also include a band cell count. Band cells (also called immature granulocytes) are precursors to granulocytes, a type of WBC that includes neutrophils. An elevated band cell count (ie, bandemia) is sometimes referred to as a "left shift" associated with granulopoiesis, the process by which new granulocytes are created. It is typically interpreted as a sign of acute inflammatory response, most commonly in the setting of an active infection.

Platelet Count

Maintenance of hemostasis within the body relies on the presence of adequate numbers of functional platelets coupled with sufficient clotting factors. The **platelet count**, often documented using the abbreviation Plt, is useful in assessing the number of circulating platelets in a patient. The normal range for a whole blood sample is 150 to 350 × 10^3/µL. Elevated levels of platelets are seen in patients with certain myeloproliferative disorders (diseases in which the bone marrow produces too many RBCs, WBCs, or platelets; examples include polycythemia and chronic myelogenous leukemia), most notably after severe bleeding or following splenectomy. Decreased platelet counts may occur when disease causes decreased production of these cells in the bone marrow. Often **thrombocytopenia**—an abnormally low level of platelets—is associated with splenomegaly, disseminated intravascular coagulation (DIC), or high levels of circulating platelet antibodies (such as after massive transfusions).

Two thrombocytopenic conditions often seen in critical care patients are heparin-induced thrombocytopenia (HIT) and idiopathic thrombocytopenic purpura (ITP). HIT is an antibody response to a complex formed by platelet factor 4 (PF4) and heparin; it results in platelet activation, leading to significant and sometimes life-threatening thromboses. HIT occurs in 5% of patients exposed to heparin, regardless of the route or dose used, and is treated by rapidly discontinuing all heparin products. ITP is an antibody reaction against platelet antigens and can be difficult to diagnose. In adults, it tends to be a chronic condition, but it may also be present in critically ill patients being treated for other conditions.

Proteins

Total Protein

One of the most basic protein tests, **total protein**, examines the total quantity of protein in a blood sample. This quantity consists of mostly albumin and immunoglobulins. The normal range for total protein in a serum sample is 6.0 to 8.0 g/dL, and variations are almost always due to fluctuations in serum albumin levels. As a consequence, most clinicians focus on albumin levels. While a commonly performed lab test, total protein has no clinical relevance to the CCTP.

Albumin

By far the most common protein in the body is **albumin**. Albumin serves many functions: It acts as a transport protein (for free fatty acids, bilirubin, hormones, and drugs), functions as a free-radical scavenger, and serves as the main source (70%) of protein-generated oncotic pressure. This osmotic pressure enables colloids to move from one side of the cell membrane to the other as needed and contributes to the maintenance of adequate intravascular volume. The normal range for albumin is 3.5 to 5.0 g/dL.

A low level of albumin may be due to increased catabolism of the protein (as seen in malnutrition), decreased production, or edema in the spaces between the cells in the tissue. Decreased production is seen in patients who have liver damage or other liver disease. **Hypoalbuminemia** (an abnormally low level of albumin) from increased interstitial sequestration can occur in high-vascular-permeability states and leads to diseases such as acute respiratory distress syndrome. High levels of albumin generally indicate dehydration; that is, they are not pathologic.

Lactate

Adequate indicators of a patient’s end-organ perfusion and oxygenation that can serve as a gold standard for measuring perfusion continue to be sought. One of the best and most readily available standard tests used to assess a patient’s end-organ perfusion and oxygenation is the venous **lactate** level. Once tissue perfusion and oxygen levels in the cells and tissues decrease too much, cells switch to anaerobic metabolism. This mechanism allows the cells to continue to use glucose, albeit less efficiently than if perfusion and oxygenation were adequate. This inefficient metabolic process produces lactic acid as a by-product, which may be measured in the form of serum lactate. Perfusion and oxygenation of the cells and tissues of the body’s end organs are considered inadequate if the serum lactate level in the blood is greater than 2 mmol/L (normal range, 0.5 to 1.5 mmol/L).

Lactate levels are a global indicator of perfusion and oxygenation; that is, they do not indicate exactly which tissues are inadequately perfused or oxygenated. Apart from being nonspecific, lactate levels are relatively slow to respond to adequate resuscitation with fluid and oxygen, generally improving only over the course of several hours. Once tissue perfusion and oxygenation return to normal, anaerobic metabolism ceases and lactate is no longer produced. The remaining lactate is then converted into nontoxic metabolic by-products in the liver and kidney and, eventually, to CO_2 and water. Serial lactate measurements can suggest trends in end-organ perfusion, whereas a single lactate value simply provides a snapshot of the current state.

Lactate Dehydrogenase

In the absence of a functioning citric acid cycle, pyruvate (the end product of glycolysis) is metabolized to lactate. (The citric acid cycle is discussed in Chapter 10, *Resuscitation, Shock, and Blood Products*.) The enzyme that catalyzes this reaction is **lactate dehydrogenase (LDH)**. As this enzyme is found in almost all tissues of the body, the LDH level is not sensitive or specific for any disease. The normal range of LDH is 100 to 200 U/L.

The usefulness of the LDH measurement in the clinical setting comes from analysis of LDH's isoenzyme forms (LD_1 to LD_5). Various organs, tissues, and cells differ in terms of the amount of each isoenzyme found within them. For example, LD_1 is found largely in the heart, kidneys, and RBCs. Other tissues, such as skeletal muscle and the liver, contain relatively high amounts of LD_5.

The LDH value was once considered a useful aid in the diagnosis of AMI but has been replaced in routine use by troponin analysis (discussed later in this chapter). LDH can also be helpful in diagnosing *Pneumocystis jirovecii* pneumonia and determining the severity of pancreatitis. In addition, LDH levels are followed in patients with implanted ventricular assist devices, in whom they can provide an early warning of pump thrombosis.

Creatine Kinase

Creatine kinase (CK) is found in muscle, liver, lung, GI, brain, kidney, and spleen tissues. If any of these tissue cells become damaged, CK is released into the vascular space. Most often, CK levels are used to diagnose and monitor response to treatment of rhabdomyolysis. This condition can result from significant exertion (eg, running a marathon), crush or burn injuries, seizures, or prolonged unconsciousness. Though this application is less common today since the advent of troponin analysis, CK has also been used as a less specific marker for myocardial infarction. With myocardial damage, CK levels rise within 4 to 8 hours, peak within 12 to 24 hours, and return to normal within 2 to 4 days. The normal range for the total CK level is 40 to 150 U/L.

The MB fraction of CK, or CK-MB, refers primarily to CK in the heart muscle. The normal range for the CK-MB level is 0 to 7 ng/mL. When this level is less than 10 ng/mL, a myocardial event is unlikely. Results ranging between 10 and 12 ng/mL are not conclusive, and additional workup and serial lab tests are required in such cases. A level of more than 12 ng/mL is indicative of a myocardial event.

Troponin

Troponin is a key protein involved in muscle contraction. This protein has three subunits: T, C, and I. The I subunit has three separate isoforms, one of which is found only in cardiac muscle. Troponin is expressed in the serum *only after* cellular necrosis releases the respective cellular contents. Thus, measurement of the troponin levels offers some advantage over measurement of the CK and LDH levels because CK and LDH are normally present in the serum.

Normal values for the various troponins depend on the method used to do the test, but, in general, the normal ranges are 0 to 0.4 ng/mL for troponin I (often abbreviated cTnI) and 0 to 0.1 ng/mL for troponin T. Elevations in cTnI following myocardial injury are detectable in a serum sample after 4 hours; tests for cTnI are 97% sensitive and 95% specific at 6 hours after an AMI. Peak levels are expressed 8 to 12 hours post injury, but the protein may still be detected 5 to 7 days later. Not only is the cTnI level useful in detecting AMI, but it has also been shown to be predictive of adverse outcomes in patients with severe unstable angina. Newer high-sensitivity cardiac troponin T (hs-cTnT) tests have demonstrated the ability to reliably rule out AMI within even shorter time intervals from the onset of symptoms.

B-Type Natriuretic Peptide

The **B-type natriuretic peptide (BNP)** is released by the ventricles in response to higher filling pressures. The normal value for BNP is less than 167 pg/mL. A high level can be indicative of abnormal ventricular function or heart failure if it is outside the expected range.

Besides evaluating response to heart failure therapies, BNP is used to assess the probability of heart failure in patients presenting with dyspnea. In this application, values greater than 400 pg/mL strongly correlate with heart failure as the cause of dyspnea, whereas values less than 100 pg/mL negatively predict heart failure as a cause of dyspnea. The middle range of 100 to 400 pg/mL has very poor sensitivity and specificity for predicting or excluding heart failure. Additionally, numerous other conditions, such as renal insufficiency, tend to affect BNP values. BNP values are typically most informative when trended over time to assess improvement or exacerbation of heart failure.

Inflammatory Markers

Procalcitonin

Procalcitonin (PCT) is a peptide precursor of calcitonin. Evidence suggests that serum PCT levels rise significantly in the setting of an inflammatory response to a serious bacterial infection such as sepsis. While PCT levels have not yet been integrated into routine evaluation of infection, they are increasingly being used to identify serious bacterial infection in young children and to distinguish bacterial from viral infection when deciding whether to prescribe antibiotics. Reference ranges vary by context, but a typical normal PCT threshold is less than 0.5 µg/L.

C-Reactive Protein

C-reactive protein (CRP) is an acute-phase protein produced by the liver. CRP levels rise quickly in the context of inflammation due to its multiple roles in inflammatory processes. Testing CRP is a useful but nonspecific means to evaluate for the presence of an inflammatory response, including those triggered by infection, autoimmune processes, or tissue damage. Values less than 10 mg/L are typically considered normal.

Erythrocyte Sedimentation Rate

The **erythrocyte sedimentation rate (ESR)**, sometimes abbreviated as “sed rate,” is the rate at which RBCs settle at the bottom of a tube containing a blood sample. ESR values rise in the context of an inflammatory response, leading to the use of this test as a marker of the acute-phase reaction, similar to CRP. However, ESR tends to be less specific than CRP due to multiple other factors that can lead to elevated levels. Evidence suggests that ESR threshold values should vary by context, but in general normal is defined as less than 20 mm/h in females and less than 15 mm/h in males, with higher thresholds in older populations.

Liver Function Tests

Although not truly tests of liver function, elevated **liver function test (LFT)** results suggest liver damage or injury. LFTs measure enzymes that normally appear, to some extent, in liver cells. When the liver is damaged, these enzymes often spill out into the vasculature. LFTs include aspartate aminotransferase, alanine aminotransferase, total bilirubin, direct bilirubin, and alkaline phosphatase.

Aspartate Aminotransferase

Found in large amounts in the liver, the intracellular enzyme **aspartate aminotransferase (AST)**, previously called serum glutamic-oxaloacetic transaminase (SGOT), is also found in skeletal muscle, the brain, RBCs, and the heart. Damage to any of these cells causes them to release their contents, which can then be detected in a blood sample. Low levels of AST are not of serious consequence, considering that the normal range for this enzyme is 10 to 30 U/L. Elevated levels are seen in liver damage, especially with acute conditions such as acute hepatitis or biliary tract obstruction. Chronic liver damage (due to alcoholic cirrhosis, hepatitis, and liver cancer) also produces elevation of the AST level, although the **alanine aminotransferase (ALT)** level (described in the next section) is affected more dramatically. Acute hepatitis is marked by significant elevations in AST and ALT, whereas AST and ALT may or may not remain elevated in patients with advanced cirrhosis. Elevations in AST may occur in a setting of right heart failure, hypoxia (global or end-organ), or extensive trauma.

Alanine Aminotransferase

Like its counterpart AST, ALT, previously called serum glutamic-pyruvic transaminase (SGPT), is found in large amounts in the liver, kidney, skeletal muscle, and heart. Similar to the findings with AST, the normal range for ALT is 10 to 40 U/L, with low levels considered to be of no consequence. The causes of an elevated ALT level mirror the causes of an elevated AST level, with the exception that the ALT level is higher than the AST level in acute processes and lower than the AST level in chronic processes. The ALT test is considered slightly more specific than the AST test for hepatic injury because fewer organs have ALT than have AST. The ratio of AST to ALT is an important diagnostic tool and is explained further in the calculation section in this chapter.

Although AST and ALT are found in the heart, neither AST nor ALT measurement is valid for diagnosing myocardial infarction. Elevated levels of ALT may be prolonged because this enzyme has a long half-life (between 36 and 60 hours). As a consequence, levels may appear elevated even after resolution of the hepatic dysfunction.

Total Bilirubin

All RBCs are metabolized eventually, with bilirubin being one of the by-products of their breakdown. The initial by-product is unconjugated and, therefore, not water soluble (**indirect bilirubin**). When bilirubin is conjugated in the liver, it becomes **direct bilirubin**, which is ultimately excreted in the bile. The normal range for the total bilirubin level is 0.3 to 1.2 mg/dL. The total bilirubin level (direct plus indirect) is often elevated in patients with liver disease; thus, this level is often used as a measure of liver health. Other causes of elevated levels of total bilirubin include biliary tract obstruction and RBC hemolysis.

Direct Bilirubin

In the medical laboratory, bilirubin may be fractionated to determine the respective levels of unconjugated (indirect) and conjugated (direct) bilirubin. Although such tests are sometimes unreliable, the cause of elevated total bilirubin levels may often be derived from the fractionated levels. The indirect bilirubin fraction is typically elevated in conditions characterized by massive **hemolysis**, such as massive blood transfusions or blood transfusion reactions. If only the direct or indirect bilirubin level is reported, the other value may be obtained by subtracting the reported level from the total bilirubin level. The normal values for direct and indirect bilirubin are 0.1 to 0.3 mg/dL and 0.2 to 0.9 mg/dL, respectively.

Alkaline Phosphatase

Alkaline phosphatase is found in almost all body tissues and is manufactured by the bone, liver, intestine, and placenta. It is essential for proper digestion and absorption of nutrients through the mucous membranes of the GI tract. The measurement of alkaline phosphatase is clinically useful for testing liver function and, in particular, for diagnosing a common bile duct obstruction. The normal range is 30 to 120 U/L.

Elevated LFT values are often described as having either a hepatocellular pattern or a cholestatic pattern. Transaminitis—that is, elevated AST and/or ALT levels—typically indicates hepatocellular damage, such as from viral or alcoholic hepatitis. In contrast, a cholestatic pattern, indicated by elevated alkaline phosphatase and bilirubin levels, suggests biliary obstruction, such as from gallstones or a mass. Both patterns can be present simultaneously, but relatively greater disturbances in one pattern over the other can suggest the primary etiology.

Amylase

A key enzyme used by the body to metabolize carbohydrates, **amylase** is produced by the salivary glands and the pancreas. Tissues such as the ovaries, small and large bowels, and skeletal muscle also produce small amounts of amylase. The normal range for amylase is 27 to 131 U/L. Tests for amylase are used to assess for pancreatic insufficiency or damage: Levels of this enzyme are elevated not only with pancreatic disease (such as pancreatitis, pancreatic cancer, and diabetic ketoacidosis), but also with bile duct obstructions and head trauma. A sign of pancreatic insufficiency, low amylase levels are seen in people with cystic fibrosis.

Lipase

The pancreatic enzyme **lipase** metabolizes lipids. Generally considered more specific than amylase for identifying pancreatic disease, lipase is also produced by the liver, intestine, and stomach. The normal range for lipase is 31 to 186 U/L. In acute pancreatitis, the levels of lipase and amylase are elevated, but the lipase level stays elevated longer. Although measurements of lipase levels have poor sensitivity in terms of identifying chronic pancreatitis and pancreatic cancer, elevated levels are often seen with both diseases. Like amylase levels, lipase levels are often elevated in patients with bile duct obstruction or biliary disease.

Coagulation

Assessment of the coagulation system involves looking at the intrinsic and extrinsic pathways of the coagulation cascade, which are discussed in more detail in Chapter 10, *Resuscitation, Shock, and Blood Products*. The intrinsic pathway (initiated within the body, such as by platelet damage) begins with the activation of factor XII and then factors XI and IX; it ultimately results in the activation of factor X, which initiates the common pathway of coagulation. The extrinsic pathway (initiated outside the body, following tissue injury) begins with tissue factor and factor VII; it also leads to activation of factor X and, in turn, initiates the common pathway of coagulation. Fibrin is eventually produced, resulting in a clot.

Coagulation studies can be used to assess the body’s ability to form and prevent clots. This information can be very helpful when abnormal clotting is suspected, in the setting of hemorrhage, or in the preoperative setting. The enzymes involved in coagulation are synthesized in the liver. Some clinicians consider assessments of these enzymes to be the true liver function tests because they are products of the liver, rather than merely being markers of liver cell damage. Many coagulation assessments are functions of time and, therefore, are reported in units of seconds.

Prothrombin Time

A key step in coagulation is the creation of thrombin from prothrombin by prothrombin activator, which is a collection of activated substances. The **prothrombin time (PT)** is the rate of prothrombin's conversion to thrombin in a blood sample, and it represents the function of the extrinsic pathway. The normal range is 10 to 13 seconds. The PT may be increased in liver disease or with warfarin therapy, and decreased with low levels of vitamin K, in DIC, and after massive transfusions. This measurement is also used to assess for correct therapeutic effect of warfarin.

Activated Partial Thromboplastin Time

The **activated partial thromboplastin time (aPTT)** indicates the health of the intrinsic and common pathways of the coagulation system. Genetic diseases, such as hemophilia A, hemophilia B, and von Willebrand disease, may cause elevated aPTT levels. The aPTT is often used to assess for DIC, in which the level is often grossly elevated relative to the normal range of 25 to 40 seconds. Heparin therapy also results in elevated aPTT. Some patients being moved by interfacility transport may be receiving heparin therapy or anticoagulant prophylaxis. The aPTT is used to assess for the correct therapeutic effect of heparin.

International Normalized Ratio

Owing to lack of standardization in measuring the PT within different laboratories (especially internationally), a normalizing index has been created based on the international sensitivity index. The normal range for the **international normalized ratio (INR)** is 0.9 to 1.3. Increased ratios are seen in the same diseases in which PT is increased and in persons receiving anticoagulants.

The typical anticoagulation target for the INR depends on the indication and the type of anticoagulant used. For atrial fibrillation and DVT, and after pulmonary embolus, a usual INR target is 2.0 to 3.0.

For mechanical heart valves and some circulatory support devices, a target of 2.5 to 3.5 may be preferred. An INR greater than 5 with bleeding generally requires treatment.

Factor Xa

Factor Xa levels, also known as anti-Xa levels, are most commonly used to inform dosing of anticoagulation therapy. In particular, heparin and low-molecular-weight heparin primarily act by inactivating thrombin and factor Xa, so the factor Xa assay can be used to measure the activity of these medications. By trending factor Xa levels over time, providers can adjust the dosing of anticoagulation therapy to maintain therapeutic levels in the blood, thereby optimizing the benefit (ie, reduce clotting) and limiting the risk (ie, reduce bleeding).

Thromboelastography

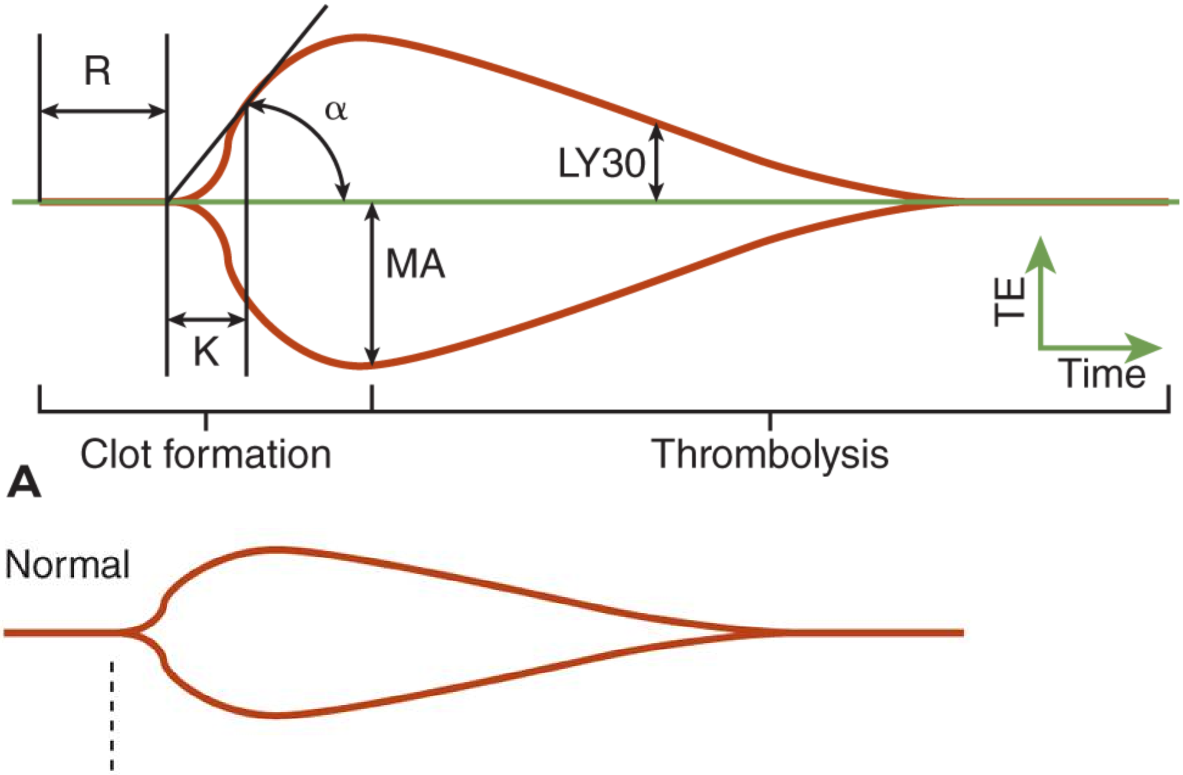
Thromboelastography (TEG) is a test used to describe the global viscoelastic properties of a sample of whole blood. It can provide a real-time assessment of clot formation by quantifying the interaction of platelets and the coagulation cascade. TEG typically generates five measures of interest based on the timing of landmark stages in clot formation and degradation, as well as attributes of a waveform. These measures can provide both quantitative and rapid qualitative information.

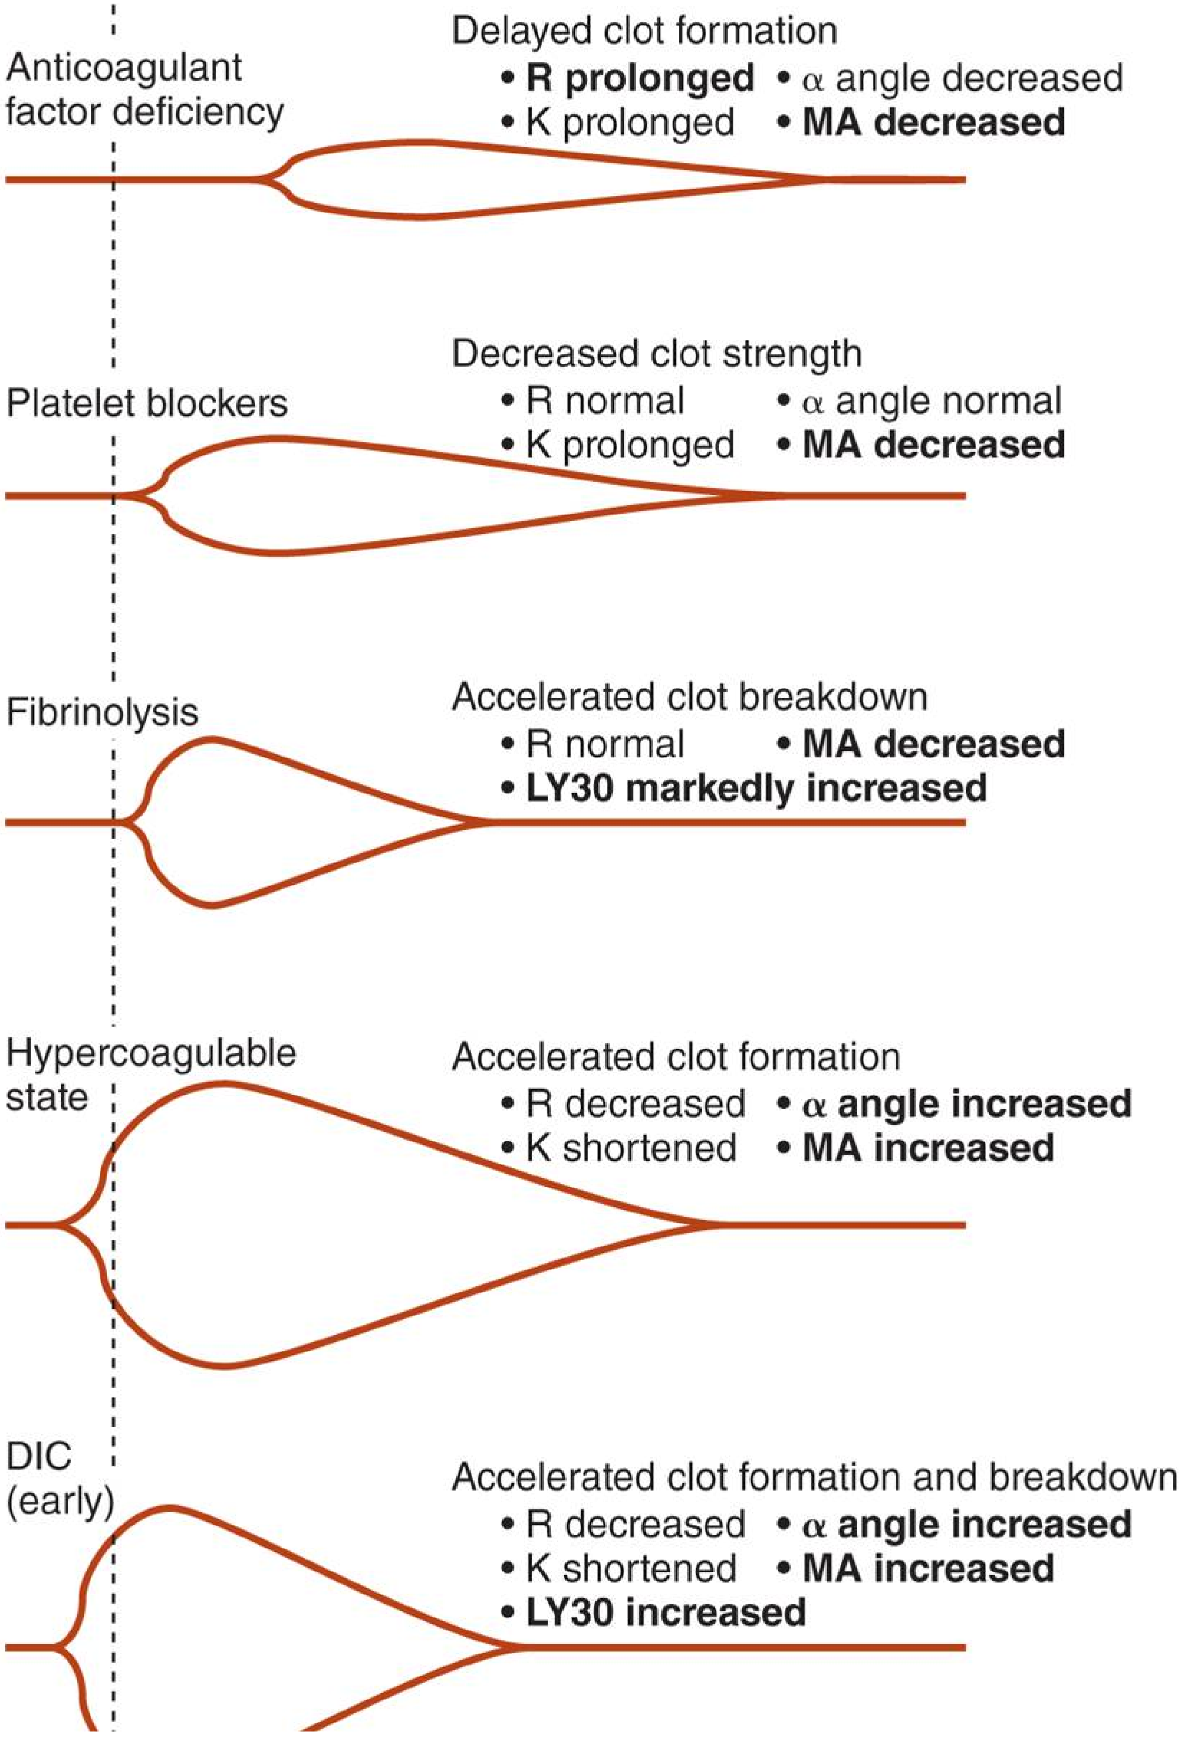
- **Reaction time (R time).** R time extends from the initiation of the test until the first detection of clot formation. Normal values typically range from 4 to 8 minutes. The R time can be used to assess clotting factor function.
- **Clot formation time (K time).** K time is the duration from initial clot formation (where R time is $t = 0$) until a standardized level of clot strength is achieved. Normal values typically range from 1 to 4 minutes. The K time can be used to assess fibrinogen and platelet count.

- **Alpha (α) angle.** The α angle is measured between the baseline and the initial slope of the waveform. Normal values typically range from 47° to 74°. The alpha angle can be used in conjunction with the K time to assess fibrinogen and platelet count.
- **Maximum amplitude (MA).** MA is the maximum amplitude of the waveform. Normal values typically range from 55 to 73 mm. MA value can be used to assess platelet function.
- **Lysis time (LY30).** LY30 is the percentage decrease in amplitude 30 minutes after achieving MA. Normal values typically range from 0% to 8%. LY30 can be used to assess fibrinolysis.

Finally, a G value can be calculated to provide an overall assessment of clot strength, which depends on the health of the entire coagulation cascade. Normal values typically range from 5.3-12.4 dynes/cm^2.

Some of the pathologic conditions described by TEG are shown in **FIGURE 9-8**.





Anticoagulant factor deficiency
Delayed clot formation
• **R prolonged**
• α angle decreased
• K prolonged
• **MA decreased**
Platelet blockers
Decreased clot strength
• R normal
• α angle normal
• K prolonged
• **MA decreased**
Fibrinolysis
Accelerated clot breakdown
• R normal
• **MA decreased**
• **LY30 markedly increased**
Hypercoagulable state
Accelerated clot formation
• R decreased
• **α angle increased**
• K shortened
• **MA increased**
DIC (early)
Accelerated clot formation and breakdown
• R decreased
• **α angle increased**
• K shortened
• **MA increased**
• **LY30 increased**

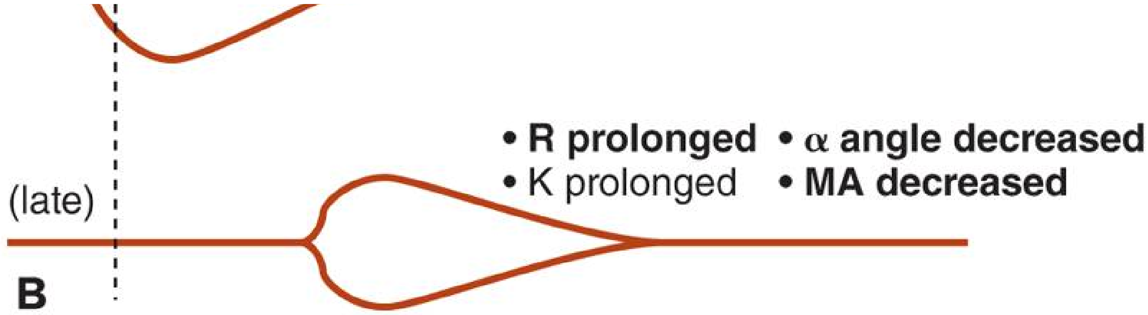


FIGURE 9-8 Visual representation of thromboelastography. **A.** General principle. **B.** Specific pathologic findings. (These images are exaggerated for emphasis.)

Abbreviations: DIC, disseminated intravascular coagulation; K, clot formation time; LY30, lysis time; MA, maximum amplitude; R, reaction time; TE, thromboelastic efficiency.

Description Description

D-Dimer

The D-dimer test was introduced earlier as an example of specificity and sensitivity. D-Dimer is a fibrin degradation product that can be detected in the blood and serves as an indicator of fibrinolysis. The D-dimer test is typically used to assess the presence of clotting when a hypercoagulability state is suspected, meaning both clot formation and clot degradation exist, such as in the diagnosis of DVT. A typical reference level is less than 500 ng/mL, but evidence suggests that higher thresholds are appropriate with increasing age. Given the D-dimer test's profile as highly sensitive but less specific, it is often used as an initial screening test for the diagnosis of DVT or pulmonary embolism within relevant decision tools and practice guidelines (eg, Wells criteria, PERC [pulmonary embolism rule out criteria] rule).

Osmolality

The blood contains numerous components that contribute to its tendency to give or extract free water when blood is placed near a semipermeable membrane. As noted in the chemistry review section, this tendency is commonly called osmolarity, although it is measured as osmolality in clinical medicine. Physiologically, the normal range for osmolality is 275 to 295 mOsm/kg. Although this value was used in the past to assess fluid volume status, the most common current application of serum osmolality is to titrate hyperosmolar infusions (such as mannitol) used in patients with elevated intracranial pressure.

Ethanol

Laboratory analysis may have not only patient care implications, but also legal ramifications. For example, ethanol (also called ethyl alcohol [EtOH]) is not a normal physiologic product in the body; therefore, the ethanol value reported on lab tests if the person has consumed no alcohol is 0 mg/dL. Many labs actually report this ethanol level as <10 mg/dL, which is considered a negative test result for alcohol. In most states, an ethanol level greater than 80 mg/dL is considered positive when an individual is suspected of driving under the influence of alcohol. Lethal levels of ethanol are considered to range from 300 to 400 mg/dL but must be interpreted within the proper clinical context.

Calculated Values

Sometimes in clinical medicine, the result of an individual lab test is subsequently used in a formula for further analysis. For example, a particular lab result may be used only in relation to another test as part of a ratio, or it may be part of a complex formula used to summarize many findings in a coherent manner. From a mathematical standpoint, it is extremely important to not change the order of the ratio variables. For example, a BUN:Cr ratio is not equal to a Cr:BUN ratio. If the ratios are not calculated correctly, deviations from normal cannot be properly interpreted.

Blood Urea Nitrogen:Creatinine

The **blood urea nitrogen:creatinine (BUN:Cr)** ratio is an index used to determine the cause of acute increased levels of BUN and Cr, two metabolites that indicate renal pathology. A normal ratio is 10:1 to 20:1. If this ratio is increased, dehydration, GI bleeding, or increased catabolism may be the cause. Such conditions are called “prerenal” because they are causes of renal dysfunction that are extrinsic to the kidney. A decreased ratio may be present in patients with acute tubular necrosis or autoimmune injury, referred to as “intrarenal” causes associated with direct kidney damage. However, many variables affect this ratio, and BUN:Cr is a less useful marker in patients with chronically elevated values.

Anion Gap

Disturbances in the overall electrical or acid–base balance of the body result from disease and can result in further deterioration in a patient’s condition. The primary pathology is usually related to increased production or intake of physiologically active substances, or to respiratory or kidney problems that interfere with their clearance. The major contributors to the overall electrical charge are Na^+, Cl^-, and HCO_3^-. Their relationship, called the **anion gap (AG)**, is portrayed in the following equation:

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

The normal range for the AG is 8 to 12 mEq/L. An increased AG indicates that unmeasured anions (such as in lactic acid) are present.

One example where the AG can help guide treatment is with states of acidosis such as diabetic ketoacidosis (DKA). As the acidosis progresses, the AG will trend up. As the acidosis is treated and corrected, the AG will trend down. In patients with DKA, when the AG returns to normal levels, it may be interpreted as signaling resolution of the acidotic state.

Blood Gases

A typical **arterial blood gas (ABG) panel** assesses a patient's acid–base status (pH) based on CO_2 tension ($Pa{CO_2}$), HCO_3^-, and base excess (BE). Measures of the patient's oxygen status, oxygen tension (partial pressure of oxygen [$Pa{O_2}$]), and oxygen saturation ($Sa{O_2}$) are also provided as part of the ABG panel. There are many reasons for assessing a patient's blood gas parameters, and any patient in the intensive care unit is likely to meet at least one of these criteria.

Venous blood gas (VBG) analysis can be performed as an alternative to the ABG panel, though certain parameters require different reference ranges or are altogether unhelpful when analyzed in venous rather than arterial blood. For simplicity, our discussion of acid–base status focuses on ABG analysis.

Acid–Base Status

The acid–base balance reflects how well the body's respiratory and metabolic systems are functioning. If they are working properly and in harmony, then there is a balance. When they are not, acidosis or alkalosis can occur. Importantly, abnormal values of CO_2 and HCO_3^- can represent primary disturbances or secondary compensatory processes in response to other stimuli; therefore, these values must be interpreted in conjunction with the pH and, of course, within the clinical context.

Hydrogen Ion Concentration

A direct measure of the acid–base status of the patient, hydrogen ion (H^+) concentration, more commonly referred to as pH, quantifies the amount of unbuffered H^+ present. Physiologic pH is related to the amount of CO_2 and the amount of HCO_3^-. An increase in the $P{CO_2}$ will result in a smaller fraction component, which translates into a lower pH (acidic). Conversely, an increase in the HCO_3^- will cause a larger fraction component and, therefore, will result in an increased pH (alkaline). The inverse of each of these disturbances will result in the respective opposite effect on the pH. In other words, a decrease in $P\text{CO}_2$ will increase pH, while a decrease in $H\text{CO}_3^-$ will decrease pH. Based on the other components of the blood gas panel, the pH derangement (acidosis or alkalosis) can be classified as metabolic or respiratory, respectively.

The normal range for the arterial pH is 7.35 to 7.45; the normal range for the venous pH is slightly lower, 7.31 to 7.41. The body can handle minor variations in pH relatively well. By contrast, once deviations in pH become extreme—for example, 7.0 or less, or 7.6 or more (arterial)—normal physiologic reactions may be drastically affected. With large derangements in serum pH, many proteins and enzymes cease to carry out their normal functions, and vasopressors are inactivated. For example, in patients with severe acidosis, epinephrine is rendered physiologically inactive. Few body systems or enzymes function at extremely low pH levels; a pH of 6.888 is considered to be generally incompatible with survival.

Partial Pressure of CO_2

The natural by-product of cellular respiration, CO_2 is transported back to the lungs by a number of mechanisms. CO_2 exists in the blood as a soluble gas, whose presence is measured as a partial pressure—that is, the partial pressure of CO_2 ($Pa\text{CO}_2$). Because alterations in respiratory function substantially affect the $Pa\text{CO}_2$, this parameter is considered the respiratory component of the blood gas analysis. If the $Pa\text{CO}_2$ is above or below the normal range of 35 to 45 mm Hg, a respiratory derangement is present. Hypercapnia (high $Pa\text{CO}_2$) generally indicates that the patient is experiencing hypoventilation (low minute ventilation), whereas hypocapnia (low $Pa\text{CO}_2$) generally signals the presence of hyperventilation (high minute ventilation). This derangement may be primary (ie, respiratory acidosis or alkalosis) or secondary (ie, compensated metabolic acidosis or alkalosis).

Bicarbonate

In the blood gas panel, whereas $Paco_2$ represents the respiratory component, as noted earlier, Hco_3^- represents the metabolic component. If there is a metabolic aspect to an acidosis- or alkalosis-related condition, a corresponding derangement in Hco_3^- will be seen: The level of this ion will be decreased in metabolic acidosis and increased in metabolic alkalosis. Physiologic alterations in Hco_3^- concentration can also compensate for chronic primary respiratory disturbances.

The normal Hco_3^- level is 22 to 26 mEq/L. The administration of intravenous Hco_3^- to treat metabolic acidosis is controversial.

Base Excess

Base excess (BE) is a measurement of metabolic derangement that is included as part of the ABG panel. Base excess is also known as base deficit (BD) because this value can be either a positive number (excess) or a negative number (deficit). Healthy people do not have an appreciable BE. The BE is measured in units of mEq/L and has a normal range of −2 to +3. If there is an excess amount of acid or a lack of base, the BE is negative. Conversely, if there is an abnormally small amount of acid or an excess amount of base, the BE is positive. Positive values beyond the normal range indicate an excess of Hco_3^- (base), whereas negative values less than the normal range indicate a deficit of Hco_3^-. The more extreme the metabolic derangement, the larger the BE value will be.

Some clinicians use BE value to assess for proper fluid resuscitation. If the amount of fluid present is not adequate to support the body’s metabolic activities (as in hypovolemic shock), the patient will experience ineffective energy production, which leads to a concomitant increase in the lactic acid level. The BE value in such a case may be classified as mild (−2 to −6), moderate (−6 to −15), or severe (−15 or greater). If a patient has normal vital signs with a continued high negative BE, a source for the continued shock should be sought.

Oxygenation Status

Partial Pressure of Oxygen

The **partial pressure of oxygen (Po_2)** measures the amount of oxygen dissolved in the blood. A healthy person has an arterial Po_2 in the range of 80 to 100 mm Hg. Other than in some narrowly defined cases (eg, carbon monoxide poisoning), patients do not benefit from having a Po_2 greater than 100 mm Hg; the most important consideration is simply that the Po_2 remain within the normal range. As the Po_2 falls below 80 mm Hg, the hemoglobin's affinity for oxygen decreases and oxygen is released more readily from the hemoglobin molecule, which results in hypoxia.

Oxygen Saturation

Oxygen saturation measures the percentage of potential oxygen-binding sites on hemoglobin that are currently occupied by oxygen molecules. The oxygen saturation measured transcutaneously (Spo_2), using a saturation monitor and probe, differs from the oxygen saturation calculated from an arterial or venous blood sample (Sao_2) that is reported on a blood gas report, because in the latter case Sao_2 is calculated based on other parts of the blood gas panel. The normal value for measured Sao_2 in a healthy person is greater than 93%. The calculated saturation from the blood gas values can give a falsely elevated saturation when abnormal hemoglobin variants, such as carboxyhemoglobin and methemoglobin, are present in the sample. This consideration is important: Although the Sao_2 value may appear normal, the patient might actually have a poor oxygen distribution because the abnormal hemoglobin variants cannot carry oxygen.

Carboxyhemoglobin

Because carbon monoxide binds very tightly with hemoglobin, the body's ability to transport oxygen can become extremely compromised when too much carbon monoxide is present in the body. Although some **carboxyhemoglobin (COHb)**, a hemoglobin derivative, is always present in the vasculature, normal levels of this compound are thought not to exceed 0.02 (2%). The percentage reported in testing is based on the amount of total hemoglobin.

Assessment of COHb levels is useful in confirming a diagnosis of carbon monoxide poisoning, and it may be used to guide therapy as well. Caution should be used in assessing COHb levels in smokers, as their baseline COHb levels are routinely higher than the levels of nonsmokers. COHb levels are often elevated in critically ill patients for reasons that are poorly understood.

Most blood gas analyses provide a carboxyhemoglobin level as part of a full arterial or venous blood gas report. When carbon monoxide poisoning is suspected, it is not necessary to obtain an arterial blood specimen; venous carboxyhemoglobin levels are closely correlated with arterial values.

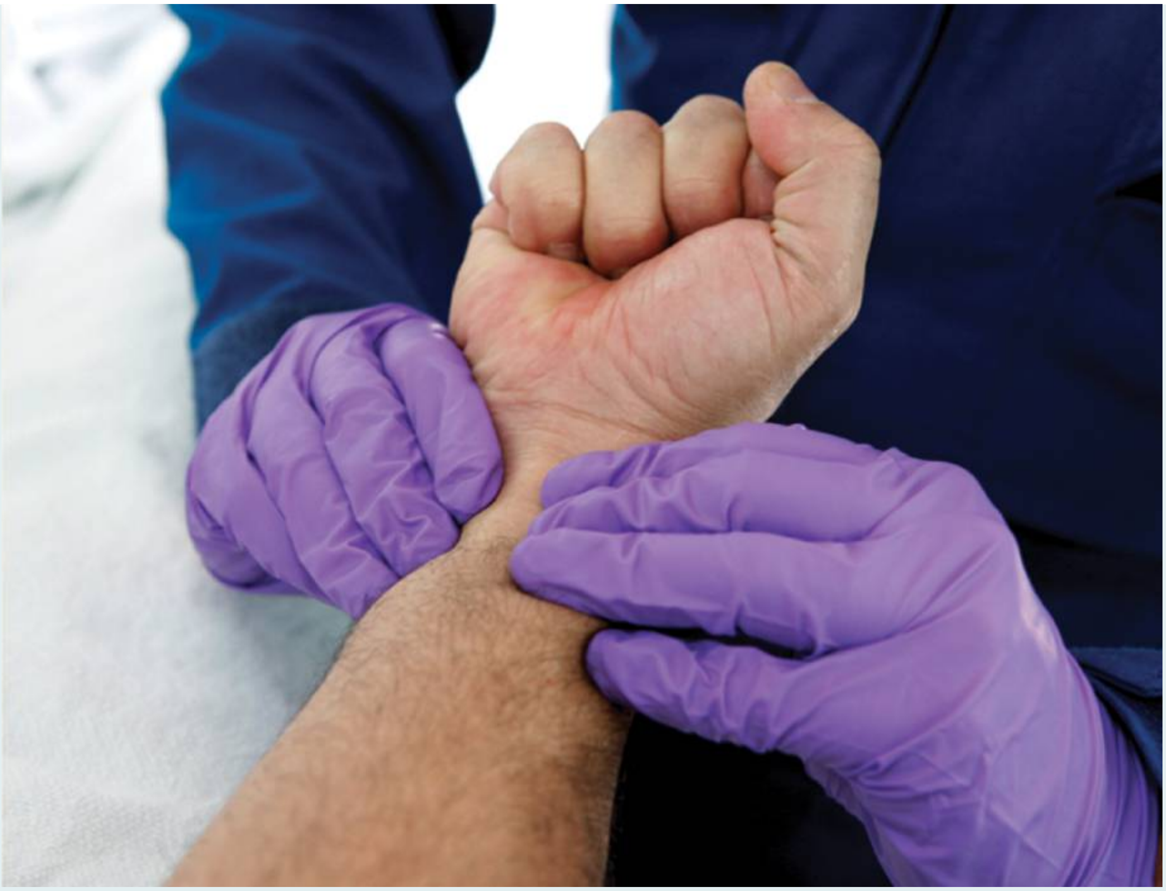
Obtaining Blood Samples

Arterial Blood Samples

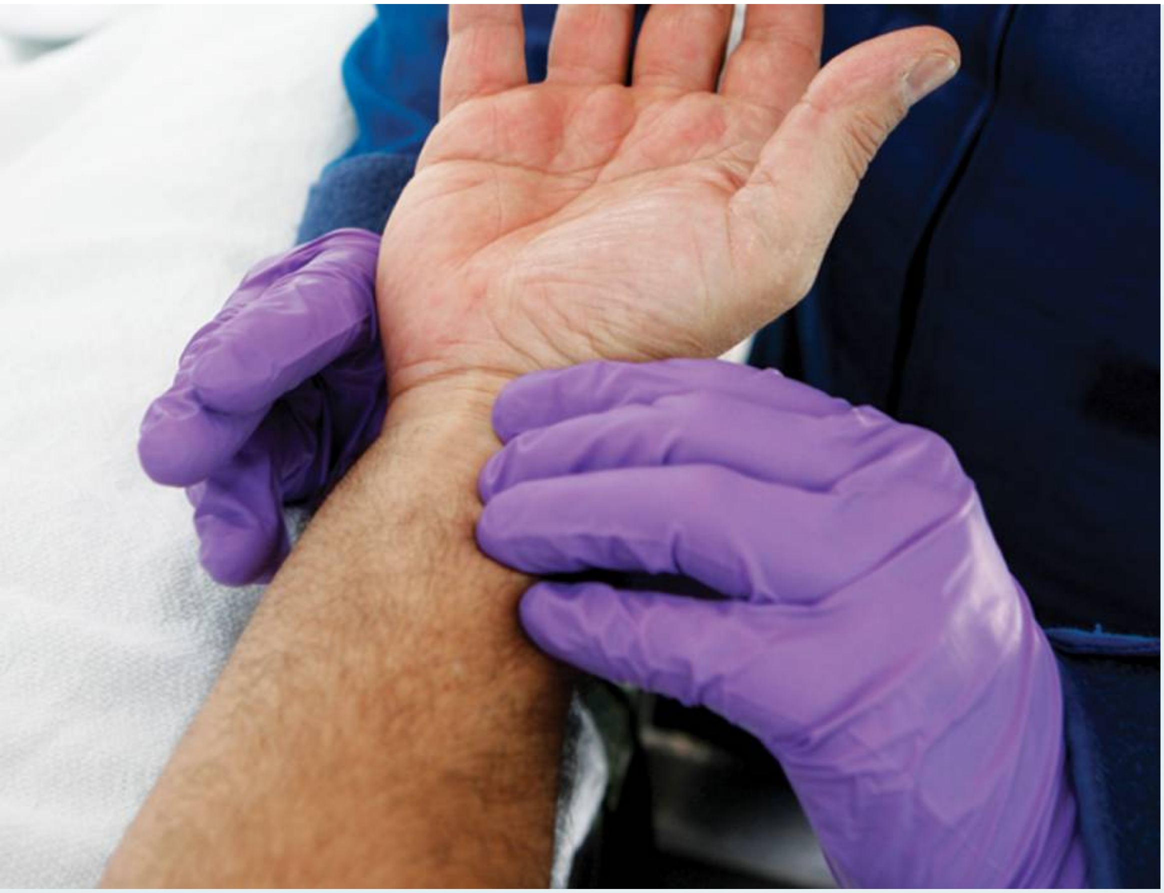
Skill Drill 9-1 shows the steps to obtain an arterial blood sample, which are also described here:

SKILL DRILL 9-1 Obtaining an Arterial Blood Sample

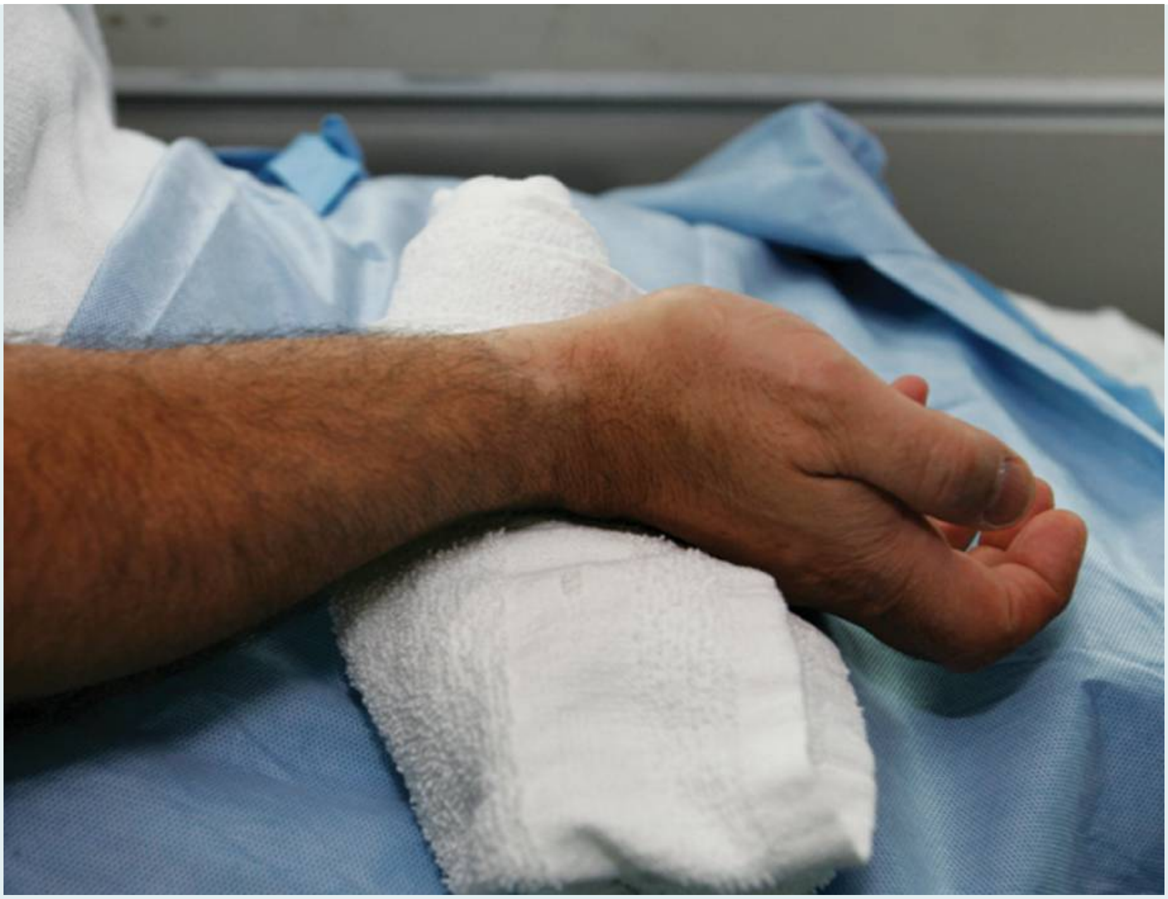
Step 1
Determine the appropriate arm from which to take the specimen.



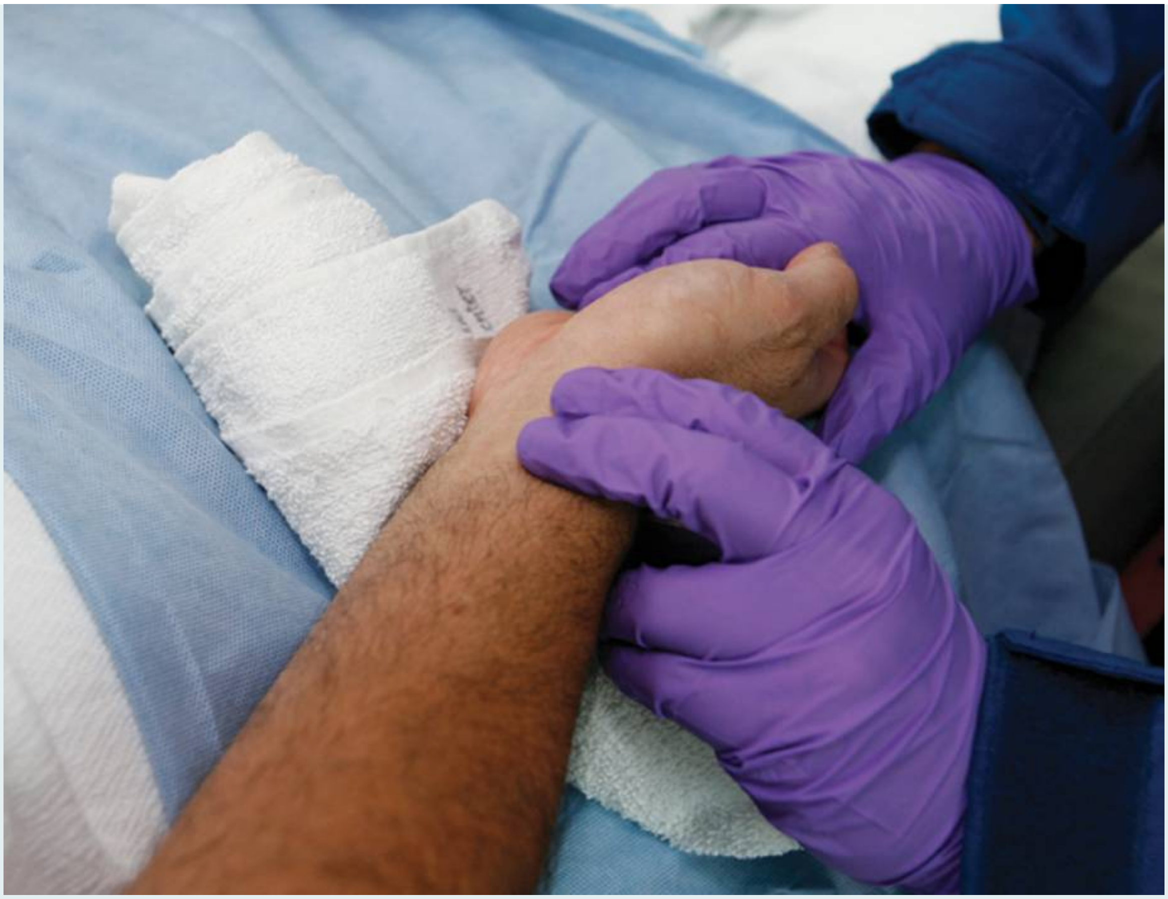
Step 2
Have the patient make a fist. Compress the radial and ulnar arteries.



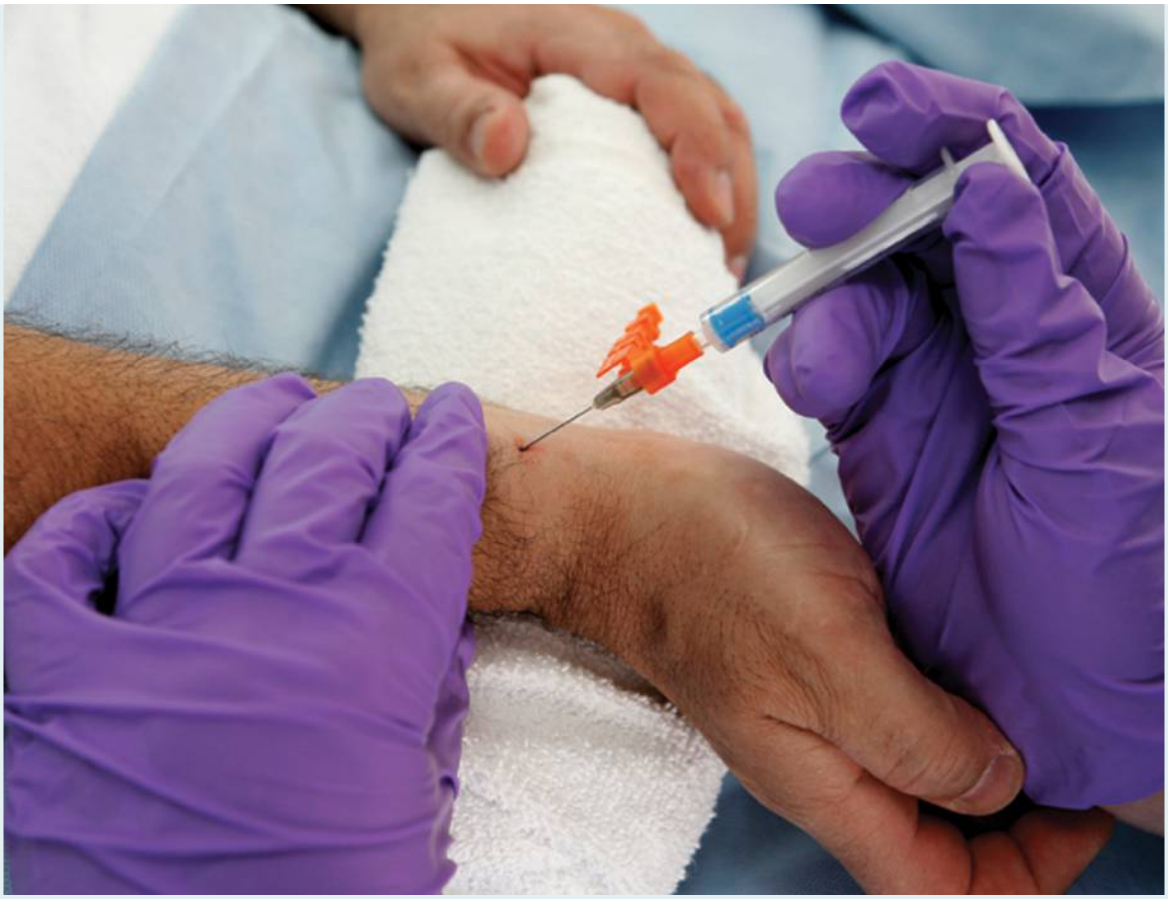
Step 3
When the patient’s hand turns white or pale, release compression of the ulnar artery and assess circulation. Repeat for the radial artery. Ensure universal precautions.



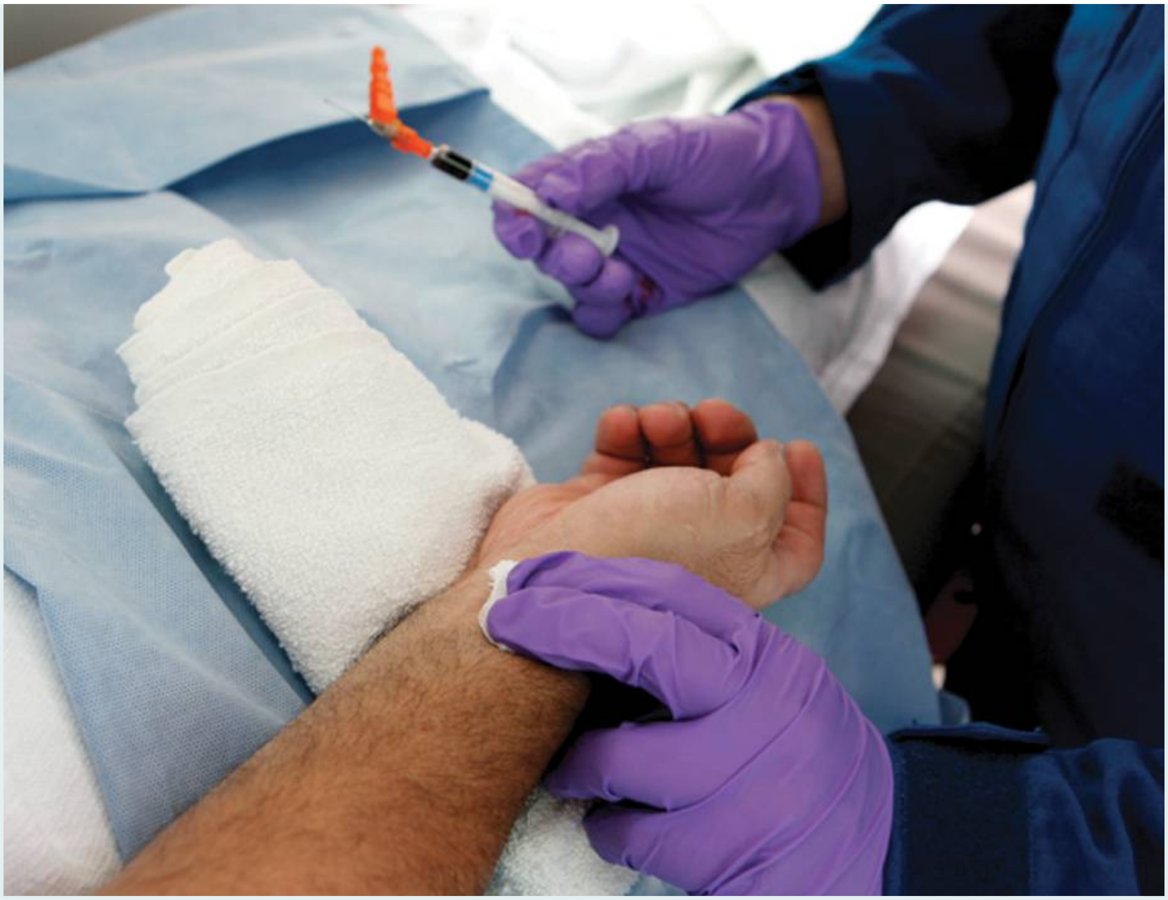
Step 4
Position the patient’s arm with a small towel roll beneath the wrist to slightly extend the wrist.



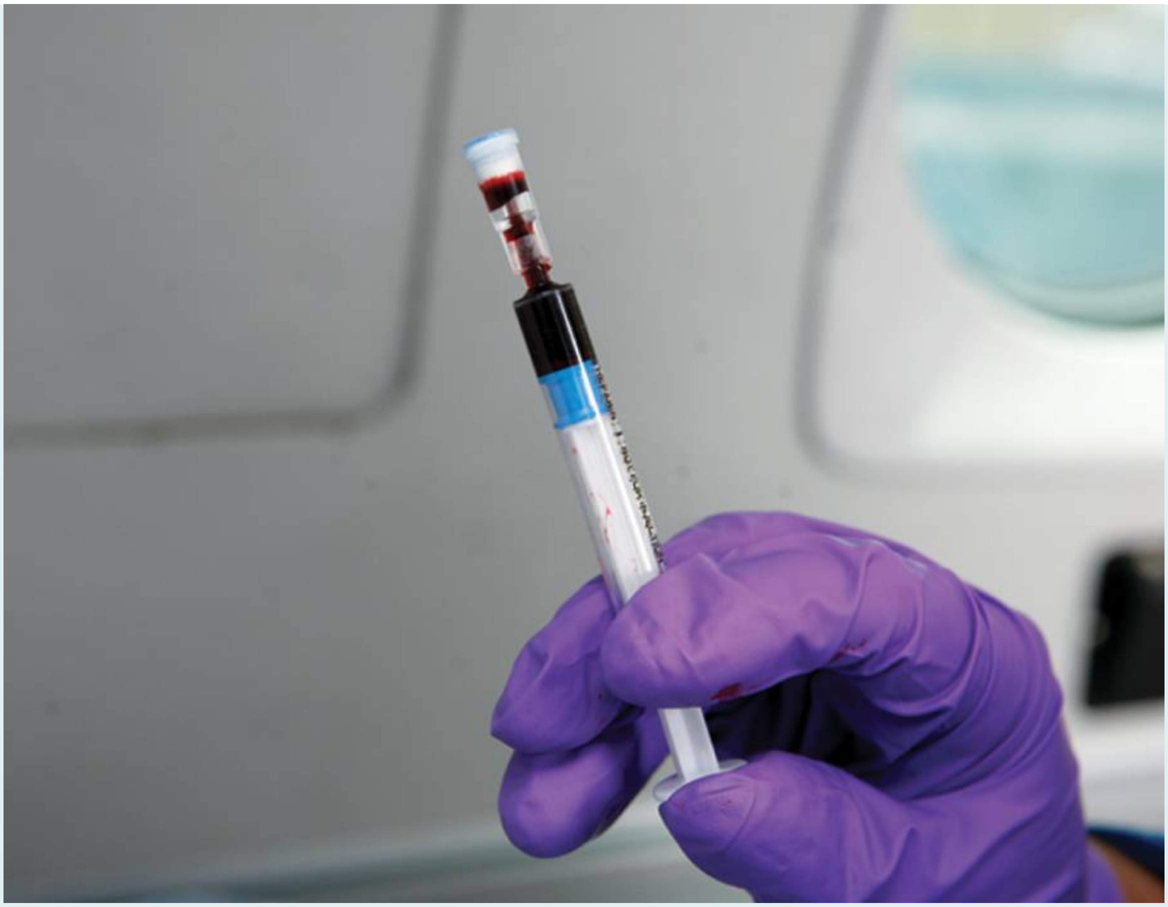
Step 5
Palpate the radial artery with your index and middle fingers.



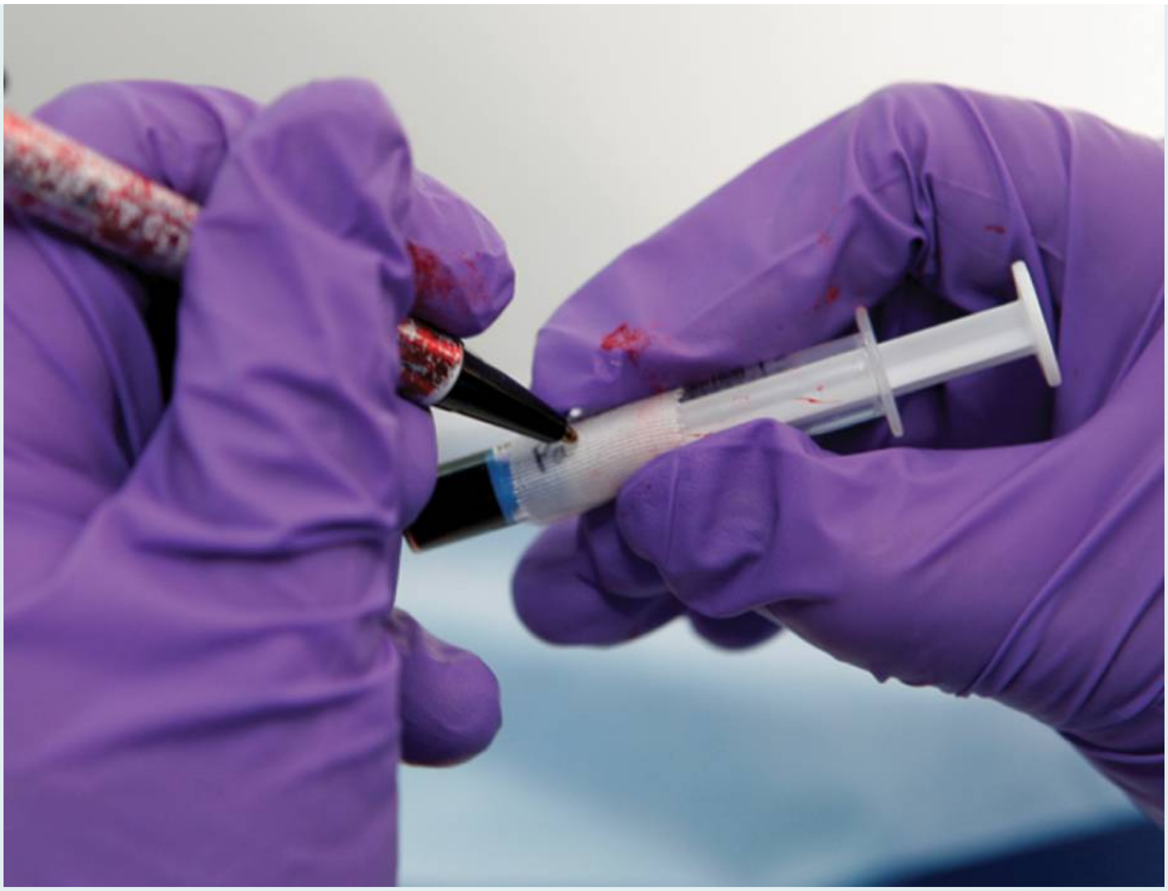
Step 6
Locate the radial artery and puncture the skin with the bevel of the needle at a 45° angle.



Step 7
Rapidly remove the needle and hold pressure on the site for approximately 2 to 5 minutes.



Step 8
Safely remove the needle and expel any air contained within the syringe.



Step 9
Label the syringe with appropriate patient identification.

Step 10
Reassess neurovascular status.

© Jones & Bartlett Learning.

1. Appropriately identify the patient. Explain the procedure. Determine the appropriate arm from which to take the specimen **STEP 1**.
2. Perform an Allen test. First have the patient raise the hand above the level of the heart, and then have the patient make a fist while you simultaneously compress the radial and ulnar arteries **STEP 2**.
3. When the patient's hand turns white or pale, release compression of the ulnar artery and assess circulation. The color should return to baseline in approximately 5 to 7 seconds **STEP 3**.
4. Repeat Steps 2 and 3 while releasing the radial artery. Sluggish return of color may indicate occlusion in one or both of the arteries.

Arterial puncture should not be performed on this extremity.

5. Ensure universal precautions.
6. If possible, position the patient’s arm with a small towel roll beneath the wrist to slightly extend the wrist (do not overextend) **STEP 4**.
7. Prepare the site per protocol.
8. Palpate the radial artery with your index and middle fingers (do not use your thumb) **STEP 5**.
9. Locate the radial artery and puncture the skin with the bevel of the needle at a 45° angle. The syringe should rapidly fill with bright red blood **STEP 6**. Do not dig or probe with the needle! If you have difficulty, slightly reposition the needle. If you continue to have difficulty, stop and restart the procedure.
10. Once the appropriate amount of blood has filled the syringe, rapidly remove the needle and hold pressure on the site for approximately 2 to 5 minutes **STEP 7**.
11. Safely remove the needle and expel any air contained within the syringe **STEP 8**.
12. Place a rubber stopper on the syringe.
13. Label the syringe with appropriate patient identification **STEP 9**.
14. Immediately perform the test or place the specimen on ice.
15. Reassess the patient’s neurovascular status **STEP 10**.

Venous Blood Samples

If the patient has a peripheral IV line and is receiving fluids or medications, if at all possible, the other extremity should be used to obtain a venous blood sample. If the patient has IV lines in both extremities, the one without IV medication or without the medication that is being tested should be used. For example, a finger-stick blood glucose sample should not be obtained in an extremity where an IV infusion containing dextrose is running. The flow of fluid or medication needs to be paused or stopped immediately prior to obtaining the blood sample; otherwise, the sample may become contaminated with infusate. Minimum discard volumes are also recommended when obtaining blood specimens from arterial and central venous lines, as discussed in Chapter 15, *Hemodynamic Monitoring*.

Blood Tube Uses

Blood tubes are selected primarily based on the preservatives or lack of preservatives that they contain. Most laboratories have specific requests regarding tube selection and the number of tubes needed. The desired tube selection is usually communicated by the laboratory **TABLE 9-2** and **FIGURE 9-9**.

TABLE 9-2 Blood Tube Uses

Blood Tube Color	Use
Lavender	Complete blood count
Red	Blood banking
Marbled	Serum chemistry tests
Blue	Coagulation studies
Green	Plasma studies
Yellow	Human leukocyte antigen typing
Navy	Trace metals
Gray	Lactate

Point-of-Care Testing

Traditionally, tests used to make clinical patient care decisions have required the health care provider to send a specimen to a laboratory, where trained personnel run the test and then report its results. Increasingly, however, demands for faster results and miniaturization of laboratory testing instruments have brought testing and reporting to the patient bedside **FIGURE 9-10**. **Point-of-care testing (POCT)** refers to testing done outside of a traditional laboratory, usually near where care is being delivered to a patient, with the results of the testing being used for clinical decision making (ie, changes in patient care). POCT is also called decentralized testing, bedside testing, and ancillary testing.

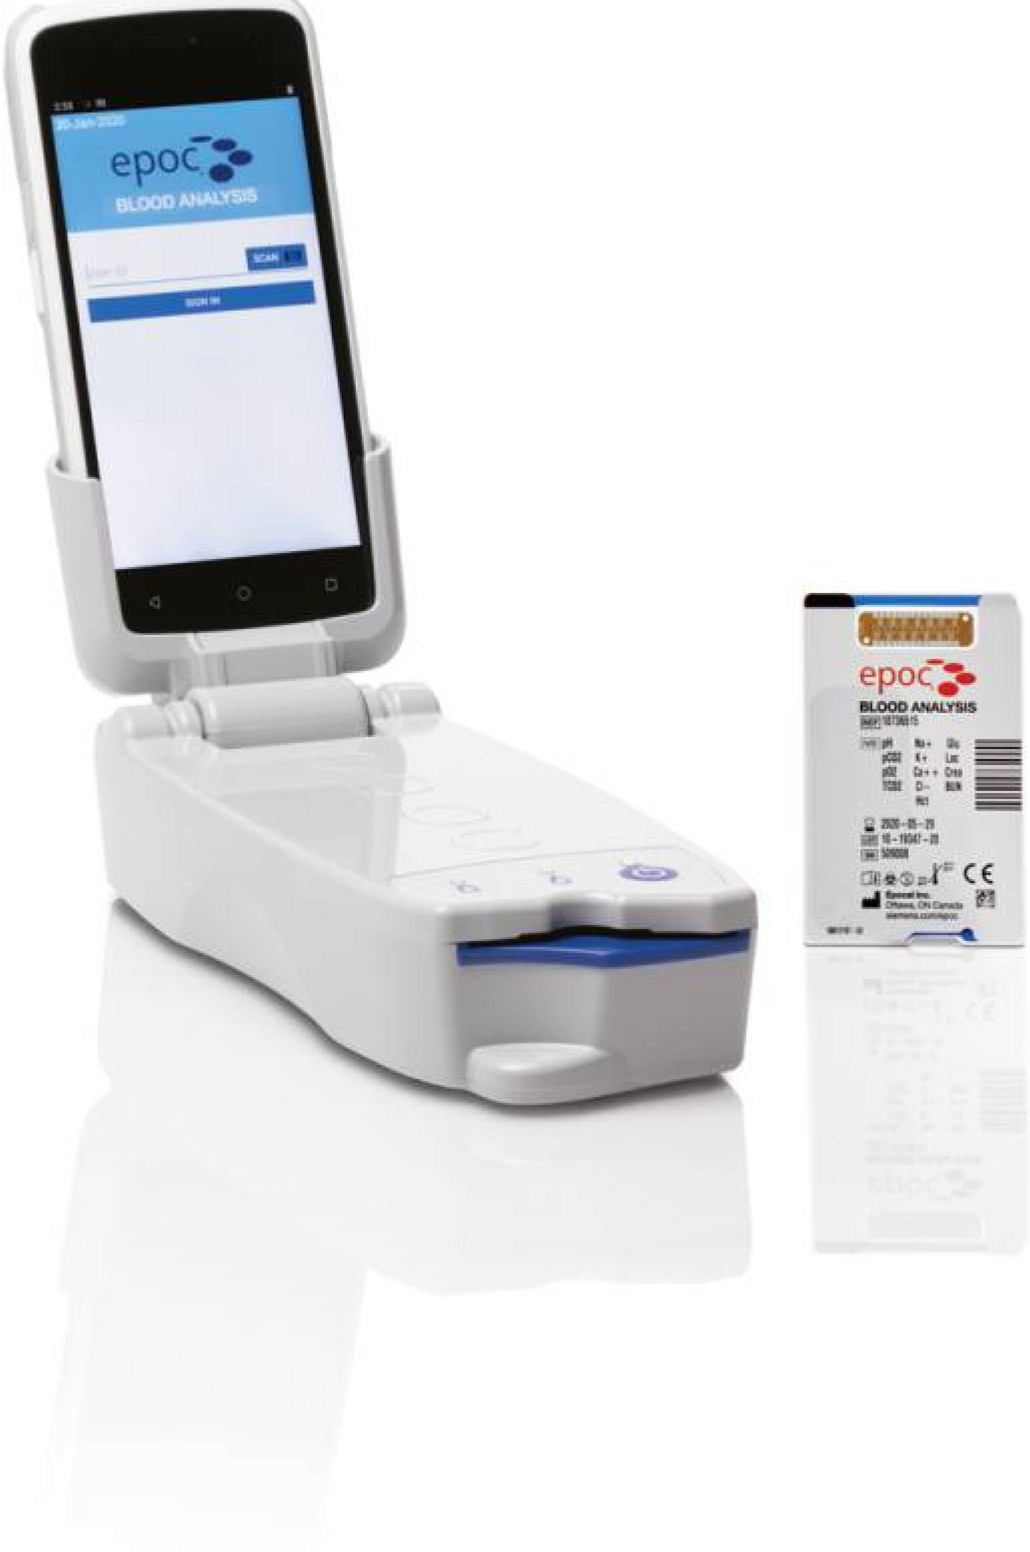

FIGURE 9-10 Point-of-care testing allows testing to be performed outside of a traditional laboratory. The epoc® Blood Analysis System is pictured.

Regulation of Laboratory and Point-of-Care Testing

Highly publicized cases of deaths attributed to missed cervical cancers from false-negative reads of Pap smears led Congress to pass the Clinical Laboratory Improvement Act (CLIA) in 1988. Today, state and federal regulations cover almost every test performed on specimens from humans, including those done in the home, physician offices, or a CCT unit.

CLIA classifies some laboratory tests as having a low risk for reporting incorrect results. These “waived tests” include tests cleared by the US Food and Drug Administration (FDA) for home use (such as certain blood glucose meters) and other tests approved for a waiver by the FDA using the CLIA criteria. Generally, these tests are very simple and highly accurate, or they pose no reasonable risk of harm if they are performed incorrectly. Health care providers who perform waived tests must have a CLIA certificate authorizing them to do so, and must carefully follow the test manufacturer’s instructions.

Nonwaived testing encompasses all other laboratory tests except for provider-performed microscopy. Such tests are divided into moderate or high complexity categories. Providers performing nonwaived testing must have a CLIA laboratory certificate, be inspected, and meet CLIA quality standards, which mandate regular proficiency testing of all test operators.

Implications for Critical Care Transport Professionals

It is critical for CCTPs to be familiar with any POCT equipment they use and to know whether a test they perform is classified as waived, moderate complexity, or high complexity, as this status determines the applicable CLIA or state laboratory requirements. Based on field experience, the FDA may choose to waive tests or revoke previously issued waivers, which can impact the POCT that a CCTP may perform in the field.

In the context of POCT, the term “CLIA exempt” refers to a lab, service, or user that has been licensed or approved by a state where the state laws or regulations are equal to or more stringent than CLIA, and where the state licensure program has been approved by the Centers for Medicare and Medicaid Services (CMS). Washington and New York are two such CLIA-exempt states. CCTPs in CLIA-exempt states must comply with state testing and licensing requirements.

Multiple POCT devices are suitable for use in CCTP units, all of which require various levels of operator training, competency, and credentialing. Each manufacturer offers training to users and assistance with regulatory compliance and policy development.

Urine Lab Values

Urinalysis involves performing various laboratory tests (including some of the same tests performed on blood samples) on a patient's urine **TABLE 9-3**. Roughly one-fourth of the heart's cardiac output enters the kidneys for filtration, and the urine produced by the kidneys provides a way of investigating the patient's physiologic status. Tests performed on urine may range from simple (such as color) to complex (such as specific gravity). Many drugs can be detected in the urine for hours, days, or weeks after their use. **TABLE 9-4** lists drugs of abuse that can be tested in urine, including how long the drug can be detected in the urine after its use. Urine can also be tested for biomarkers of physiologic processes, such as in pregnancy tests that qualitatively test for the presence of human chorionic gonadotropin (hCG) in the urine.

TABLE 9-3 Common Urinalysis Values

Analyte	Normal Values Reported on a Typical Urinalysis
Color	Yellow (light/pale to dark/deep amber)
Clarity/turbidity	Clear or cloudy
pH	4.5–8
Specific gravity	1.005–1.025
Glucose	≤130 mg/dL
Ketones	None
Nitrites	Negative

Analyte	Normal Values Reported on a Typical Urinalysis
Leukocyte esterase	Negative
Bilirubin	Negative
Urobilirubin	Small amount (0.5–1 mg/dL)
Blood	≤3 RBCs × 10^6/μL
Protein	≤150 mg/dL
RBCs	≤2 RBCs/hpf
WBCs	≤2–5 WBCs/hpf
Squamous epithelial cells	15–20 squamous epithelial cells/hpf
Casts	0–5 hyaline casts/lpf
Crystals	Occasionally
Bacteria	None
Yeast	None

Abbreviations: hpf, high-power field; lpf, low-power field; RBCs, red blood cells; WBCs, white blood cells

© Jones & Bartlett Learning.

TABLE 9-4 Drugs of Abuse That Can Be Detected in Urine

Drug	Length of Time Detected in Urine
Alcohol	7–12 hours
Amphetamine	48 hours
Barbiturate	24 hours (short acting); 3 weeks (long acting)

Drug	Length of Time Detected in Urine
Benzodiazepines	3 days
Cocaine	6–8 hours (metabolites, 2–4 days)
Heroin	36–72 hours
Marijuana	3 days to 4 weeks (depending on dose)
Methadone	3 days
Methaqualone	7 days
Morphine	48–72 hours
Phencyclidine	8 days
Propoxyphene	6–48 hours

© Jones & Bartlett Learning.

Color

Color may be the most simplistic laboratory analysis performed. This assessment simply notes the urine color, which is often classified as yellow, pale, clear, and so forth. Urine's color is a function of concentration, with more concentrated urine being darker yellow. Various other particulates in the urine can affect the color as well. If the person's glomeruli or renal tubular system is damaged and blood is spilling into the urine, the urine may be reddish. Brown or tea-colored urine often reflects the presence of large amounts of protein in the urine and is a hallmark sign of rhabdomyolysis.

Appearance

Similar to color, urine appearance is a rather coarse assessment. Appearance is categorized as clear (similar to color) or **turbid** (cloudy or opaque). Turbidity can be indicative of a bladder infection and should be examined further.

Specific Gravity

Specific gravity is a chemical property of a fluid that relates its density to the density of water. Distilled water is arbitrarily given a specific gravity of 1, so fluid that is denser than water has a specific gravity greater than 1. The more concentrated a urine sample is, the denser the sample and the higher its specific gravity will be. Conversely, a low specific gravity indicates a more dilute urine sample. At the simplest level, athletes measure specific gravity to assess their hydration status. Higher-than-normal specific gravity would reflect volume depletion in an otherwise healthy athlete.

The normal range for urine specific gravity is 1.003 to 1.035; in the setting of impaired ability to concentrate urine, the specific gravity may approach 1.001. Numerous factors can affect the kidney's ability to concentrate the urine. For example, if the pituitary gland secretes an abnormally low level of antidiuretic hormone, this condition may lead to diabetes insipidus. This metabolic disorder impairs the ability of the kidney to concentrate the urine (ie, the body reabsorbs free water), so the specific gravity of urine will be very low (ie, there would be copious amounts of dilute urine). Other disorders, such as glomerulonephritis and pyelonephritis, may also impair the kidney's ability to concentrate urine.

pH

The H^+ concentration in the urine can be a useful marker for metabolic acidosis. Unlike serum pH, urine pH has a relatively wide normal range, 4.5 to 8. Patients with acidic urine often have large amounts of unbuffered acid (eg, lactic acid or keto acid). Salt wasting may also occur as the body excretes a positive ion (eg, Na^+) to counteract the negatively charged acid salt of lactate or keto acetate.

Certain renal abnormalities may render the kidneys unable to excrete H^+ in the urine, even in the presence of overwhelming metabolic acidosis. This abnormality is called **renal tubule acidosis (RTA)**. Four types of RTA are distinguished, although the specifics of each type are not included here. Nevertheless, CCTPs should be able to identify the presence of RTA, defined as an arterial pH of less than 7.35 and a urine pH of greater than 6. Generally, the biggest concern is that the kidneys are not able to concentrate urine, which will cause wasting of potassium and magnesium.

Glucose

The presence of glucose in the urine (**glycosuria**) is almost always indicative of elevated serum glucose levels. In healthy people, the urine does not contain any glucose, so the normal value of this marker is 0. If glucose is present, its amount is graded on a scale of mild to severe, expressed as +1, +2, +3, or +4. The presence of glycosuria may not always signal ineffective insulin production or function (as in diabetes mellitus). For example, in some cases it may result from the administration of a carbohydrate-containing intravenous fluid such as 5% dextrose in water. The specific context for the patient will dictate when a value outside the normal range is pathologic.

Ketone Bodies

Fat catabolism occurs when the available supply of glucose does not suffice to satisfy the tissues’ need for energy. If the body does not completely break down fat into CO_2 and water, ketone bodies are produced. The term **ketone bodies** describes a number (typically three) of organic products: acetoacidic acid, acetone, and beta-hydroxybutyric acid. Acetoacidic acid and beta-hydroxybutyric acid are keto acids that are produced as by-products during a starvation state in which the body is forced to rely on metabolism of lipid stores for energy. For example, diabetic ketoacidosis occurs when inadequate insulin is present and cells are unable to use glucose as a source of energy, forcing the body to engage in lipid metabolism, which yields ketone bodies as a by-product. Although ketone bodies are not normally found in the urine, their presence can help identify inadequately controlled diabetes mellitus. Other causes of **ketonuria** (ketone bodies in the urine) include alcoholic ketoacidosis and starvation ketosis.

Grading of the level of ketonuria uses the same system as grading of the amount of glucose in urine: +1, +2, +3, or +4.

Protein

Although the body excretes 40 to 80 mg of protein (one-third of which is albumin) in the urine each day, this amount is below the detectable threshold for typical tests; thus, the normal reference value in a qualitative test for protein would be negative (or not detectable). Urinary protein is one of the most important assessments for kidney disease. Detectable levels of urinary protein (proteinuria) can result from either renal causes (such as glomerulonephritis, polycystic kidneys, diabetic nephropathy, toxic nephropathy, nephrosclerosis, and nephritic syndrome) or extrarenal causes (such as preeclampsia, multiple myeloma, urinary tract disease, amyloid disease, systemic lupus erythematosus, heart failure, and constrictive pericarditis).

Blood and Hemoglobin

The presence of blood in the urine is highly suggestive of kidney or urinary tract damage. Recall that blood is not able to cross the glomerular membrane and enter the filtrate. Thus, the presence of hemoglobin in the urine (**hemoglobinuria**) most often indicates traumatic passage of RBCs through the collecting ducts, urinary bladder, or urinary tract. Urinary hemoglobin may also result from filtering of serum hemoglobin during hemolytic transfusion reactions or certain blood disorders such as hemolytic anemia.

The presence of RBCs in the urine (**hematuria**) may indicate the presence of glomerular membrane or urinary tract disease. The cause may be an infectious process (commonly a urinary tract infection), neoplasm, ureterolithiasis, or trauma. Note that RBCs detected in a urinalysis performed soon after placement of an indwelling urinary catheter may merely reflect trauma from insertion of the catheter.

Myoglobin in the urine (myoglobinuria), caused by rhabdomyolysis, can also cause a positive hemoglobin result. Myoglobinuria, which may indicate a serious threat to the kidneys, can be distinguished from hemoglobinuria by a positive urine hemoglobin result combined with a negative urine RBC result.

Electrolytes

To better understand how the body is eliminating certain electrolytes, a quantitative analysis is performed on the urine. Similar to a basic metabolic panel, this panel analyzes numerous components of the urine. Although their discussion is beyond the scope of this text, urine electrolytes can be useful in clinical management as well, particularly when analyzed alongside serum values.

Diagnostic Imaging

Diagnostic imaging is typically performed by a technologist, and the resulting images are often interpreted by a physician on site or possibly sent off site for interpretation. Typically, copies are included with the patient's charts upon transfer. Note that summaries of findings alone from imaging studies performed at the sending facility are generally insufficient for use at the receiving facility. For example, a typed report describing a femur fracture that requires operative repair will not allow the receiving facility to verify the quality of the images, perform an independent assessment of the findings, and use the data to plan interventions. To undertake an appropriate assessment, the receiving facility must receive a copy of the images, typically stored on a physical disc, unless they can be shared and accessed electronically.

The CCTP should be familiar with these studies and be able to perform basic interpretation for obvious abnormalities, such as long bone fractures, masses, and catheter and tube placements. Contrast dyes can also be used to enhance these imaging modalities, depending on the indication. It is important to have a system for analyzing imaging results and to use that system every time. Think of this process as being akin to the steps of a primary exam: Completing the same steps in the same order will prevent the CCTP from overlooking findings. Extensive interpretation of imaging studies requires significant training and is beyond the scope of this text.

Standard Radiographs

One of the oldest and still frequently used diagnostic imaging modalities is standard or plain **radiography**. Such images can be obtained rapidly and used for quick diagnostics in patient care.

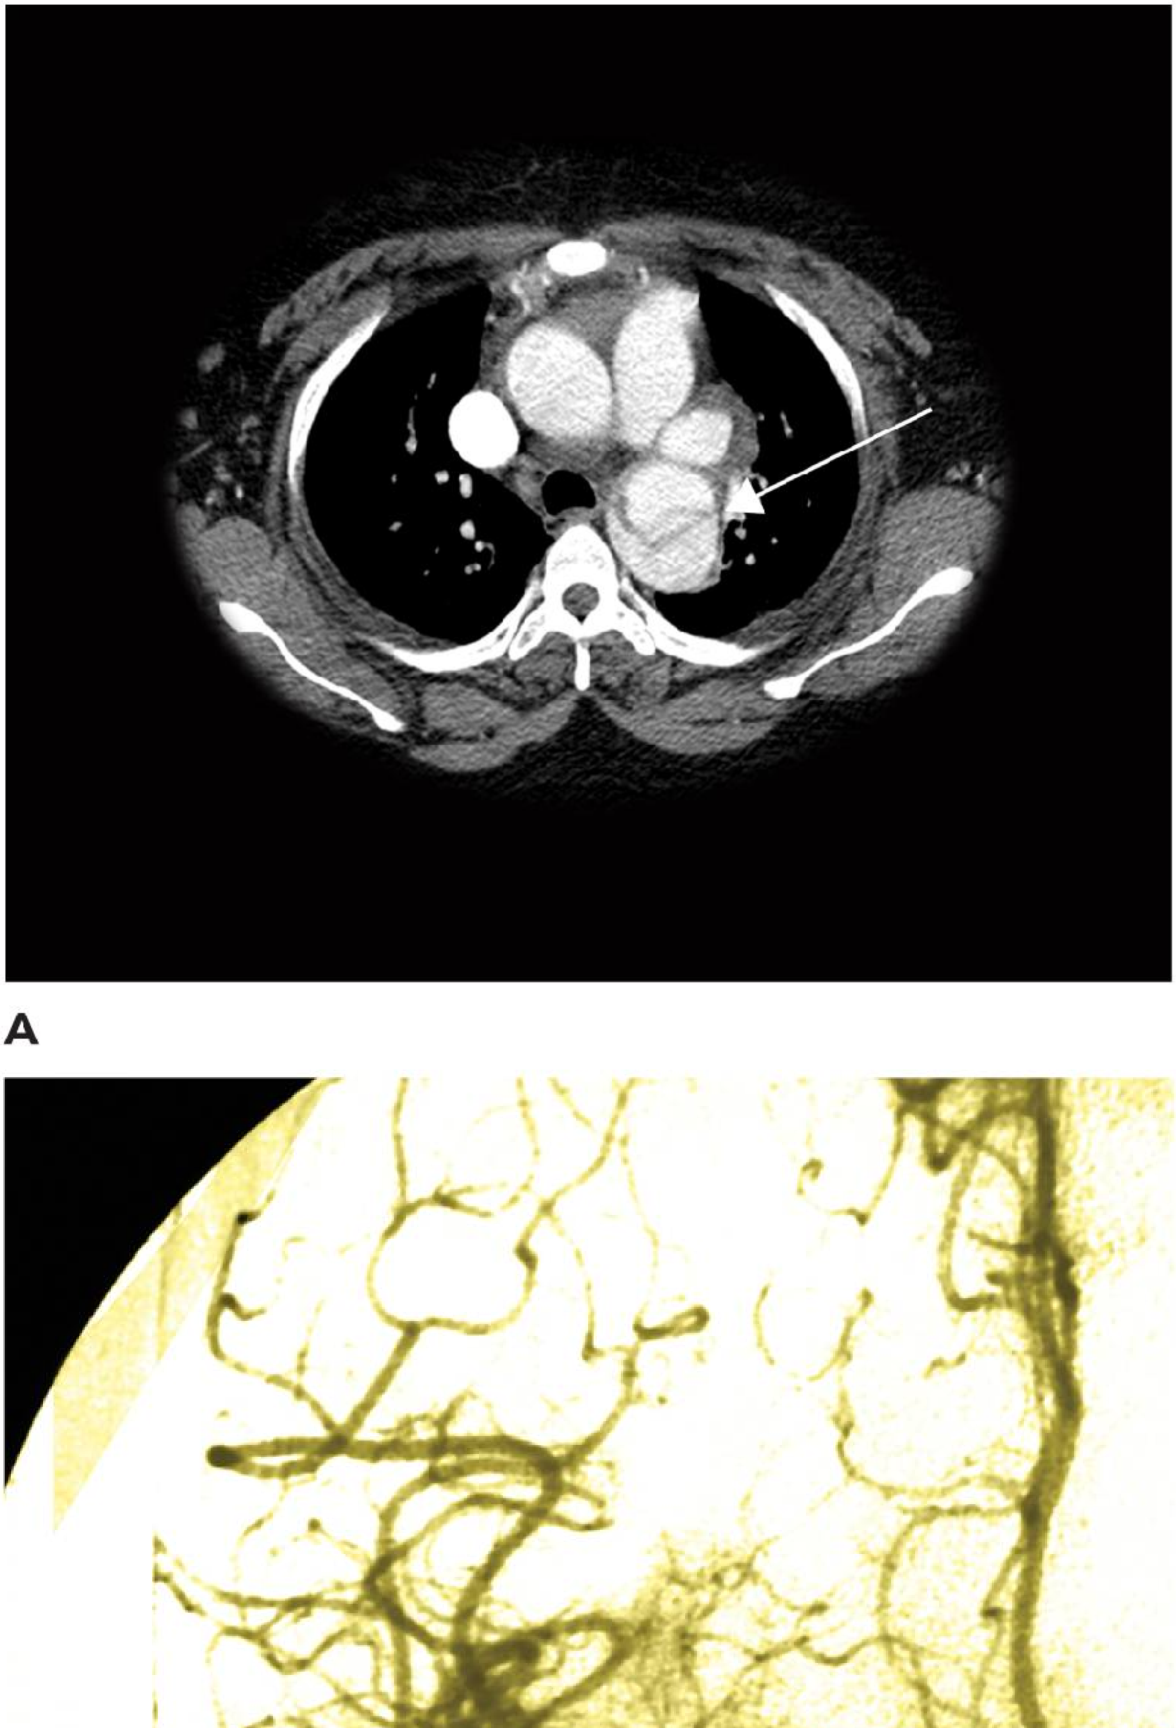
To create a radiograph, radiation (in the form of x-rays) is projected through the tissue and onto a photographic plate. Different densities of the body cause gradation changes in black and white on the film. Dense objects such as bone or blood appear white on the images, whereas less dense objects such as air appear black. Objects with a medium density such as tissues will appear as shades of gray.

Radiographs can be very useful to examine the integrity of the skeletal system (eg, fractures, dislocations), identify the abnormal presence of air or fluid (eg, hemothorax, pneumoperitoneum), and identify or evaluate foreign bodies (eg, bullet fragments in a gunshot wound, placement of an endotracheal tube or central venous catheter). Radiographs generate two-dimensional images that capture the various densities in the path of the radiation. The lack of a third dimension that would indicate the relative depth of objects, however, makes it difficult to evaluate multiple objects of interest within this axis. Therefore, multiple views can be combined to add greater perspective, such as lateral and anteroposterior (AP) views. Radiography provides the basis for more advanced imaging modalities, such as computed tomography and fluoroscopy (continuous radiography that can provide a radiographic image to guide procedures in real time).

Computed Tomography

Computed tomography (CT), also called computerized axial tomography (CAT) scanning, is an imaging method in which cross-sectional images of the structures in the body plane are reconstructed by a computer program to generate three-dimensional images. Focused beams examine an area of interest and are reconstructed by computer to give a high-resolution view. During this imaging study, the patient lies on a table that moves into and out of the scanner device. (The use of CT may be limited in patients with morbid obesity, because they may not fit into the scanner or may exceed the table’s operating limits.) CT scans are typically analyzed by choosing one plane—axial, sagittal, or coronal—and scrolling through a series of two-dimensional slices within that plane to compile a three-dimensional model of the target.

CT scans are commonly used when it is necessary to evaluate different characteristics of tissues, bones, and organs. Because the resulting images are essentially generated using a series of radiographs, low densities (eg, air) are dark and high densities (eg, bone) are white, although various viewing profiles can be used to magnify the contrast between various densities of interest. Unlike conventional radiographs, CT allows differences to be quantified, which can allow for differentiation of tumors from soft tissue, old fractures from new ones, air from fluid, and blood clots from normal blood. The views, or slices, can pick up abnormalities not seen with traditional plain radiography. Interpreting a CT scan can reveal conditions such as aortic dissection, lung injuries, abdominal organ injuries, fractures, pulmonary emboli, pleural effusions, and acute respiratory distress syndrome **FIGURE 9-11**. Interpretation of CT scans is beyond the scope of the CCTP, although it is reasonable to develop a cursory understanding of CT images.



A

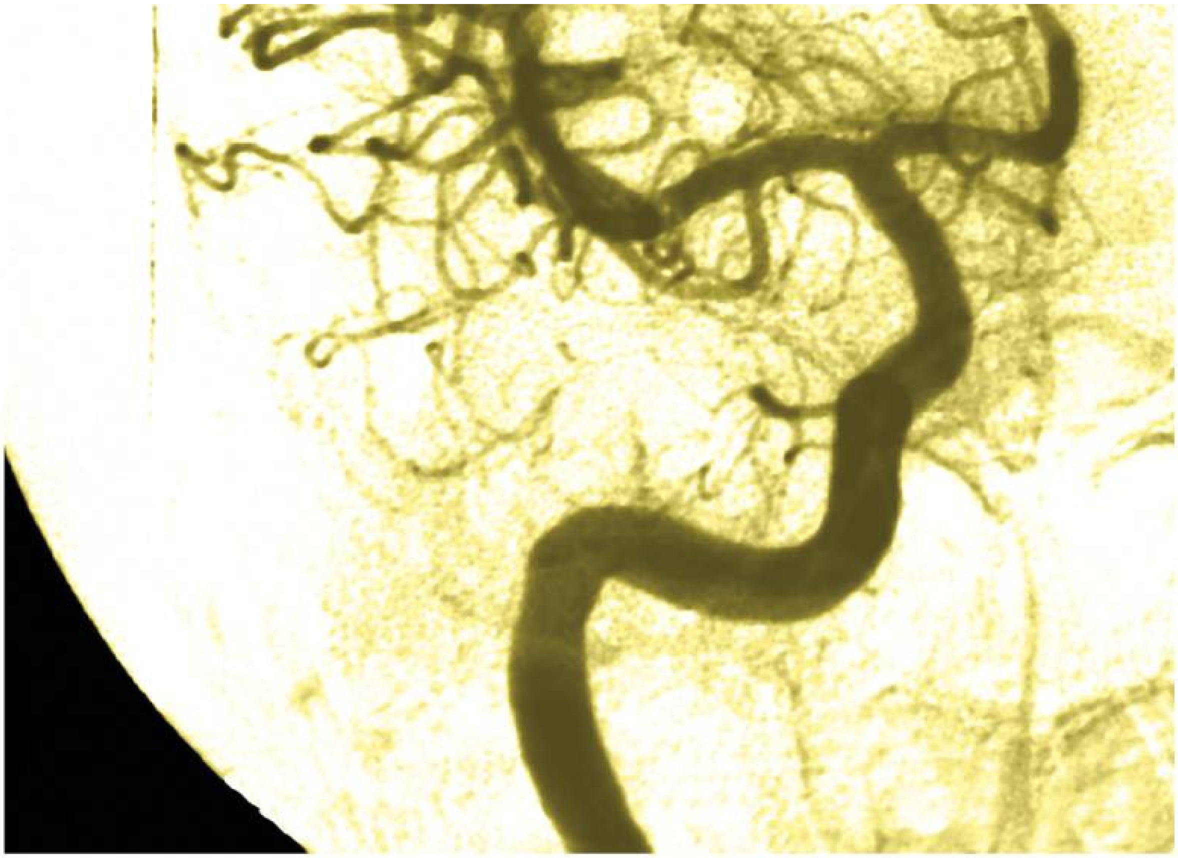


FIGURE 9-11 Computed tomography scans. **A.** Acute aortic dissection. **B.** Frontal view of a cerebral angiogram showing recanalization.

A: © Living Art Enterprises, LLC/Science Source; **B:** © Science History Images/Alamy Stock Photo.

In recent years, CT scanning has undergone major improvements; the newest technologies offer significantly reduced scan times, multiple and finer slice capabilities for greater three-dimensional resolution, and improved overall image quality. CT scans are now a standard diagnostic tool in many disciplines, despite the growing concern about the significantly greater radiation exposure experienced by patients from this imaging modality compared to conventional radiography and the resultant increase in cancer risk. Specifically, a single CT scan can generate radiation exposure equivalent to 5,000 chest radiographs. However, recent advancements in this technology have also resulted in CT protocols that have dramatically reduced the amount of radiation required to generate adequate images, thereby lowering risk.

When transporting a critically ill patient who has had a recent CT scan, the CCTP should attempt to obtain an electronic copy of the scan from the transferring facility to expedite care on arrival at the receiving center. Often scans can be shared between facilities through electronic medical record portals.

CT angiography (CTA) refers to CT imaging that uses intravascular contrast to visualize blood vessels in addition to the surrounding tissues. CTA can be used to diagnose blockages in blood flow (eg, pulmonary embolism, acute ischemic stroke), stenosis (ie, narrowing of a blood vessel), aneurysm (ie, dilation of the blood vessel wall), or dissection (eg, tear in the blood vessel wall).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is primarily a diagnostic imaging technique; it is most commonly used to visualize the internal structure and function of the body. Most MRI studies are structural, meaning they provide a static three-dimensional image of anatomy. However, functional MRI (fMRI) can also be used to collect physiologic data over time; for example, brain fMRI can be used to track brain activity associated with changes in blood flow across time overlaid on a neuroanatomic image.

MRI provides a much greater contrast between the different soft tissues of the body than a CT scan does. As a result, this technology is especially useful in brain, spinal cord, musculoskeletal, cardiovascular, and oncologic imaging. Another benefit of this imaging modality is that the patient is not exposed to radiation. Even so, despite significant recent advancements in MRI technology that have made MRI faster and more accessible, CT scans remain faster to perform and are more widely used throughout the United States.

MRI uses a large circular magnet and radio waves to align the water molecules in the tissues and generate signals from atoms in the body. An image is obtained based on both this alignment and the speed at which molecules alter or release signals. The strength of the magnetic field requires MRI-compatible patient monitoring, infusion pumps, and special ventilators for intubated patients. When done, such studies are typically used to provide exquisitely detailed images of the brain, spine, skeletal system, heart, abdomen, or pelvis.

MRI may be limited by the patient’s size or ability to tolerate an enclosed tunnel like environment for the greater duration of time required to complete MRI studies compared to CT. Certain preexisting ferrous metals in the patient’s body may also contraindicate such scans. Many advances have been made in the size and openness of the MRI device, as well as the speed with which it can complete an imaging sequence, allowing for a more tolerable environment.

It is important to adhere to safety guidelines with MRI machines, because the powerful magnet will cause certain metal objects to launch with great force or heat to dangerous temperatures. Keeping your equipment and any other metals you may be wearing away from the control area is essential.

Positron Emission Tomography

Positron emission tomography (PET) is a functional imaging modality used to visualize physiologic changes over time or distinguish various levels of physiologic activity between tissues. The equipment and procedure are similar to those used in CT imaging; indeed, these modalities are often combined as a single procedure (PET-CT imaging).

In PET, radiotracers (ie, radioactive substances) attached to a carrier drug are injected into the patient, or are ingested or inhaled by the patient. Gamma radiation is then emitted, which enables the clinician to detect the radiotracers as they move within the body. The behavior of these tracers reveals processes such as changes in blood flow or differences in metabolic activity. Areas of disease often appear as bright spots on PET scans.

Applications of a PET scan include the following:

- Measuring temporospatial changes in brain activity. For example, this study can help reveal which brain structures are most active when performing a particular task.
- Locating regions of the heart that might be vulnerable to myocardial infarction. This imaging shows myocardial tissue with decreased metabolic activity during a period of increased myocardial stress.
- Identifying metastatic disease in patients with cancer. Tumors are highly metabolically active, so cancerous tissues will absorb a greater amount of radiotracer than surrounding tissues. In turn, they can be easily visualized on PET scans even if they would otherwise be very difficult to identify using other modalities based on tissue density.

Imaging for Polytrauma

The imaging studies commonly used in trauma have already been covered in this section, but a few special considerations for trauma patients are worth noting for CCTPs. The evaluation of polytrauma patients in the acute setting can be associated with numerous challenges—for example, impaired patient participation (secondary to injury and related distraction, therapy, or substance use, among other causes); distraction of providers due to obvious patient injuries; and limitations in the initial trauma survey due to other procedures or immobilization. Although providers are trained to overcome these challenges, imaging studies tend to provide highly valuable data that can mitigate these challenges and aid in diagnosing occult injury, evaluating surgical candidacy, and planning for surgery. Therefore, thorough imaging of the polytrauma patient and sharing of the original studies (often saved on physical discs) and radiology reports are essential aspects of interfacility transport communication.

In **CT polytrauma**, also known as a pan-scan, the imaging protocol typically includes CT of the head, cervical spine, chest, and abdomen/pelvis, with the results being combined to generate a continuous image from the top of the head through the pelvis.

Additional images (eg, face, spine) can sometimes be generated through image reconstruction. A CT polytrauma should include each of the previously mentioned components to be considered complete.

Importantly, the CT polytrauma is *not* a substitute for the comprehensive physical exam conducted during the secondary trauma survey. In fact, the physical exam is essential to identify injuries that lie outside the scope of the CT polytrauma and to determine the need for additional imaging tests such as imaging of the extremities or more specific imaging tests than those used in the basic CT polytrauma protocol. Moreover, neither the reported physical exam performed at the sending facility nor the imaging studies can substitute for the physical exam performed by the CCTP.

Cardiac Imaging

Cardiac imaging includes a broad array of imaging modalities, many of which lie outside the scope of this text. However, a basic introduction to a few common studies of the heart can be useful for CCTPs. Classic indications for various types of cardiac imaging include concern for structural disease (eg, valvular disease), acute coronary syndrome (eg, blockages in the coronary arteries, regions of hypokinetic or damaged myocardial tissue), or inflammatory conditions (eg, pericarditis, myocarditis, endocarditis).

Echocardiography is the use of ultrasonography to produce dynamic images of the heart (ie, live images of heart activity). Such studies can provide a wealth of information about cardiac function, including left ventricular ejection fraction (a measurement of how much blood is being pumped by the heart with each beat, where normal values typically range from 50% to 75%), valvular disease (ie, problems with heart valves, such as regurgitation or stenosis), wall motion abnormalities (ie, specific regions of the heart that are hypokinetic), presence of effusion (ie, fluid around the heart), and other structural changes (eg, hypertrophy, dilation, or changes in relative size that might indicate abnormal pressures). Transthoracic echocardiography is performed by placing an ultrasonography probe on the skin of the chest, whereas transesophageal echocardiography is performed by using a probe inside the esophagus to obtain higher-quality images for particular diagnostic indications (eg, endocarditis, intracardiac thrombus).

Cardiac MRI is an MRI study of the heart that obtains high-resolution images of the myocardial tissue and surrounding structures. Common indications for cardiac MRI include assessment of the health and composition of the myocardium, such as in patients with myocarditis or cardiac amyloidosis, or assessment of tissue viability following myocardial infarction. It is also used to evaluate valvular disease, cardiac masses, and pericardial disease.

Myocardial perfusion imaging, often referred to as a stress test, is a noninvasive imaging study to assess the perfusion of myocardial tissue via the coronary arteries. Myocardial perfusion imaging is classically performed on patients experiencing angina to evaluate coronary artery disease and resultant myocardial hypoperfusion as a cause of the chest pain. Rather than directly visualizing the blood vessels supplying the heart, myocardial perfusion imaging uses a variety of imaging techniques to detect regions of the heart that are hypoperfused during increased myocardial stress. Clinicians typically induce a state of increased myocardial stress either by having the patient perform physical exercise (ie, a physical or exercise stress test) or by administering a drug that increases myocardial activity and simulates the effects of exercise (ie, a chemical or pharmacologic stress test).

Coronary CTA provides direct visualization of the coronary arteries, typically to aid in the diagnosis of coronary artery disease. In contrast to myocardial perfusion imaging, which provides assessment of the physiologic consequences of coronary artery disease during times of myocardial stress, coronary CT provides anatomic assessment of blockages within the coronary arteries.

Coronary angiography is a minimally invasive imaging study performed using coronary catheterization, a procedure in which a physician inserts a catheter into the vasculature and guides it into the coronary circulation. Coronary angiography is one of several procedures that can be performed during a coronary catheterization procedure. During this study, locally injected contrast dye enables radiographic images of flow through the coronary arteries to evaluate blockages in the vessels. Unlike myocardial perfusion imaging, which evaluates the consequences of coronary artery disease in the form of myocardial hypoperfusion, and coronary CTA, which directly visualizes the coronary arteries, coronary angiography provides direct dynamic imaging of flow through the coronary arteries. This highly sensitive test can both identify the location of blockages and estimate the percentage degree of blockage within coronary vessels, providing very helpful information for interventions performed during the coronary catheterization procedure and for planning future therapy.

Ultrasonography

Ultrasonography is an imaging modality that uses high-frequency sound waves to visualize both static and dynamic anatomic structures. Sound waves are transmitted into the body, and based on the time it takes for them to be reflected back to the probe, an image is constructed. Because the sound waves must be reflected to form an image, they are often referred to as echoes. This principle allows for the real-time visualization of moving elements such as cerebral blood flow with transcranial Doppler studies, or the visualization of moving tendons to assess for tears and other injuries.

While most imaging modalities are largely the domain of radiology, ultrasonography has transcended any one individual medical specialty and is now frequently used by providers at the bedside in the ED, ICU, and various specialty clinics. In some agencies, it is even used in the prehospital setting. The routine use of ultrasonography for bedside procedures has significantly increased its safety margin.

As with MRI, ultrasonography has the advantage of not exposing the patient to ionizing radiation. As such, it is often used for frequent repeat examinations in the point-of-care setting to assess for progression of disease or response to therapy. It has the further advantage of being extremely portable, with some devices consisting of a lightweight ultrasonography probe that can plug into a smartphone or tablet.

One of the most common uses of point-of-care ultrasonography (POCUS) in the ED setting is in the evaluation of trauma. The focused assessment with sonography for trauma (FAST) examination became a standard part of the initial assessment of major trauma in the United States in the 1990s. By obtaining standardized views of the right upper quadrant (perihepatic), left upper quadrant (perisplenic), and retrovesicular space (around the bladder), the operator can assess for the presence of free intraperitoneal fluid. At least one view of the heart, typically the subcostal, is also included to assess for the presence of fluid around the heart causing cardiac tamponade. A highly experienced point-of-care ultrasonographer can detect as little as 100 mL of free fluid; the average user typically will not detect free fluid volumes of less than 500 mL. Any positive findings generally necessitate immediate intervention in the setting of an unstable patient. However, a degree of caution and clinical judgment must be exercised because ultrasonography will not differentiate the type of free fluid, which means ascites will have the same appearance as blood on the images.

POCUS has also seen increased use for thoracic imaging and is sometimes incorporated into trauma assessment, in a protocol known as an eFAST (extended FAST) exam. Since ultrasonography allows for visualization of moving structures, it can be used to assess for the presence of normal lung motion, typically referred to as lung sliding. A lack of normal lung motion, particularly in a trauma patient, may indicate a pneumothorax, though other pathology (eg, consolidations) can also cause the absence of lung sliding.

Ultrasonography is also used to assess for the presence of pleural effusion, both in the setting of trauma (raising concern for hemothorax) and in more routine situations. A further use of ultrasonography in this setting is to assist with drainage of the effusion; it can be used to identify landmarks for the site of the procedure or even to provide direct visualization of needle entry into the pleural space.

Technique

To obtain the cardinal views of the eFAST exam, the operator typically begins with the right upper quadrant view, as this is the most sensitive anatomic location for detecting peritoneal free fluid. All ultrasonography probes have an indicator on one side that corresponds with the indicator on the screen. In this view, the indicator is pointed cephalad, toward the patient's head. Ideally, the operator will have a view displaying the liver, right kidney, and diaphragm. Fluid, if present, will normally collect in the Morison pouch, also termed the hepatorenal space **FIGURE 9-12**. The right upper quadrant view should include the tip of the liver to be considered adequate.

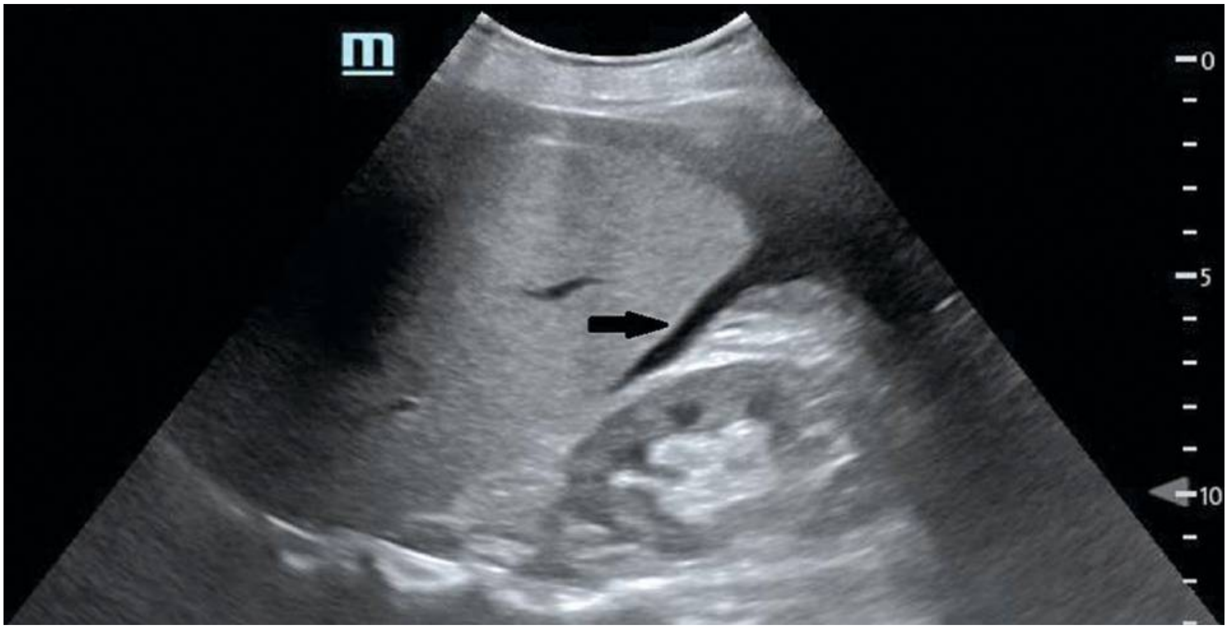

FIGURE 9-12 A right upper quadrant view from a focused assessment with sonography for trauma (FAST) exam demonstrating free fluid in the hepatorenal space. Note that the fluid appears darker than the surrounding tissue. This is because the fluid is less echogenic than the tissue and, therefore, reflects fewer sound waves.

© Jones & Bartlett Learning.

Following interrogation of the right upper quadrant, the left upper quadrant is typically visualized. In this view, the indicator is again pointed cephalad and the view will include the spleen, left kidney, and diaphragm. In this view, fluid will most often collect between the spleen and diaphragm.

Next, the retrovesicular view is obtained. This view has classically been referred to as the pelvic view, but that term is somewhat of a misnomer because the peritoneal space, not the pelvic space, is visualized. The indicator is once again pointed cephalad, with the probe placed midline above the bladder. Fluid will be seen cephalad to the bladder if present. In this view it is important to identify the bladder, which may often be recognized by its smooth edges, because peritoneal free fluid combined with a decompressed bladder may often be interpreted as a false-negative result.

The subcostal view of the heart is obtained next. In this view, the indicator is typically toward the patient’s right, with the probe placed beneath the xiphoid process. Of note, when this view is obtained in traditional echocardiography, the indicator is pointed toward the patient’s left. This view is used to visualize the heart and allows for assessment of gross pathology. Most importantly, it allows the ultrasonographer to assess for the presence of pericardial effusion.

To complete the eFAST exam, the probe is placed in the midclavicular line of the right and left chest in the second or third intercostal space, with the indicator again cephalad. The interface between the parietal and visceral pleura will have a shimmering appearance, termed “sliding” under normal circumstances. Absence of this finding may indicate a pneumothorax, which in certain clinical settings (eg, high pretest concern for tension pneumothorax) is an indication for decompression.

Applications

Ultrasonography has been used for cardiac imaging, an application called echocardiography, since 1953 **FIGURE 9-13**. In the point-of-care setting, it is used most frequently for applications such as assessing gross left ventricular systolic function, looking for evidence of right heart strain, assessing volume responsiveness, finding significant valvular disease, or assisting during CPR to assess for reversible causes (eg, tamponade) or to look for cardiac standstill. Cardiologists will perform significantly more detailed studies than are typically obtained in the point-of-care setting, including the assessment of blood flow across all valves, which clinically may produce a murmur in an otherwise structurally normal-appearing heart. Sometimes transesophageal echocardiography is also used due to its higher sensitivity (compared to transthoracic echocardiography) for detecting pathology such as valvular vegetations.

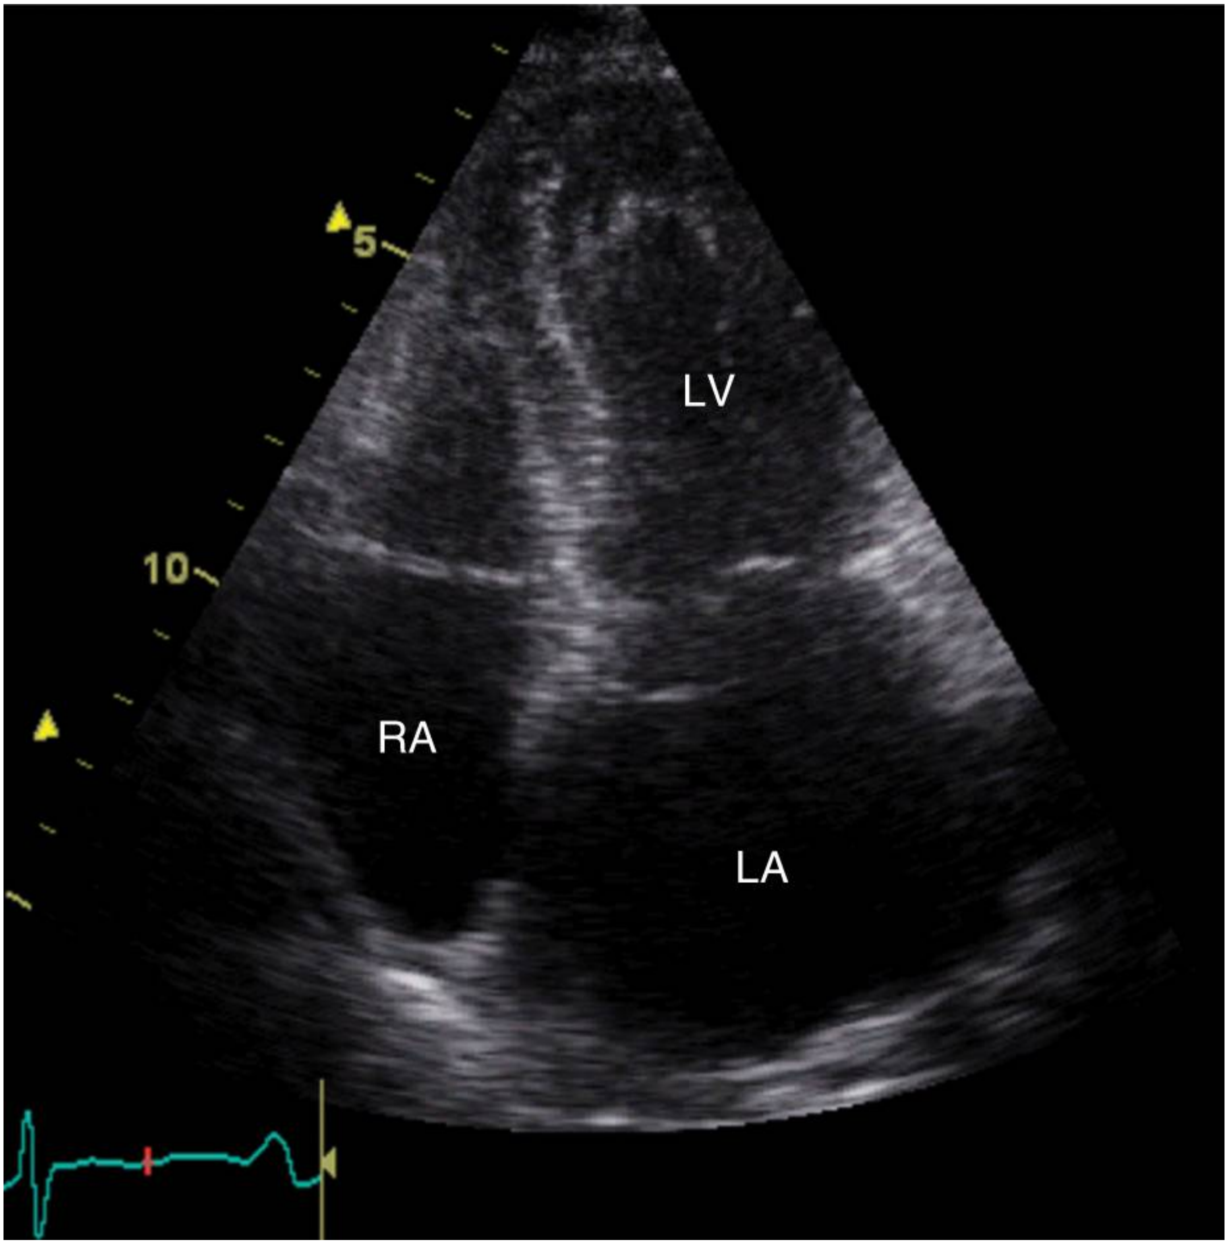

FIGURE 9-13 An echocardiogram. A four-chamber view in systole and diastole shows normal left ventricular systolic function but severely enlarged left atrium.

Abbreviations: LA, left atrium; LV, left ventricle; RA, right atrium

The use of ultrasonography during cardiac arrest has gained widespread acceptance in the emergency medicine, critical care, and anesthesia communities over the past several years. One of the initial uses was to distinguish pulseless electric activity (PEA) with electrical mechanical dissociation (EMD) from PEA with true cardiac standstill. Several studies have examined the differences in outcomes for these two conditions; they have typically demonstrated a greater than 25% probability of return of spontaneous circulation in patients with PEA and EMD and a less than 5% probability in patients with PEA and true cardiac standstill. POCUS can be used to help identify reversible causes of cardiac arrest, one of which was previously mentioned in the discussion of the eFAST: pericardial effusion causing tamponade physiology.

POCUS can also be used to assess the chambers of the heart. A dilated right atrium is consistent with pressure overload, which in the setting of cardiac arrest may indicate a massive pulmonary embolism. Underfilled ventricles are consistent with hypovolemia, necessitating aggressive volume resuscitation. Mechanical activity in synch with electrical activity with absent palpable pulses may indicate severe hypotension or vasoplegia requiring the use of additional pressors.

Ultrasonography is used extensively in abdominal imaging. It is considered the standard of care when evaluating the gallbladder for acute cholecystitis because it enables excellent visualization of the gallbladder (including the presence of stones), measurement of the common bile duct, and assessment for point tenderness at the site. Similarly, it provides excellent visualization of the liver and can help providers assess intrahepatic blood flow. It is used in the assessment of appendicitis, particularly in the pediatric population; younger patients tend to be thinner than adults, and the use of radiation is of higher concern in this group. Ultrasonography is also increasingly used for the identification of small bowel obstruction.

Ultrasonography for Identifying Appendicitis

While CT imaging remains the standard of care in the United States for identification of appendicitis and other bowel pathology in the adult population, ultrasonography has become the first-line test in Japan and several other countries.

Ultrasonography is a mainstay in vascular imaging because it enables the assessment of the direction, velocity, and turbulence of blood flow. It is the standard of care for screening and monitoring of abdominal aortic aneurysms and for identifying DVT of both the upper and lower extremities. In this type of study, the probe is used to evaluate the compressibility of the vein; as the operator applies pressure and attempts to collapse the vein, a thrombus will prevent complete compression.

For decades, ultrasonography has been used to evaluate the uterus during pregnancy, partially due to its excellent safety profile compared with other imaging modalities. Both transabdominal and transvaginal imaging are used to assess for the presence of an intrauterine pregnancy early in the course of gestation and further along the course to track development. In the emergent setting, ultrasonography can be used to evaluate for intrauterine pregnancy versus ectopic pregnancy or for ovarian torsion and the presence of ovarian cysts.

As it applies to the genitourinary system, ultrasonography is used in the evaluation of the testicles to identify testicular torsion, epididymitis, and other pathology. It can also help visualize the kidneys and bladder to assess for hydronephrosis and the presence of stones. Doppler ultrasonography allows for the visualization of flow from the ureters into the bladder, the absence of which strongly suggests obstruction.

Ophthalmology was one of the first specialties to adopt the use of ultrasonography and continues to make frequent use of the technology. Since the eyes are superficial fluid-filled structures, they are ideal for imaging with ultrasonography. Ocular ultrasonography is a mainstay in emergency medicine to help identify pathology such as lens subluxation, retinal detachment, and vitreous hemorrhage. It can also be used to identify ocular foreign bodies, just as it is used to find soft-tissue foreign bodies.

One of the most common uses of ultrasonography at the bedside remains its application for procedural guidance. It is routinely used for vascular access procedures ranging from placement of peripheral intravenous catheters to placement of central venous catheters and arterial lines. When used for vascular access, the target vessel is centered on the screen and needle entry is directly visualized. The operator slowly advances the probe to maintain constant visualization of the needle tip as it passes through the soft tissue and enters the targeted structure. Ultrasonography is used to find pockets of intraperitoneal fluid when preparing for paracentesis; as in drainage of pleural effusions, it can be used to visualize and direct needle entry. Frequently, ultrasonography is used to find peripheral nerves, allowing for the injection of local anesthetic and the performance of nerve blocks; this remains one of the most common uses of the modality in anesthesia. Finally, ultrasonography provides excellent visualization of soft tissue, allowing for the identification and drainage of abscesses.

Summary

One of the core goals of CCTPs is to form as complete a clinical picture of the patient as possible. Each patient presents with a unique hemodynamic and ventilatory status, which may be associated with various degrees of end-organ dysfunction. Laboratory analysis allows clinicians to assess or confirm the status of a particular system or organ. A key principle of laboratory interpretation is that no lab result should be analyzed in isolation. Repetition of tests (trending) and confirmation of findings through multiple testing modalities can create a more informed, accurate picture of the patient's condition. If adherence to that principle is maintained throughout the course of the patient's care, clinicians can be confident that their consideration of lab values is of the highest caliber.

The results of a variety of laboratory and point-of-care tests may be used by CCTPs in assessing and treating patients, including tests performed on blood samples, blood gas tests, and urinalysis. In addition, CCTPs must be familiar with the various diagnostic imaging studies and be able to interpret them for obvious abnormalities.

TABLE 9-5 summarizes normal and abnormal lab values.

TABLE 9-5 **Normal and Abnormal Lab Values for Adults[a]**

Name	Abbreviation	Normal	Critically Low	Critically High
Electrolytes and Other Chemicals				
Sodium (mEq/L)	Na^{-}	134–142	<125	>145
Potassium (mEq/L)	K^{+}	3.7–5.1	<3.0	>5.0
Chloride (mEq/L)	Cl^{-}	98–108	Varies	Varies
Calcium, total (mg/dL)	Ca^{+2}	8.6–10.3	<6.5	>13.5
Calcium, ionized (mmol/L)	Ca^{+2}_{i}	1.15–1.27	Varies	Varies

Complete Blood Count (CBC)				
Hematocrit (%)	Hct	41–50	<20	>60
Hemoglobin (g/dL)	Hgb	12.0–17.4	<7	>20
Erythrocytes (× 10^6/mL)	RBC	4.0–5.5	Varies	Varies
Leukocytes (/mL)	WBC	4,500–11,000	<2,000	>30,000
Arterial Blood Gases				
Percentage of hydrogen ions	pH	7.35–7.45	<7.2	>7.6
Partial pressure of oxygen (mm Hg)	Pao_2	80–100	<40	N/A
Partial pressure of carbon dioxide (mm Hg)	$Paco_2$	35–45	<20	>77
Bicarbonate (mEq/L)	Hco_3^-	21–28	<10	>40
Base excess (mEq/L)	BE	−2 to +3	<−5	>+5

[a] It is important to know the normal range for the laboratory where the specimen is tested. Data from Fischbach FT, Fischbach MA, Stout K, eds. *Manual of Laboratory and Diagnostic Tests*. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2017.

Description

CASE STUDY

You have been dispatched to transport, via helicopter, a 37-year-old man whose pretransport diagnosis is acute renal failure after renal transplantation.

You arrive at a rural hospital at the base of a mountainous region. The physician gives you the following history: The patient and his friend took a day hiking trip into the mountains and got lost. A search-and-rescue team was dispatched after 24 hours. The patient and friend were found 48 hours later. Both were severely dehydrated and confused; they had only a little water to sustain themselves during their ordeal. The patient underwent kidney transplantation approximately 1 year ago. Before today, he has not had any difficulties with the transplant. The patient has missed 2 days of his transplant antirejection drugs. The search-and-rescue team inserted a large-bore IV catheter and provided fluid resuscitation to the patient with 2,000 mL of normal saline before getting him to the local hospital.

The staff gives you the following report: The patient is now alert and oriented with generalized weakness. He has had a total intake of 2,500 mL of normal saline. He has an indwelling urinary catheter in place with 100 mL of urine output since the catheter was placed. His current vital signs are as follows: temperature, 96.0°F (35.6°C); heart rate, 88 beats/min; respirations, 20 breaths/min; and oxygen saturation, 98% with 4 L/min of oxygen per nasal cannula. His blood pressure is 150/90 mm Hg. He has two large-bore IV catheters in place. His current ECG shows a normal sinus rhythm, with a rate of 88 beats/min. There are tall, peaked T waves in the precordial leads V_1 through V_6. His QRS complex is prolonged, measures 130 milliseconds, and shows an incomplete right bundle block pattern.

Lab analysis reveals the following results: sodium, 135 mEq/L; potassium, 7.3 mEq/L; chloride, 100 mEq/L; and total calcium, 8.8 mg/dL. The patient's BUN is 70 mg/dL and his creatinine is 3.0 mg/dL. The physician says that the CBC and glucose levels were normal. He also says that the CK and myoglobin levels were elevated; he does not remember the exact numbers but will send hard copies along on the transport. The physician tells you that the patient is being transported to tertiary care (45 minutes by air) for emergency dialysis and management of his renal failure.

You give the patient 1 g of calcium gluconate IV. You reassess the ECG and notice that the QRS complex is narrower at 90 milliseconds (within normal limits) and the T wave is less peaked. You elect to promptly transport this patient, realizing that he still needs emergency treatment, but the rest of the medications can be given en route. During the transport, you administer 50 mL of 50% glucose in water solution ($D_{50}W$) IV, followed by 10 U of regular insulin IV; sodium bicarbonate, 50 mEq IV; and 5 mg of albuterol in 3 mL of normal saline via nebulizer.

1. What are your priorities in care before this transport?
2. What are your priorities in care during this transport?
3. Which reassessment parameters are important during this transport?

Analysis

In evaluating the situation, you realize that this patient is in acute renal failure with hyperkalemia. You also realize the renal failure could be a result of his severe dehydration, transplant rejection, and/or rhabdomyolysis; however, your transport priority is the hyperkalemia. The markers for emergency treatment of hyperkalemia are profound muscle weakness and marked ECG changes. This patient has generalized weakness and an intraventricular conduction delay along with peaked T waves, and he requires immediate treatment. The most important emergency intervention is the administration of calcium, which directly antagonizes the membrane actions of hyperkalemia. Either calcium chloride or calcium gluconate may be administered. Calcium chloride contains three times as much elemental calcium as calcium gluconate and should be given via a central line placed at the hospital. You elected to give 1 g of calcium gluconate IV. You reassess the ECG and notice that the QRS complex is narrower at 90 milliseconds (within normal limits) and the T wave is less peaked. The effects of calcium are usually seen in 3 to 5 minutes and last approximately 30 to 60 minutes.

While en route, you also want to drive the potassium back into the cells by increasing the availability of insulin; therefore, you administer 10 U of regular insulin IV, followed by 50 mL of $D_{50}W$ IV (the $D_{50}W$ prevents hypoglycemia). These effects are seen within 15 minutes, usually peak in 60 minutes, and can last for several hours.

Another medication that promotes the shift of potassium into the cells is sodium bicarbonate. Raising the systemic pH will also release hydrogen ions from the cells; potassium is then shifted back into the cell to maintain a neutral state. You gave sodium bicarbonate, 50 mEq IV. The effects of this therapy are usually seen within 30 minutes and last a few hours.

Beta-2 adrenergic agonists (such as insulin) also drive potassium back into the cells by increasing the Na^+/K^+ ATPase activity needed for the sodium pump. To accomplish this effect, you elected to give 5 mg of albuterol in 3 mL of normal saline via nebulizer. The onset of action of this therapy is about 30 minutes, and the effects last 2 to 3 hours.

During transport, it is imperative to continuously assess the patient's ABCs. This patient's airway has remained patent, his respiratory rate has been 16 to 20 breaths/min, and oxygen saturation has been 98% with 4 L/min of oxygen. Continuous cardiac monitoring has shown a normal sinus rhythm with a heart rate in the 80s, a normal-appearing T wave, and a normal QRS complex at 90 milliseconds.

You have point-of-care laboratory testing available during transport. You check the patient's blood glucose level and find that it is 130 mg/dL. You are also able to test basic electrolytes en route, and the results are as follows: sodium, 140 mEq/L; potassium, 4.4 mEq/L; chloride, 103 mEq/L; and total CO_2, 23 mEq/L. The patient's extracellular potassium level is now within normal limits.

Last, you assess the patient's strength, because he was previously weak. He has a much stronger upper grip strength, which is equal, and has equal and strong dorsiflexion of his feet. His urine output en route is approximately 200 mL. The patient reports that he generally feels much better.

The patient was admitted directly to the ICU, where you gave a report to the nursing and physician staff. The plan was to restart his antirejection medication and monitor serial lab values to see if the hyperkalemia and kidney function improved. If they did not, emergency dialysis would be performed.

PREP KIT

Ready for Review

- Laboratory tests—including laboratory examinations of the patient's blood, urine, cerebrospinal fluid, or other body fluid—can be very useful in determining the seriousness of a patient's condition or preparing for potential problems en route to the hospital.
- A CCTP must know the normal ranges for each lab value, as well as each test's associated physiologic meaning.
- The value of laboratory analysis is determined by the test's accuracy (a marker of whether the value measured by a test conforms to the true value), precision (a marker of tolerance or variation within multiple measurements), sensitivity (the ability of a certain test to accurately rule out a condition), and specificity (the ability of a certain test to accurately confirm a condition).
- A normal range for a test indicates the values that 95% of healthy individuals would have for the particular test. It may or may not be reflective of the patients who are being transported by CCTPs.
- Although abnormal lab values cannot be ignored, it is essential that they be assessed within the context of the patient's entire clinical picture. Abnormal lab values can arise due to acute or chronic conditions and can be due to primary problems or secondary compensatory processes.
- Errors in specimen collection, identification, and labeling or errors in laboratory analysis procedures may result in erroneous values being reported.
- A culture and sensitivity (C and S) report can be determined for any type of specimen. The culture results will reveal what is causing an infection; in bacterial infections, the sensitivity results will indicate which antibiotic will most effectively treat the organism causing the infection.

- The ionic components of plasma that are analyzed in the laboratory are known as electrolytes; they include sodium (Na^+), potassium (K^+), chloride (Cl^-), calcium (Ca^{+2}), and magnesium (Mg^{+2}).
- Fluid characteristics assessed in the laboratory include osmotic pressure, which arises in a space divided by a semipermeable membrane owing to differences in the concentrations of solutes (dissolved substances) found in the solutions on either side of the membrane. Osmotic pressure depends only on the number of particles in the fluid, not on the size of the particles.
- Concentration is the amount of a substance present in a given volume of fluid. In the physiologic system, most concentrations are incredibly small, leading to use of units such as millimoles (mmol), milliequivalents (mEq), and milliosmoles (mOsm) to quantify them.
- Different laboratories may have different normal ranges for the same tests. Laboratory reports should always provide the reference ranges for their tests, which are the proper ones to use for the specific patient.
- Thousands of different kinds of proteins are found in the human body, and specific laboratory tests examine the amounts of the various types of protein present in a sample. For example, tests may assess levels of enzymes, which act as catalysts for biochemical reactions.
- In laboratory testing, groups of related tests can be performed as a single unit, called a panel (or profile).
- The basic metabolic panel examines the electrolytes and metabolites in the extracellular fluid; it is one of the most basic and fundamental assessments done in the emergency department or intensive care unit.
- Serum sodium is a convenient marker for a patient’s fluid status and is one of the key components of the serum osmolality calculation. An abnormal sodium level will not manifest as electrocardiographic (ECG) changes.

- Elevated sodium levels are treated with diuretics and restricted fluid intake; the net effect of this treatment is expected to be lower intracerebral pressure. Hyponatremia (an abnormally low level of sodium in the blood) is often encountered in patients with endocrinopathies, congestive heart failure, renal failure, or liver disease and in patients taking diuretics.
- Hyperkalemia (an abnormally high level of potassium in the blood) can lead to cardiac arrhythmias. Potassium levels of 5.5 to 6.5 mEq/L can result in the classic peaked T waves on an ECG, with flattened P waves occurring when the potassium level exceeds 7.0 mEq/L. Hyperkalemia can be an artifact of a hemolyzed sample, or it can reflect a true emergency; therefore, this finding should always be correlated with a clinical exam, an ECG, and often a repeat sample.
- Older patients (especially patients taking digitalis) are more likely to develop arrhythmias and ECG changes with hypokalemia (an abnormally low level of potassium in the blood).
- For any patient with a cardiac history, altered renal function, liver disease, or gastrointestinal disturbances, or any patient receiving insulin, a recent potassium level should be available for review before transport.
- Patients with hypochloremia (an abnormally low level of chloride in the blood) may have impending renal dysfunction. Patients taking diuretics may also have abnormally low chloride levels.
- Venous HCO_3^- levels below the normal range could indicate metabolic acidosis or respiratory alkalosis, whereas elevated levels could indicate metabolic alkalosis or respiratory acidosis.
- Urea, which is considered a useful marker for adequate kidney function, is measured via the blood urea nitrogen (BUN) test. The BUN level tends to increase with age as a consequence of gradually declining renal function.
- Creatinine levels can be used to assess kidney function, although some patients may have an increased creatinine level with adequate renal function. Geriatric patients with increased

creatinine levels may have more kidney damage than might be suspected by testing the creatinine level.

- The glomerular filtration rate (GFR) is a measurement of the overall filtration rate of all the functioning nephrons; changes in GFR can suggest improvement or decline in kidney function.
- The glucose level is commonly assessed in the field with a point-of-care testing device, and prehospital care providers often measure the blood glucose level of patients with altered mental status.
- Total calcium is increased in elevated parathyroid hormone states such as hyperparathyroidism and parathyroid-secreting tumors. It is decreased in renal insufficiency, hypomagnesemia, and hyperphosphatemia; in patients who have undergone a massive blood transfusion; and in patients who have a decreased parathyroid hormone state.
- Low levels of ionized calcium can cause serious arrhythmias and are especially pronounced in prolonged cardiac arrest. Calcium administration may be warranted in patients with hyperkalemia, hypocalcemia, or toxic levels of calcium channel blockers.
- Magnesium levels can be affected by disruptions of several body systems, in particular the gastrointestinal and endocrine systems. High magnesium levels are rarely encountered, but low levels may be seen with gastrointestinal distress, vomiting and diarrhea, hepatic cirrhosis, and pancreatitis.
- A complete blood count (CBC) includes measurements of hematocrit (the percentage of cells in a venous blood sample), hemoglobin (the protein responsible for carrying oxygen to the body’s cells and, to a lesser extent, CO_2 back to the lungs), red blood cells (erythrocytes), white blood cells (leukocytes, an integral aspect of inflammatory response), and platelets (useful for assessing coagulation status).
- Protein-based tests include those for total protein and albumin. With albumin, abnormally low levels indicate liver disease,

whereas abnormally high levels lead to acute respiratory distress syndrome.

- Lactate levels are a global indicator of poor perfusion and oxygenation; they do not indicate which specific tissues are inadequately perfused or oxygenated.
- Lactate dehydrogenase levels can be helpful in diagnosing *Pneumocystis jirovecii* pneumonia, determining the severity of pancreatitis, and assessing patients with implanted ventricular assist devices as an early warning of pump thrombosis.
- Elevated levels of creatine kinase (CK) are indicative of muscle damage, such as in the context of rhabdomyolysis. The MB fraction of CK (CK-MB) can be used as a more specific marker for the diagnosis of acute myocardial infarction.
- Elevations of cardiac troponin I following myocardial injury are detectable in a serum sample after 4 hours; thus, this protein can be used to assess for acute myocardial infarction. High-sensitivity cardiac troponin T (hs-cTnT) tests can accurately detect myocyte damage even earlier.
- The B-type natriuretic peptide (BNP) is released by the ventricles in response to higher filling pressures. Its level can be indicative of abnormal ventricular function or heart failure if outside expected ranges.
- Elevated liver function test results may indicate the presence of liver damage. They measure enzymes that normally appear in liver cells, such as aspartate aminotransferase, alanine aminotransferase, bilirubin, and alkaline phosphatase. Different patterns in these tests can be suggestive of hepatocellular damage versus biliary obstruction.
- Tests of pancreatic function include measurements of amylase (an enzyme used by the body to metabolize carbohydrates) and lipase (more specific than amylase for identifying pancreatic disease).
- Lab tests assessing the coagulation system focus on the prothrombin time (the time from creation of thrombin from

prothrombin by the enzyme prothrombin activator), activated partial thromboplastin time (used to assess for various diseases), and the international normalized ratio.

- Thromboelastography is a method used to assess the viscoelastic properties of whole blood that combines multiple measurements of platelet function, the coagulation cascade, and their interaction.
- Ethanol (ethyl alcohol) levels are used to assess blood alcohol concentration in the context of alcohol consumption. Owing to the legal implications of ethanol measurements, precise protocols often govern the technique for obtaining the blood sample and storing and analyzing it.
- An increased BUN:creatinine ratio may indicate dehydration, gastrointestinal bleeding, or increased catabolism. A decreased ratio may be present in patients with acute tubular necrosis or autoimmune injury.
- Disturbances in the overall electrical balance of the serum can indicate disease; the anion gap is a measure of this balance.
- A typical arterial blood gas (ABG) panel assesses a patient’s acid–base status and oxygen status.
- The acid–base balance (pH)—which is assessed based on CO_2 tension ($PaCO_2$), HCO_3^-, and base excess (BE)—indicates how well the body’s respiratory and metabolic systems are functioning. Abnormalities result in acidosis or alkalosis.
- Oxygenation status is measured by assessing the partial pressure of oxygen, as well as arterial (PaO_2) and oxygen saturation (SaO_2) levels.
- Assessment of carboxyhemoglobin levels is useful in confirming a diagnosis of carbon monoxide poisoning, and potentially for guiding therapy as well.
- When possible, initial blood samples should be obtained before administering IV fluids or medications.
- If the patient has an IV line and is receiving fluids or medications, the other extremity should be used for taking a blood sample, if

possible. If the patient has lines in both extremities, the one without IV medication or without the medication that is being tested should be used.

- CCTPs must be familiar with any point-of-care testing equipment they use and know whether a test they perform is classified as waived, moderate complexity, or high complexity, because this status determines the applicable regulatory requirements.
- Urinalysis involves performing laboratory tests on a patient's urine that range from simple (eg, color or appearance) to complex (eg, specific gravity). Many drugs of abuse (or their metabolites) can be detected in the urine for a considerable amount of time after the drug's use.
- Other tests performed on urine include pH, glucose, ketone bodies (a prominent finding in diabetic ketoacidosis), protein (one of the most important assessments for kidney diseases), and blood and hemoglobin (which are not normally found in urine).
- The CCTP should be familiar with diagnostic imaging studies and be able to perform basic interpretation of their results for obvious abnormalities, such as long bone fractures, masses, and catheter placements.
- Radiographic studies are two-dimensional images that can be useful to examine the integrity of skeletal system, identify the abnormal presence of air or fluid, and identify or evaluate foreign bodies.
- Computed tomography (CT) is a three-dimensional imaging modality in which cross-sectional images of a body plane are reconstructed by a computer. A CT scan can reveal abnormalities not seen with traditional plain radiography. The CCTP should obtain a copy of the scan from the transferring facility to expedite care on arrival at the receiving center.
- Magnetic resonance imaging provides for a much greater contrast of the different soft tissues of the body than a CT scan does, which makes it especially useful in brain, spinal cord, musculoskeletal, cardiovascular, and oncologic imaging. This

rapidly evolving technology is becoming faster and more accessible over time.

- Positron emission tomography is a functional imaging modality that uses radiotracers to visualize physiologic changes over time or distinguish various levels of physiologic activity between tissues.
- CT polytrauma, also known as a pan-scan, is an imaging protocol that typically includes CT of the head, cervical spine, chest, and abdomen/pelvis to generate a continuous image from the top of the head through the pelvis. Using the CT polytrauma, additional images can sometimes be generated through image reconstruction.
- Cardiac imaging includes a broad array of imaging modalities designed to assess for structural disease, acute coronary syndrome, or inflammatory conditions.
- Ultrasonography does not expose the patient to any radiation and has the advantage of being a very portable imaging technology that can obtain dynamic images over time to assess organ function and guide procedures.
- One of the most common uses of point-of-care ultrasonography in the emergent setting is in the evaluation of trauma. The focused assessment with sonography for trauma (FAST) examination is a standard assessment component in the context of major trauma.
- Ultrasonography is commonly used at the bedside for procedural guidance.

Vital Vocabulary

accuracy A measure of the likelihood that an average of a set of test values will be similar to the true value.

activated partial thromboplastin time (aPTT) A value that represents the intrinsic coagulation pathway’s clotting ability; also known as partial thromboplastin time (PTT).

alanine aminotransferase (ALT) An intracellular enzyme found in large amounts in the liver and in the kidney, skeletal muscle, and heart; formerly known as serum glutamic-pyruvic transaminase (SGPT).

albumin The most common protein in the body; it acts as a transport protein, is a free radical scavenger, and serves as the main source of protein-generated oncotic pressure.

alkaline phosphatase An enzyme that is essential for proper digestion and absorption through the mucous membranes in the gastrointestinal tract; it is clinically useful for testing liver function and for diagnosing a common bile duct obstruction.

amylase A key enzyme used by the body to metabolize carbohydrates; it is produced primarily by the salivary glands and the pancreas.

anion A negatively charged ion.

anion gap (AG) A summary of the relationship among the three major contributors to the overall electrical charge (Na^+, Cl^-, and HCO_3^-); abnormal AG values may signal disturbances in the overall electrical and acid–base balance of the serum and presence of disease.

arterial blood gas (ABG) panel A collection of lab values used to analyze the following characteristics of blood: pH, partial pressure of CO_2 (in arterial blood), partial pressure of oxygen (in arterial blood), concentration of bicarbonate ion, base excess (indicating whether the patient is acidotic or alkalotic), and oxygen saturation of the hemoglobin molecule.

aspartate aminotransferase (AST) An intracellular enzyme found in large amounts in the liver and in skeletal muscle, the brain, red blood cells, and the heart; formerly known as serum glutamic-oxaloacetic transaminase (SGOT).

bacteremia The presence of bacterial infection in the blood.

base excess (BE) A measure of metabolic derangement that is part of the arterial blood gas panel; also known as base deficit (BD), as the value can be either positive (excess) or negative (deficit).

bicarbonate (HCO_3^-) An ion that is present in the blood; its measurement represents the metabolic component of the arterial blood gas panel.

blood urea nitrogen (BUN) A test used to measure urea, which is a biomarker for adequate kidney function.

blood urea nitrogen:creatinine (BUN:CR) A calculated index used to determine the cause of increased levels of blood urea nitrogen and creatinine.

B-type natriuretic peptide (BNP) A polypeptide whose value is indicative of abnormal ventricular function and congestive heart failure.

carboxyhemoglobin (COHb) A measure of the amount of hemoglobin–carbon monoxide complexes in the blood.

cardiac imaging A broad array of modalities used to assess the cardiac system for structural disease, acute coronary syndrome, inflammatory conditions, and other conditions.

cation A positively charged ion.

CBC with differential An expanded panel of lab tests that includes counts of specific types of white blood cells in the blood, such as neutrophils, lymphocytes, monocytes, eosinophils, and basophils.

computed tomography (CT) An imaging modality in which x-rays are used in a 360° rotation around an object to generate a computed three-dimensional model that can be viewed as multiple slices through a given plane; also called computerized axial tomography (CAT) scan.

concentration The amount of a substance present in a given volume of fluid.

C-reactive protein (CRP) An acute-phase reactant used to identify inflammatory response.

creatine A major storehouse of intramuscular high-energy phosphate.

creatine kinase (CK) An enzyme that cleaves the high-energy phosphate from creatine in muscle tissues and transfers it to adenosine diphosphate to yield adenosine triphosphate; its measurement is used in the assessment for muscle damage.

creatinine (Cr) A chemical waste product of creatine that results from muscle metabolism.

CT polytrauma An imaging protocol that typically includes computed tomography (CT) of the head, cervical spine, chest, and abdomen/pelvis to generate a continuous image from the top of the head through the pelvis; also called a pan-scan.

D-dimer test A test of hypercoagulability that detects a fragment from the fibrinolysis process; the test can be used to help diagnose and monitor diseases and conditions related to inappropriate clotting, such as deep venous thrombosis.

direct bilirubin Conjugated bilirubin; the result of bilirubin's conjugation in the liver, which is ultimately excreted in the bile.

enzymes Proteins that act as catalysts for biochemical reactions within the body.

erythrocyte sedimentation rate (ESR) The rate at which red blood cells settle at the bottom of a tube containing a blood sample. This test is used to identify inflammatory response and is generally less specific than testing C-reactive protein.

glycosuria The presence of glucose in the urine.

hematocrit The percentage of formed elements (cells) in a venous blood sample.

hematuria The presence of red blood cells in the urine.

hemoconcentration Decreased fluid in the blood, which means that concentrations of other blood components increase.

hemoglobin The protein responsible for carrying oxygen to the body's cells and, to a lesser extent, carbon dioxide back to the lungs.

hemoglobinuria The presence of hemoglobin in the urine.

hemolysis Destruction of red blood cells, sometimes following massive blood transfusions or blood transfusion reactions.

hyperchloremia An abnormally high level of chloride in the blood.

hyperkalemia An abnormally high level of potassium in the blood.

hypoalbuminemia An abnormally low level of albumin in the blood.

hypochloremia An abnormally low level of chloride in the blood.

hypokalemia An abnormally low level of potassium in the blood.

hyponatremia An abnormally low level of sodium in the blood.

indirect bilirubin A by-product of the metabolism of red blood cells that is unconjugated and, therefore, not water soluble.

international normalized ratio (INR) A comparative rating of a patient's prothrombin time to help standardize the prothrombin time when planning treatment.

ionic bond A type of chemical bond formed between oppositely charged ions.

ionized calcium Calcium that is not bound or chelated; also called free calcium. Its value is useful in assessing for renal failure, nephrotic syndrome, acid–base derangements, and decreases or elevations in chelating compounds.

ketone bodies Organic products of fat catabolism—specifically, acetoacidic acid, acetone, and beta-hydroxybutyric acid.

ketonuria The presence of ketone bodies in the urine.

lactate The form of lactic acid that is physiologically present in the body.

lactate dehydrogenase (LDH) An enzyme that catalyzes the metabolism of pyruvate (the end product of glycolysis) to lactate in the absence of a functioning citric acid cycle.

leukocytosis An abnormally high number of white blood cells.

lipase A pancreatic hormone that metabolizes lipids.

liver function test (LFT) A test for liver damage that measures enzymes that normally appear in liver cells but may spill out into the vasculature with parenchymal damage.

magnetic resonance imaging (MRI) A diagnostic imaging technique that uses a powerful magnet to align water molecules present in body compartments to visualize the internal structure and function of the body; a three-dimensional image is obtained from this alignment and the speed at which molecules alter or release.

neutropenia An abnormally low neutrophil count.

normal range A range of values encompassing the results that 95% of healthy people would have for the particular test.

osmolality The amount of dissolved substance in 1 kg of water.

osmolarity The amount of dissolved substance in 1 L of water.

osmosis The diffusion of water across membranes.

osmotic pressure The pressure created in a space divided by a semipermeable membrane owing to differences in concentrations of solutes found in the solutions on either side of the membrane.

panel Groups of related tests that are performed as a single unit; also called a profile.

partial pressure of oxygen (Po_2) A measurement of the amount of oxygen dissolved in the blood.

platelet count A measurement of the number of platelets in the blood, which is useful for assessing a patient's coagulation status.

point-of-care testing (POCT) Testing done outside of a traditional laboratory, usually near where care is being delivered to a patient, with the results of the testing being used for clinical decision making; also called decentralized testing, bedside testing, and ancillary testing.

positron emission tomography (PET) A functional imaging modality that uses radiotracers to visualize physiologic changes over time or distinguish various levels of physiologic activity between tissues.

precision A measure of how a value is likely to be the same every time a test is performed.

procalcitonin A peptide precursor of calcitonin used to identify serious bacterial infection.

prothrombin time (PT) A value that represents the extrinsic coagulation pathway's clotting ability by taking into account various clotting factors, fibrinogen, the prothrombin ratio, and the international normalized ratio.

radiography basic imaging modality that uses x-ray radiation to generate a two-dimensional image of the internal form of an object.

red blood cell (RBC) count A measure of the total number of erythrocytes in the blood.

renal tubule acidosis (RTA) An inability to excrete H^+ in the urine, even in the presence of overwhelming metabolic acidosis.

sensitivity The ability of a certain test to maximize the number of true positives that test positive.

specific gravity The chemical property of a fluid that relates its density to the density of water.

specificity The ability of a certain test to minimize the number of true negatives that test positive.

thrombocytopenia An abnormally low blood platelet count.

thromboelastography (TEG) A method used to assess the viscoelastic properties of whole blood that combines multiple measurements of platelet function, the coagulation cascade, and their interaction to form clots.

total protein The total quantity of protein in a blood sample.

troponin A key protein involved in muscle contraction that is present in the serum only after cellular necrosis releases the cellular contents of cardiac muscle (such as after myocardial infarction).

turbid Cloudy or opaque.

ultrasonography A technique for mapping the echoes produced by high-frequency sound waves transmitted into the body; the denser material reflects waves back to a transducer that produces an image. It is typically used for obstetrics, gynecology, and abdominal diagnostics.

urinalysis Laboratory tests performed on a patient's urine.

white blood cell (WBC) count A measure of the total number of leukocytes in the blood.

CHAPTER 10

Resuscitation, Shock, and Blood Products

Amar Deshwar, MD
Sean Kivlehan, MD, MPH

OBJECTIVES

After completing this chapter, you will be able to:

1. Discuss cellular respiration (p 410).
2. Describe oxygen transport and utilization of oxygen by the cell (pp 411–414).
3. Summarize the pathophysiology of shock and its stages: compensatory, decompensatory (progressive), and refractory (irreversible) (pp 414–419).
4. Describe the clinical manifestations associated with the various shock states (pp 414–419).
5. Explain the classification of shock: cardiogenic, hypovolemic, distributive (neurogenic and anaphylactic), and septic (pp 420–432).
6. Identify from a patient presentation which type and stage of shock the patient is experiencing (pp 420–432).
7. Define the following terms: infection, sepsis, sepsis syndrome, systemic inflammatory response syndrome (SIRS), septic shock, and multiple organ dysfunction syndrome (MODS) (pp 419, 430–432).
8. Describe the epidemiology and pathophysiology of shock, sepsis, SIRS, and MODS (pp 432–435).
9. Identify the signs and symptoms that describe the patient in shock, sepsis, SIRS, or MODS (pp 423, 426, 428, 429, 438).
10. Discuss assessment and management of the patient with shock, sepsis, SIRS, and MODS (pp 420–432).
11. List the parameters that should be monitored during the transport of a critical patient experiencing shock, sepsis, SIRS, or MODS (pp 424, 426, 428, 430).
12. Identify the interventions necessary during transport of the critically ill patient experiencing shock, sepsis, SIRS, or MODS (pp 421, 424, 426, 428, 430, 438, 439).
13. Discuss pharmacologic agents used in the treatment of the patient with shock or MODS (pp 427–430).

14. Discuss blood administration, including the ABO blood system, various blood products, and the procedure for administering blood (pp 440–449).
15. Describe the types of adverse transfusion reactions and their etiology (pp 449–451).
16. Summarize management concerns related to blood transfusions (pp 451–452).

Introduction

Shock, sepsis, and multiple organ dysfunction syndrome (MODS) are complex disorders that affect the body in multifaceted dimensions. As unique as each of these conditions is, collectively they share a common denominator—a breakdown in oxygen supply and demand. When oxygen delivery to the cells is compromised, those cells become damaged. A cascade of unfortunate events begins with localized tissue damage and may eventually progress to organ failure and death. Before learning about the pathophysiology of shock, sepsis, and MODS, it is imperative to grasp the basic physiology of how the cell and the microcirculation function. After all, the cell and the microcirculation are the first to experience the insult of inadequate oxygen supply.

Cellular Respiration

All cells require a continuous supply of oxygen, glucose, and other nutrients for normal metabolic function and homeostasis. However, another essential element is also needed for cells to function properly: energy. Energy is required to maintain cellular metabolic processes, much like electricity is needed to power manufacturing plants. The mitochondria within the cell take the nutrients supplied and convert them into energy in the form of adenosine triphosphate (ATP), the primary energy-carrying molecule in the body.

Adenosine triphosphate is manufactured through a complex process known as cellular respiration. Essentially, cellular respiration involves three parts: glycolysis **FIGURE 10-1**, the Krebs cycle **FIGURE 10-2**, and the electron transport chain, otherwise referred to as oxidative phosphorylation. These three components work together in an aerobic environment to produce large amounts of ATP.

Description

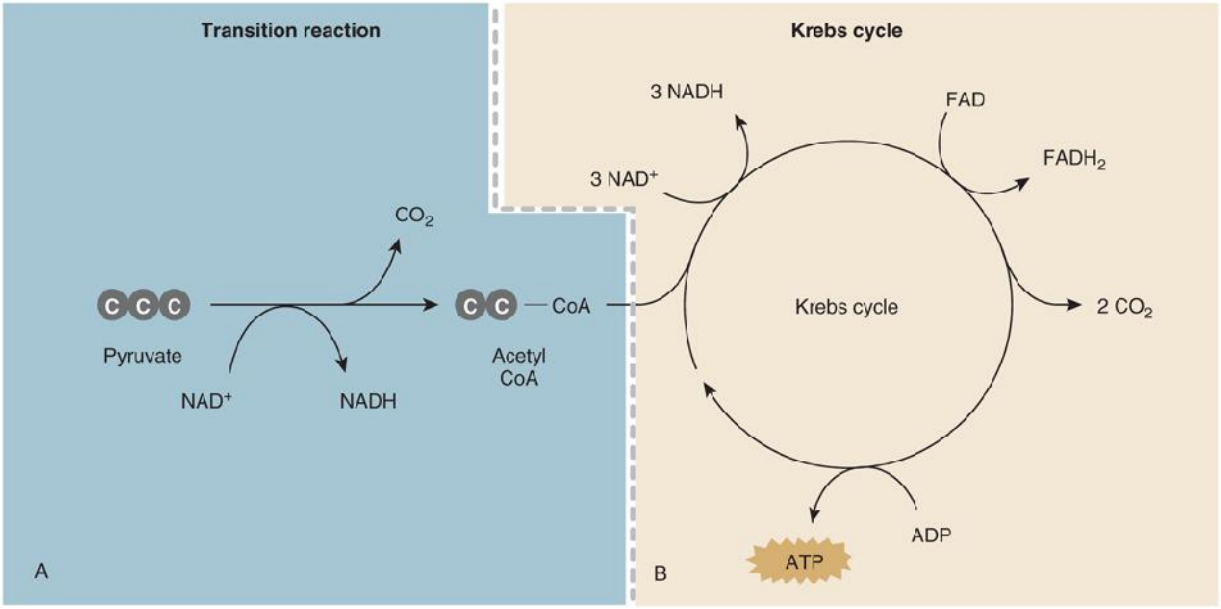

FIGURE 10-2 The Krebs cycle. **A.** Coenzyme A (CoA) is created. **B.** In the mitochondrion, the Krebs cycle liberates two carbon dioxide molecules and produces one adenosine triphosphate (ATP) molecule per pyruvate molecule. Its main products, however, are NADH (a reduced form of nicotinamide adenine dinucleotide) and FADH$_2$ (a reduced form of flavin adenine dinucleotide), which bear high-energy electrons that are transferred to the electron transport system. *Abbreviation*: ADP, adenosine diphosphate

© Jones & Bartlett Learning.

Description

The Krebs cycle and the electron transport chain can work only in the presence of oxygen. However, glycolysis—the breakdown of glucose for energy—can occur in an aerobic or anaerobic environment. When there is not enough oxygen for aerobic metabolism of glucose, glycolysis must work alone to produce ATP. This solo attempt to support cellular respiration leads to decreased production of ATP molecules and increased production of lactic acid. As a result, cells are damaged and tissue function is impaired, leading to a cascade of injurious effects.

In the ATP molecule, the critical component for energy production is triphosphate. Oxygen molecules connect these phosphate groups to each other within ATP. Under normal conditions, these oxygen molecules have a negative charge and, therefore, repel each other.

This property produces the potential energy of ATP. Removing just one of the phosphate groups from this molecule results in conversion of ATP to adenosine diphosphate (ADP) and a release of energy. This conversion from ATP to ADP is crucial for supplying the energy required for biologic functions.

In **aerobic metabolism**, the ultimate acceptor of electrons is oxygen. The mitochondria use glucose, amino acids, and fatty acids combined with oxygen and ADP to produce ATP, carbon dioxide, water, and heat. The energy is stored as ATP, and the resultant carbon dioxide is eliminated by way of the respiratory tract.

In **anaerobic metabolism**, an alternative pathway converts glucose to pyruvic acid with the simultaneous production of ATP; however, significantly less ATP results from this process. This process also results in the production of lactate, which is released into the extracellular fluid and decreases the pH of body fluids. Overall, anaerobic metabolism is less efficient than aerobic metabolism.

Microcirculation and the Cell: Oxygen Transport and Utilization

Understanding the imbalance between oxygen supply and demand is critical to understanding the pathophysiology of shock, sepsis, and MODS. To a large extent, the pathophysiology associated with these disorders can be compared with the mechanisms of injury in trauma. When EMTs and paramedics respond to a vehicular trauma scene, they can identify injuries and correlate the injuries to the impacts the patient endured. Indeed, this activity is part of a good scene size-up. The same principle carries over to understanding the cell and the **microcirculation**—the nexus between the arterioles and venules, consisting of the capillaries that course between cells of the various organs. These tiny conduits are large enough to allow passage of a single red blood cell (RBC). In cases of shock, sepsis, and MODS, the "crash site"—that is, the injury and its impact—is hidden deep within the body, at the cellular level.

For cells to function properly, oxygen is required. Oxygen is a key nutrient in maintaining the homeostatic balance within the body. Put another way, the body can maintain homeostasis only when the supply of oxygen is sufficient to meet its cellular demands. To achieve this balance, each of the body's systems must be intact and functioning normally, and the respiratory system must allow oxygen and carbon dioxide exchange across the alveolar-capillary membrane.

Once this transfer occurs, arterial blood transports oxygen to the tissues. Oxygen may be dissolved in plasma (3%) or bound to hemoglobin (97%). Given that the majority of oxygen in the body is bound to hemoglobin, it is important to have an ample supply of hemoglobin. Simple formulas exist to determine the oxygen-carrying capacity of hemoglobin. As a standard, 1 g of hemoglobin carries approximately 1.39 mL of oxygen. (Note: Some texts state that 1 g of hemoglobin carries only 1.34 to 1.36 mL of oxygen, based on the theory that a certain percentage will be bound to methemoglobin, and not to hemoglobin.) Oxygen-carrying capacity is determined by using the following formula:

$$\text{Hemoglobin (Hgb)} \times 1.39 = \text{Oxygen} - \text{Carrying Capacity}$$

If the hemoglobin level is low, blood can be administered to optimize the oxygen-carrying capacity.

It may also be necessary to determine the total amount of oxygen in the arterial blood. The **arterial oxygen content (Cao_2)** formula is used to calculate this value. The normal arterial oxygen content is 17 to 20 mL per 100 mL of blood. The following formula is used to determine the arterial oxygen content:

$$Cao_2 = (Hgb \times 1.39 \times Spo_2) + (0.0031 \times Pao_2)$$

Use of the arterial oxygen content formula helps verify the importance of hemoglobin, oxygen saturation (Spo_2), and arterial partial pressure of oxygen (Pao_2). However, hemoglobin and oxygen saturation have a greater impact on arterial oxygen content than does Pao_2. For this reason, some clinicians use an abbreviated formula for measuring arterial oxygen content:

$$Cao_2 = Hgb \times 1.39 \times Spo_2$$

TABLE 10-1 explains the components of the arterial oxygen content formula.

TABLE 10-1 Components of the Arterial Oxygen Content Formula

Arterial Oxygen Content Formula: $Cao_2 \cdot (Hgb \cdot 1.39 \cdot Spo_2) \cdot (0.0031 \cdot Pao_2)$

Hgb	97% of oxygen bound with Hgb	Hgb × 1.39 = Oxygen-carrying capacity

Arterial Oxygen Content Formula: $Cao_2 \cdot (Hgb \cdot 1.39 \cdot Spo_2) \cdot (0.0031 \cdot Pao_2)$

1.34–1.39 (varies in literature)	Each gram of Hgb is capable of carrying 1.39 mL of oxygen	
SpO_2	The amount of oxygen carried on Hgb	Oxygen-carrying capacity × SpO_2
0.0031	0.0031 mL O_2/100 mL plasma/mm Hg Also known as the solubility coefficient for oxygen	0.0031 × PaO_2 = Amount of oxygen dissolved in plasma
PaO_2	Partial pressure of oxygen dissolved in plasma (normal is 0.8–1.0 mm Hg)	

Abbreviation: Hgb, hemoglobin

© Jones & Bartlett Learning.

The cardiovascular system delivers oxygen-rich blood to the tissues. A number of factors can affect this transport process, including blood volume, viscosity, and arterial elasticity. However, the primary determinants of transport effectiveness are blood pressure (BP) and cardiac output. Systolic blood pressure (SBP) depends primarily on **cardiac output (CO)**, the force and volume of blood ejected from the ventricles during systole. Cardiac output, in turn, depends on heart rate and the components of stroke volume—preload, afterload, and contractility. Diastolic blood pressure (DBP) depends on peripheral resistance, which is determined by arteriolar vasoconstriction. Knowing the BP is necessary to calculate the **mean arterial pressure (MAP)**, which can provide information on how well organs are being perfused. Overall, an adequate cardiac output and a stable BP are essential for proper perfusion and general performance of the body.

The amount of oxygen delivered to the tissues each minute is reflected in the **oxygen delivery (Do_2)**. Oxygen delivery is a calculated formula that combines arterial oxygen content with cardiac output. **TABLE 10-2** discusses the components of the formula shown here (CO represents cardiac output, and CaO_2 represents arterial oxygen content):

$$DO_2 = CO \times CaO_2$$

TABLE 10-2 Oxygen Transport and Utilization: Formula Description

Step	Formula Component	Normal Values
Arterial oxygen content (CaO_2)		
1. Transfer of oxygen across the alveolar-capillary membrane	$(Hgb \times 1.39 \times SpO_2) + (0.0031 \times PaO_2)$	17–20 mL/100 mL arterial blood
2. Adequate Hgb to carry the oxygen		
Oxygen delivery (DO_2)		
3. Adequate cardiac output to deliver the oxygen-rich blood to the tissues	$CO \times CaO_2$	640–1,400 mL/min
Oxygen consumption ($\dot{V}O_2$)		
4. Appropriate release of oxygen from Hgb	$CO \times Hgb \times 13.9 \times (SpO_2 - SvO_2)$	180–280 mL/min

Step	Formula Component	Normal Values
5. Adequate utilization of oxygen by cells	Oxygen extraction ratio (ERO_2) $\frac{\dot{V}O_2}{DO_2}$	25%

Abbreviations: Hgb, hemoglobin; PaO_2, partial pressure of oxygen; SpO_2, oxygen saturation; SvO_2, venous oxygen saturation

© Jones & Bartlett Learning.

If the arterial oxygen content is normal and oxygen delivery is below normal, measures should be taken to enhance the CO. These measures include fluid challenges and administration of an inotropic agent. Once all measures to increase the CO have been attempted, pressor support is used.

When the oxygen-bound hemoglobin reaches the capillaries, the hemoglobin releases the oxygen to the cells in exchange for cellular waste. The amount of oxygen used by the cells and tissues is reflected in **oxygen consumption ($\dot{V}O_2$)**. It is calculated as follows:

$$\dot{V}O_2 = CO \times Hgb \times 13.9 \times (SpO_2 - SvO_2)$$

This formula is unique because it subtracts the percentage of oxygen saturation in the venous bed (SvO_2) from the oxygen saturation in the arterial bed (SpO_2). Mixed venous oxygen saturation (SvO_2) is measured much like an arterial blood gas (ABG), except that in measuring the venous saturation, blood is drawn from the distal port of the pulmonary artery (PA) catheter. This value reflects how well the body's tissues are able to extract and use the oxygen attached to hemoglobin. A sample from the distal port of the PA catheter provides a global perspective on how well the tissues are utilizing oxygen. The problem with this test is that some tissues may extract more or less oxygen than others. For example, pulmonary and cardiac tissues extract approximately 40% of the oxygen from hemoglobin. As a result, the SvO_2 of venous blood drawn directly from the cardiovascular or pulmonary circulation will normally be approximately 60%. In contrast, the skin typically extracts only approximately 5% of the oxygen from hemoglobin.

Using the tip of the PA catheter to measure SvO_2 provides an average of the oxygen extracted from hemoglobin throughout the body. The normal SvO_2 level measured in the pulmonary artery is approximately 60% to 80%. When this value is abnormal, there is no way to specify which tissue bed or organ is responsible for the dysfunction. Some specialty catheters allow for direct SvO_2 measurements.

Under certain circumstances, oxygen is more readily extracted from hemoglobin or more readily bound to hemoglobin—a property sometimes referred to as hemoglobin’s affinity for oxygen. This affinity for oxygen depends on the PaO_2, the pH of the blood, the level of carbon dioxide in the blood, the ambient temperature, and the effects of BPG (2,3-biphosphoglycerate—a chemical that binds to deoxygenated hemoglobin, which helps RBCs release oxygen).

The oxyhemoglobin dissociation curve reflects the effects of PaO_2 on the oxyhemoglobin saturation of RBCs; this curve is shown in Chapter 6, *Respiratory Emergencies and Airway Management*. Specifically, as the PaO_2 decreases, the amount of oxygen bound to hemoglobin in the arterial blood decreases, so that less oxygen is available for utilization by the tissues. A rightward shift of the dissociation curve causes decreased affinity for oxygen by hemoglobin. Conditions that cause a rightward shift include increased carbon dioxide level, BPG level, and temperature as well as decreased pH. A leftward shift of the dissociation curve leads to an increased affinity for oxygen by hemoglobin; in other words, oxygen is more readily bound to hemoglobin, and the body can maintain oxygen saturation with a lower PaO_2. However, release of the bound oxygen to tissues becomes more difficult. The conditions that cause a leftward shift are the opposite of those that cause a rightward shift—namely, decreased carbon dioxide level, BPG level, and temperature and increased pH.

Finally, it is the responsibility of the cells to use the oxygen. The $\dot{V}o_2$ is dependent on the Do_2. The relationship between these two components is reflected in the **oxygen extraction ratio (ERo_2)**, which is defined as follows:

$$ERo_2 = \frac{\dot{V}o_2}{Do_2}$$

Under normal conditions, only 25% of the oxygen delivered to the tissues is extracted. Therefore, the normal Svo_2 when measured in the pulmonary artery is approximately 75%. This allows the body a buffer zone for periods of low oxygen delivery when the cells must extract more oxygen. For example, if the Do_2 drops to 600 mL/min, for $\dot{V}o_2$ to remain within normal limits (180–280 mL/min), the ERo_2 will need to increase 33%. If the $\dot{V}o_2$ drops, cells are forced to work under anaerobic conditions. Mortality rates increase as $\dot{V}o_2$ is compromised. Therefore, treatment is geared toward maximizing $\dot{V}o_2$, which is done partially by maintaining an adequate oxygen supply, providing hemoglobin through administration of blood products, and optimizing cardiac output. If one or more of these components breaks down, the body will suffer a loss of homeostasis.

Shock

Shock is a whole-body response to an inadequate supply of oxygen within cells, tissues, and organs from one or multiple causes. The beginning stages of shock occur at the cellular level. When oxygen supply to the microcirculation is diminished, cells are forced to function in an anaerobic environment, which leads to widespread cellular hypoxia. Shock is a progressive condition that functions on a continuum; however, it is commonly classified into three stages: compensatory, decompensated, and refractory shock.

Compensatory Stage

When the oxygen supply to the microcirculation decreases, as a compensatory mechanism to maintain blood flow to the heart, brain, and adrenal glands, the microcirculatory blood flow to other tissue beds is severely restricted. The initial stage of shock begins as blood flow into the microcirculatory beds decreases to a point that oxygen delivery to the cells falls below the level required to maintain normal aerobic cellular function. Initially, the tissues respond to the restricted oxygen delivery by consuming excess oxygen, thereby increasing oxygen consumption. Eventually, however, the oxygen oversupply is exhausted and cells are unable to extract enough oxygen. The mitochondria cannot function aerobically to produce ATP, secondary to hypoxemia. This anaerobic environment leads to increased lactate and carbon dioxide levels. With ATP production severely reduced, cells are unable to maintain homeostasis and, more specifically, microcirculatory flow to the heart, brain, and adrenal glands.

In the early stages of shock, there are only very subtle clinical signs and symptoms of hypoperfusion, and sometimes no signs at all. Vital signs may change temporarily. For example, the heart rate and respiratory rate may increase, and the MAP may fall somewhat, but the body’s compensatory mechanisms are able to return these values to baseline. Research has demonstrated that lactic acidosis begins to increase in the initial stage of shock. Serum lactate elevation is a useful early marker of shock, as it begins to rise before obvious clinical signs materialize. When early signs of shock are recognized, the transport team should increase the frequency of their vital signs checks and monitor the patient closely.

The body uses its own physiologic mechanisms in an attempt to maintain cellular homeostasis. There are three types of compensatory mechanisms, all of which are controlled by the sympathetic nervous system: neural **FIGURE 10-3**, hormonal **FIGURE 10-4**, and chemical **FIGURE 10-5**. The neural mechanism is typically thought of first. It is reflected in the vital signs and physical assessment as an increased heart rate, increased contractility, and vasoconstriction, which help shunt blood to vital organs. In reality, all three compensatory mechanisms—neural, hormonal, and chemical—act simultaneously in an attempt to restore circulating volume and tissue oxygenation. In compensatory shock, the body is still successfully using these mechanisms in an attempt to correct the problem, making it sometimes difficult to recognize the patient in shock. Indeed, signs and symptoms of compensatory shock may be as subtle as mild tachypnea and tachycardia and slightly lower cardiac output.

Description

In compensatory shock, oxygen delivery to the tissues is severely reduced. To compensate for this imbalance, cells try to increase their oxygen consumption by pulling more oxygen from the capillary bed. However, the cells are already working in an oxygen-deprived environment. Trying to work harder in this anaerobic environment produces more lactic acid and carbon dioxide. Chemoreceptors that are strategically located in the carotid arteries and aortic arch recognize this increase in the carbon dioxide level and relay this information to the brain, which in turn stimulates an increase in the respiratory rate. A patient in compensatory shock may become tachypneic in an attempt to take in more oxygen while concurrently exhaling excess carbon dioxide. Blowing off carbon dioxide is a compensatory mechanism to lower the amount of acid in the body produced by the lactic acidosis and hypercarbia. This mechanism results in an increase in pH.

While the respiratory system is working to balance pH and pull in more oxygen while ridding the cells of waste, the heart and circulatory system are simultaneously attempting to maintain cardiac output. When the stroke volume and MAP begin to fall, baroreceptors in the carotid sinus and aortic arch recognize the change in pressure and send a signal to the vasomotor receptors in the medulla. This activates the autonomic nervous system, which stimulates the sympathetic nervous system and the anterior pituitary to release epinephrine and norepinephrine from the adrenal glands. These hormones work together to increase MAP and CO by increasing the heart rate, contractility, and peripheral vasoconstriction.

The renin-angiotensin-aldosterone system, a hormonal compensatory mechanism, is activated in response to low arterial pressures. Decreased BP stimulates the release of renin, which stimulates first the conversion of angiotensinogen to angiotensin I, and then the conversion of angiotensin I to angiotensin II. Angiotensin II increases arterial BP through four mechanisms: vasoconstriction, stimulation of the thirst receptors in the hypothalamus, stimulation of the release of aldosterone from the adrenal glands, and stimulation of antidiuretic hormone (ADH) secretion from the posterior pituitary gland. Aldosterone increases the circulatory volume by stimulating the reabsorption of sodium and water in the renal tubules.

Low arterial pressures will directly trigger the posterior pituitary gland to release ADH as well. This hormone increases water reabsorption within the kidneys and assists the adrenal hormones in enforcing vasoconstriction to nonvital areas of the body. When vasoconstriction limits the supply of oxygen and blood flow to peripheral areas, shifts in capillary fluid occur. Adequate capillary pressure depends on an adequate perfusion pressure (ie, MAP). When capillary pressure drops, the pressure balance within the capillary bed is lost. As part of the physiology of the capillary pressures, hydrostatic pressure pushes fluid out and osmotic pressure pulls fluid back in. Normally, the hydrostatic pressure at the arterial end of the capillary is higher than the osmotic pressure, causing interstitial fluid to filter through the capillary endothelium into the interstitial space. At the venous end of the capillary, the hydrostatic pressure is lower than the osmotic pressure, causing fluid to diffuse back into the capillary. A loss of the normal pressure balance in the capillaries may lead to edema. Edema results from any disturbance that alters the regulation of fluid transfer in the capillary and interstitial space. Such disturbances can include inflammation (more porous capillaries), decreased colloid osmotic pressure, increased capillary hydrostatic pressure, and lymphatic channel obstruction.

The body’s ability to compensate for shock in its early stages often masks what is happening at the cellular level. Compensatory mechanisms can cover up a low circulatory volume, poor stroke volume, and inadequate CO before any noticeable changes in the BP become evident, especially in children and healthy young adults. Even so, other signs—such as tachycardia and tachypnea, which may be subtle—are important indicators of the body’s attempt to deal with shock. Laboratory studies are also a useful adjunct to early assessments for shock, as ABGs will show a low pH indicative of acidosis. As mentioned previously, an elevated lactate level in the patient with compensated shock is a concerning finding.

Decompensatory Stage

If its underlying cause remains untreated, shock will progress to an uncompensated state. In this stage, the compensatory mechanisms fail to supply the much-needed oxygen to the cells. Patients with progressive shock exhibit more pronounced signs of shock, including a drop in MAP, altered mental status, and tachycardia. Laboratory analysis continues to show a progression of acidosis, hyperkalemia, and a climbing lactate level.

This clinical picture develops for many reasons **TABLE 10-3**. Hypotension becomes more prominent as the microcirculation loses its ability to autoregulate, leading to increased capillary permeability. Blood starts to pool in the capillary bed, increasing hydrostatic pressure. The marked change in hydrostatic pressure within the microcirculation leads to edema and third spacing, which decreases venous return to the heart—a condition evidenced in a patient in shock by the presence of mottled skin. Hemodynamic effects of this decreased preload are reflected in the BP as hypotension and through other direct and indirect preload assessments. For further discussion, see Chapter 15, *Hemodynamic Monitoring*.

TABLE 10-3 Effects of Shock on the Body

Organ or System Affected	Progressive Result of Ischemia
Heart	Arrhythmias Cardiac failure
Lungs	Pulmonary hypertension Pulmonary edema Acute respiratory distress syndrome
Brain	Ischemia or infarction
Kidney	Decreased urine output Acute tubular necrosis Renal failure
Gastrointestinal	Stress ulcer Ischemic bowel with release of toxins
Pancreas	Ischemia Myocardial depressant factor released

Organ or System Affected	Progressive Result of Ischemia
Liver	Hypoglycemia Toxicity
Hematologic and immune	Initial leukocytosis followed by leukopenia Systemic inflammatory response Disseminated intravascular coagulation
Adrenal glands	Adrenal insufficiency, leading to hypotension, and hypoglycemia

Altered blood flow to the capillary bed, particularly when combined with the inflammation that occurs in sepsis, can cause damage to endothelial cell walls, triggering activation of the intrinsic clotting cascade and development of microemboli. These microclots can form in the tissues and organs, where they inhibit cellular respiration and cause cell damage. The body uses up its clotting factors and fibrinogen faster than the liver can produce them; simultaneously, fibrinolysis occurs in an attempt to reopen the microcirculation. The imbalance between coagulation and fibrinolysis leads to **disseminated intravascular coagulation (DIC)**, a complex coagulopathy that can emerge in critically ill patients for a variety of reasons and cause both bleeding *and* thrombosis **FIGURE 10-6**. Finally, the movement of RBCs through the microclots damages the cells and can lead to **hemolysis**—that is, destruction of the RBCs. Rupture of these cells results in the release of hemoglobin and RBC remnants into the bloodstream; in addition, the decrease in the number of RBCs leads to anemia.

Description

Hypotension is also a by-product of increased anaerobic metabolism. Anaerobic metabolism produces a more acidic environment that leads to rupture of the lysosomes, which then spill their contents into the cellular cytoplasm, leading to an even more acidic environment. As the sodium-potassium pump begins to fail, sodium ions accumulate within the cell, eventually drawing fluid into the cell through osmosis. This influx causes cellular swelling and ultimately destruction of the cellular membrane. It is an important consideration in patient management, because a number of devastating effects, such as cardiac arrhythmias, can follow.

As cellular damage becomes more pronounced, cells start to die and release toxins into the microcirculation. For example, lysosomes, which normally defend cells from invaders, rupture and unleash their digestive enzymes, causing further damage within the microcirculation. Cell mediators attempt to counterattack this release and initiate the inflammatory response. The inflammatory response provoked is not isolated to a specific area, but rather occurs throughout the body.

When various complex compensatory components fail, the ensuing vasodilation, smooth muscle contraction, and increased tissue permeability collectively result in hypotension. Unfortunately, this cascade of events only gets worse as clotting mechanisms respond to cell breakdown. The inflammatory response is further discussed in the section on sepsis later in this chapter. The combination of these multifaceted systemic responses to cell breakdown can lead to the process known as systemic inflammatory response syndrome (SIRS), also discussed in detail later in this chapter.

Patients in the decompensatory stage of shock will present as hypotensive, tachycardic, tachypneic, and oliguric, and frequently demonstrate altered mental status. The presence of progressive shock indicates that the body's compensatory mechanisms have failed; this condition is a life-threatening emergency requiring immediate treatment. Patients still have a chance for recovery from this stage of shock, although mortality is significantly increased.

Refractory Stage

When a patient reaches the **refractory stage** of shock, the body's compensatory mechanisms have failed and permanent organ dysfunction has occurred. Although no consensus definition exists regarding when a patient is in this stage of shock, refractory shock is clinically marked by the need for high-dose vasopressors—though this point is also the subject of debate. At this stage, the survival and outcomes for patients are generally poor, with a mortality rate of approximately 60%; mortality rises to 80% to 90% when greater than 1 mcg/kg/min of norepinephrine is required to maintain a stable MAP.

A patient in this stage of shock will typically be minimally responsive or unresponsive, severely hypotensive, with cold, cyanotic, and/or mottled skin, and weak and thready to absent peripheral pulses. Urinary output will have progressed from oliguria to anuria.

Multiple Organ Dysfunction Syndrome

Progressive cell death results first in tissue death and eventually in organ failure. When two or more organs stop functioning, the diagnosis of **multiple organ dysfunction syndrome (MODS)** is made. MODS can be classified as primary or secondary. **Primary MODS** results from a direct insult such as trauma. **Secondary MODS**, the more common cause of organ failure, is characterized by a slower, more progressive insult to organs. It frequently results from the sepsis cascade (discussed later in this chapter).

Overall MODS mortality rates range from 44% to 76%. In patients with failure of two to four organs, mortality varies between 10% and 40%, compared to mortality up to 50% with failure of five organs and 100% with failure of seven organs. All organs can be affected in MODS, with some of these changes being amenable to tracking with laboratory values (kidneys and liver), urine output (kidneys), and mental status (brain). A decreased MAP will greatly reduce renal perfusion and function, leading to oliguria. Renal damage is reflected in elevated blood urea nitrogen (BUN) and creatinine levels. Many patients need temporary continuous bedside dialysis to address this renal failure, which greatly increases mortality. Liver damage results in a loss of detoxification ability, decreased clotting capacity, and decreased oncotic protein production. Such damage is diagnosed by markedly increased levels of total bilirubin and liver enzymes, including aspartate aminotransferase and alanine aminotransferase.

As hypotension progresses or hypoxia ensues, there comes a point when the body’s compensatory mechanisms can no longer keep the brain adequately perfused and oxygenated. The brain will then experience ischemia, and patients will experience anoxic brain injury with potentially permanent consequences. A broad array of cardiac effects may be seen, including hypotension from decreased cardiac output and arrhythmias from myocyte irritability induced by cellular hypoxia or toxin exposure. Many inflammatory mediators are released during MODS, which have effects ranging from myocardial depression to vasodilation. These mediators are the focus of ongoing research to better understand and effectively treat MODS.

TABLE 10-4 lists systems and organs commonly affected by hypoperfusion and describes associated signs of dysfunction.

TABLE 10-4 Common Effects of Hypoperfusion

System or Organ	Signs of Dysfunction
Neurologic	Altered level of consciousness Confusion
Pulmonary	Tachypnea Hypoxemia • PaO_2 <70 mm Hg • SpO_2 <90% • PaO_2:FIO_2 ratio <300 Respiratory alkalosis
Cardiovascular	Tachycardia Hypotension Altered hemodynamics • Decreased systemic vascular resistance • Decreased cardiac output • Decreased CVP Arteriovenous shunting • Cellular hypoxia • Lactic acidosis
Renal	Oliguria Anuria Elevated creatinine level
Hepatic	Jaundice Elevated enzyme levels Decreased albumin level Prolonged PT

System or Organ	Signs of Dysfunction
Hematologic	Decreased platelet count Prolonged PT/activated partial thromboplastin time Decreased protein C level Elevated D-dimer level
Adrenal glands	Hypotension Hypoglycemia

Abbreviations: CVP, central venous pressure; F_{IO_2}, fraction of inspired oxygen; Pa_{O_2}, partial pressure of arterial oxygen; PT, prothrombin time; Sp_{O_2}, oxygen saturation

Classification of Shock

Shock is traditionally classified by cause. Thus, the three primary classifications of shock are based on the conditions that cause them: cardiogenic, hypovolemic, and distributive. Distributive shock, which is characterized as a relative hypovolemia, can be further broken down into neural and chemical (eg, anaphylactic) causes. More than one type of shock may be present at the same time. For example, many trauma patients present with hypovolemic shock from the injuries they have sustained, but may also have cardiogenic or neurogenic shock.

Cardiogenic Shock

Cardiogenic shock is caused by failure of the heart to pump blood effectively. The definition of cardiogenic shock includes the following elements:

- A sustained SBP of less than 90 mm Hg for greater than 30 minutes
- Hemodynamic criteria including a **cardiac index** less than 2.2 and pulmonary capillary wedge pressure greater than 15 mm Hg
- Evidence of end-organ damage (altered mental status, urine output less than 30 mL/h, cool extremities, mottled skin)

The diagnosis of cardiogenic shock is made from the combination of clinical presentation, laboratory studies, echocardiography, and electrocardiogram (ECG). If the diagnosis remains uncertain or the presentation is atypical, a PA catheter (Swan-Ganz) can be used to measure central venous pressure (CVP) and pulmonary capillary wedge pressure (PCWP), which will be elevated in left ventricular cardiogenic shock. Measurements from a PA catheter can also assist in differentiating right versus left ventricular heart failure **TABLE 10-5**.

TABLE 10-5 Findings in Cardiogenic Shock

	Left Ventricular Heart Failure	Right Ventricular Heart Failure	Biventricular Heart Failure
Heart rate	Increased	Increased	Increased or decreased
Blood pressure	WNL in the initial stage, then decreases as patient decompensates	WNL in the initial stage, then decreases as patient decompensates	Decreased
Pulse pressure	Narrow	Narrow	Narrow
Central venous pressure/right atrial pressure	WNL	Increased	Increased
Pulmonary capillary wedge pressure	Increased	Decreased	Increased
Cardiac output/cardiac index	Decreased	Decreased	Decreased
Systemic vascular resistance	Increased	Increased	Increased
Svo_2	Decreased	Decreased	Decreased
Urinary output	Decreased	Decreased	Decreased
Jugular vein distention	Absent	Present	Present
Heart sounds	S_3	Normal	S_3 or S_4
Edema	Pulmonary	Peripheral	Systemic

Abbreviations: Svo_2, venous oxygen saturation; WNL, within normal limits

Description

Cardiogenic shock can result from numerous causes, both intrinsic and extrinsic. The most common (intrinsic) cause is left ventricular failure resulting from a large myocardial infarction (MI). Other intrinsic causes of cardiogenic shock may include right ventricular failure, valvular disorders, cardiomyopathies, septal defects, papillary muscle rupture, and sustained arrhythmias. These conditions manifest with poor contractility, decreased CO, or impaired ventricular filling. Extrinsic causes of cardiogenic shock include pericardial tamponade, effusion, pulmonary emboli, and tension pneumothorax. Some experts, including those at the American Heart Association, classify extrinsic causes as cardiogenic shock because they lead to impaired filling or emptying of the ventricles, or a combination of the two. Noncoronary causes of cardiogenic shock include myocardial contusion, pericardial tamponade, ventricular rupture, and pulmonary embolus.

Cardiogenic shock occurs in approximately 5% to 12% of patients admitted to the hospital following an MI. Populations at the greatest risk of developing this type of shock are older patients, patients with a history of diabetes mellitus, and patients with a history of MI with an **ejection fraction** (the portion of the blood ejected from the ventricle during systole) of less than 35%.

Risk stratification of patients in cardiogenic shock formerly was very high, with a mortality rate as high as 80%. Such a high mortality rate led to a very grim prognosis with little chance of survival. In recent years, newer treatment modalities have greatly improved the risk stratification, so that the prognosis for such patients is no longer quite so poor. Recent data suggest that the average mortality rate for cardiogenic shock is now approximately 50%, with the exact rate depending on risk factors and demographics, and patients have an excellent chance for long-term survival. Modern treatment modalities include early percutaneous coronary interventions, early revascularization, hemodynamic management with PA catheters, mechanical support with an intra-aortic balloon pump, and total circulatory support through the use of left-ventricular assist devices, biventricular assist devices, and extracorporeal life support. See Chapter 15, *Hemodynamic Monitoring*, and Chapter 16, *Mechanical Circulatory Support*, for further discussion of these interventions.

Cardiogenic shock occurs when the ventricles are unable to pump blood forward. Because the ventricles cannot contract normally, blood remains trapped in the ventricles. As a result, stroke volume is reduced, ultimately decreasing CO. The five major determinants of myocardial oxygen consumption are contractility, preload, wall tension, afterload, and heart rate. With inadequate oxygen supply to the periphery, cells must function in anaerobic conditions, enabling the cascade of events leading to SIRS and MODS.

Manifestations of cardiogenic shock vary depending on the underlying cause (Table 10-5). Initially, the patient exhibits signs and symptoms associated with poor CO and low BP. Both right- and left-side heart failure result in hypotension, reflected as a SBP of less than 90 mm Hg for a sustained period or a MAP that is 30 mm Hg below baseline. The decreased stroke volume causes a narrow pulse pressure (less than 25 mm Hg). Patients also demonstrate an altered mental status; cool, pale, diaphoretic skin; and a drop in urine output.

The Meaning of *Pale*

The word "pale," as used in this text, may apply to any patient whose skin presentation suggests reduced blood flow or oxygenation. In general, the mucous membranes inside the inner lower eyelid and the oral mucosa will have a pink coloration in all healthy patients, regardless of their baseline skin color; thus, a white or pale appearance of these areas in any patient suggests reduced blood flow or oxygenation.

Because providers do not necessarily know the patient's normal skin color, they should consider the observations of friends or family members on scene. Simply asking, "Does her skin look like its usual color to you?" or noting when a loved one says, "He's white as a ghost!" may offer useful insight into the person's condition.

The first compensatory mechanism that is likely to be observed is tachycardia. However, the heart cannot sustain or improve CO, and the pulse becomes weak and thready. Heart sounds may be distant, or abnormal heart sounds may appear as S_3 or S_4. Preload is elevated because the heart cannot effectively push the blood forward. This lack of forward movement may cause fluid accumulation in the lungs (acute pulmonary edema), the periphery (jugular vein distention [JVD]), or both, depending on the ventricle(s) affected. Skin becomes cool and clammy as compensatory mechanisms create systemic vasoconstriction. This increases afterload, which in turn increases the pressure that the already struggling myocardium must pump against. If the right ventricle is affected, the right atrial pressure (RAP) and CVP will also be elevated. Cardiogenic shock from right heart failure classically presents with marked JVD and an absence of pulmonary edema.

Analysis of ABGs may reflect hypoxemia with a low PaO_2 level and a corresponding metabolic acidosis with compensatory respiratory alkalosis. Acidosis develops as a result of poor perfusion due to cardiac dysfunction and the heart's inability to pump oxygen-rich blood to the peripheral tissues. Respiratory alkalosis develops as the patient becomes tachypneic and the body attempts to blow off the excess carbon dioxide generated by the increased anaerobic metabolism. Eventually, this compensatory mechanism will fail, in which case the ABGs will reflect metabolic and respiratory acidosis.

Patients with shortness of breath should receive high-flow oxygen therapy, with a goal of maintaining an Spo_2 of more than 92%. One manifestation of cardiogenic shock is pulmonary edema; when it occurs, consider positive-pressure or mechanical ventilation as guided by the patient’s clinical presentation and ABG analysis. Supportive therapy is also necessary to eliminate chest pain and reduce anxiety. Arrhythmias are common with cardiogenic shock, so administration of antiarrhythmic agents may be necessary to optimize cardiac function.

Fluid therapy is never wrong when done judiciously **FIGURE 10-7**. Isotonic crystalloids in small 200- to 250-mL (5- to 10-mL/kg) boluses may improve CO. In patients with suspected cardiogenic shock, frequently reassess vital signs, lung sounds, and heart sounds after administering fluid boluses to measure the adequacy of that therapy. Excessive crystalloids may cause new-onset pulmonary edema or worsen existing pulmonary edema.

FLIGHT MEDIC

FIGURE 10-7 Administer intravenous fluids judiciously to the critical care patient with cardiogenic shock.

© JHP Travel/Alamy Stock Photo.

Inotropic support may be needed to improve contractility, and vasopressors may be necessary for immediate hypotension treatment. The choice of vasopressor for patients with cardiogenic shock is controversial and complicated. Because the use of dopamine has been associated with higher rates of cardiac arrhythmias and mortality, norepinephrine is often the favored first-line therapy in undifferentiated cardiogenic shock. Unfortunately, all vasopressors will increase afterload through vasoconstriction, which in turn will increase cardiac workload and oxygen demand. Dobutamine and milrinone are two alternative options that will improve inotropy without increasing the systemic vascular resistance (SVR). However, these two drugs will cause peripheral vasodilation and should be avoided in the severely hypotensive patient.

Preload and afterload reductions are primary concerns in patients with cardiogenic shock that must be balanced with the need for inotropic and pressor support. Once the BP is stabilized, vasodilators are started. Nitroglycerin and nitroprusside can be used to reduce preload and afterload, respectively; however, these medications must be used in conjunction with close BP monitoring and possibly pressor support. Diuretics such as furosemide (Lasix) or bumetanide (Bumex) are frequently administered as well to reduce volume overload.

Primary management of cardiogenic shock focuses on enhancing CO while decreasing left ventricular workload. If the underlying cause is known, simple procedures to relieve the cause of cardiogenic shock should be implemented first. They may include pericardiocentesis for cardiac tamponade (if protocols allow), along with needle decompression and placement of a chest tube for tension pneumothorax. If the cause is an acute MI (AMI), revascularization should be initiated early (this in-hospital procedure is not performed during transport) and aspirin should be administered. However, clopidogrel (Plavix) and heparin should be administered only in consultation with an interventional cardiologist, as some patients with cardiogenic shock will require coronary artery bypass surgery.

When pharmacologic methods are contraindicated or fail to support the failing heart, both temporary and durable mechanical circulatory-support devices are available for patients in refractory cardiogenic shock. As a whole, the evidence to guide patient and device selection is limited and typically determined by a multidisciplinary team, which will consider multiple patient factors in making this decision. The intra-aortic balloon pump (IABP) is a temporary option for mechanical circulatory support. This large balloon catheter lies in the thoracic aorta and inflates during diastole, displacing blood in the aorta. Balloon inflation forces blood in two directions—back toward the aortic arch and the coronary arteries, and forward through the descending aorta, forcing blood into the peripheral circulation, including the renal and mesenteric arteries. The balloon deflates during systolic contraction, allowing the heart to pump against very low systemic pressures. While this device is still widely used, recent studies have shown no improvement in mortality rates with use of the

IABP. See Chapter 6, *Respiratory Emergencies and Airway Management*, and Chapter 7, *Ventilation*, for in-depth discussion of mechanical circulatory support devices.

Other percutaneous options for temporary circulatory support include the Impella, the TandemHeart, and veno-arterial extracorporeal membrane oxygenation. The Impella works as an axial flow pump, with the inflow coming from the left ventricle and the outflow moving through the proximal aorta. This design helps to increase CO and offload the burden placed on the left ventricle. The TandemHeart works as an extracorporeal pump, with the inflow cannula being placed in the left atrium and the outflow cannula in the femoral artery. As both of these devices depend on sufficient left atrial preload, right ventricular failure is a contraindication to use of both the Impella and the TandemHeart. Veno-arterial extracorporeal membrane oxygenation is an increasingly common bridge therapy that can stabilize the patient in cardiogenic shock. A cannula is placed, either centrally or peripherally, in the venous and arterial systems to support the cardiac and respiratory systems via a centrifugal pump and an oxygenator, respectively.

A left ventricular assist device (LVAD) differs from the previously discussed temporary mechanical circulatory support options. In addition to functioning as a bridge therapy to further treatments or a heart transplant, this device can be implanted as a durable option for “destination” therapy, thereby serving as long-term treatment for patients who are waiting on a transplant list or who are not candidates for transplantation. LVADs work by driving a continuous flow from the left ventricular cavity into the ascending aorta. This continuous flow replaces a typical heartbeat on auscultation with a continuous “hum” or machine-like noise, often resulting in a loss of peripheral pulses and rendering the standard noninvasive BP cuffs ineffective in obtaining a BP reading. Instead, the MAP can be calculated by attaching a manual BP cuff to a patient’s arm, inflating the pressure to more than 120 mm Hg, and then deflating it while having a Doppler ultrasound probe over the brachial artery and listening for the return of signal. The use of LVADs and other types of assist devices has grown rapidly in recent years, and they appear to be a promising bridge therapy to a heart transplant or recovery.

Hypovolemic Shock

Hypovolemic shock is present when too little blood volume is circulating within the vascular system, resulting in hypotension. Hypovolemia may be present when either internal or external loss of blood or fluids from the intravascular space occurs. Examples of conditions associated with hypovolemia include fever, vomiting and diarrhea, hemorrhage, burns, and excessive third spacing.

Signs and Symptoms

Cardiogenic Shock

- Poor CO
- Low BP (SBP of <90 mm Hg or MAP of 30 mm Hg below baseline)
- Altered mental status
- Cool, pale, diaphoretic skin
- Decreased urine output
- Weak and thready pulse
- Distant or abnormal S_3 or S_4 heart sounds
- Fluid accumulation in the lungs or limbs (for example, JVD or pedal edema)
- Tachypnea

Differential Diagnosis

Cardiogenic Shock

- Aortic dissection
- Acute valve rupture
- Chordae tendineae rupture
- Endocarditis
- Myocardial infarction
- Pulmonary hypertension
- Pulmonary embolus

- Pericardial tamponade
- Tension pneumothorax
- Dilated cardiomyopathy
- Restrictive cardiomyopathy
- Acute myocarditis

Transport Management

Cardiogenic Shock

- Perform simple procedures to relieve the cause, including the following:
    - For cardiac tamponade, perform pericardiocentesis if allowed per protocols.
    - For tension pneumothorax, also perform needle decompression and insert a chest tube.
- Provide high-flow oxygen for hypoxia (SpO_2 <92%).
- Eliminate chest pain.
- Reduce anxiety.
- Initiate hemodynamic and cardiac monitoring.
- Provide antiarrhythmic agents if arrhythmias are present.
- Provide judicious fluid therapy.
- Consider administering vasopressors to physician-ordered parameters.
- Consider administering inotropic agents to physician-ordered parameters.
    - Use these medications with caution. Research shows that high doses of inotropic agents lead to a higher incidence of mortality.
- Consider administering diuretics.
- Consider using afterload-reducing agents.
- Monitor urinary output.

Manifestations of hypovolemic shock are evident early in shock **TABLE 10-6**. The initial stage of hypovolemic shock is characterized by low circulating volume, with minimal signs of hypoperfusion. However, as the body begins to compensate for low venous return, decreased stroke volume, and low CO, patients begin to have tachycardia, hypotension, and signs of poor tissue perfusion, including pallor and delayed capillary refill. Patients become more confused and anxious as oxygen supply to the tissues is compromised and cellular metabolism is altered. Compensatory mechanisms continue to increase the SVR in an attempt to improve hemodynamics. As SVR increases and CO drops, patients exhibit cold and mottled extremities with worsening mental status. Left untreated, the shock will eventually progress to decompensated shock that is refractory to any therapy.

TABLE 10-6 Findings in Hypovolemic Shock

Heart rate	**Increased**
Blood pressure	Within normal limits in the early stages, then decreases as the patient decompensates
Central venous pressure/renal artery pressure	Decreased
Pulmonary capillary wedge pressure	Decreased
Cardiac output/cardiac index	Decreased
Systemic vascular resistance (SVR)/SVR index (SVRI)	Increased
SvO_2	Decreased
Urinary output	Decreased
Jugular vein distention	Flat
Hematocrit (percentage of whole-blood components versus plasma)	Decreased (with hemorrhage) Increased (with dehydration)

Abbreviation: Svo_2, venous oxygen saturation

© Jones & Bartlett Learning.

The hematocrit value decreases with hemorrhage—but not immediately, as all components of blood are lost equally. A decline in the hematocrit value after blood loss will happen after one to several hours if no fluids are infused in the patient (as interstitial and cellular fluid shifts occur). The hematocrit value decreases faster with exogenous fluid challenges due to hemodilution.

Hypovolemic shock caused by hemorrhage from trauma has been classified by the American College of Surgeons Committee on Trauma into four classes, each of which has its own specific characteristics and treatments **TABLE 10-7**.

TABLE 10-7 | **Estimated Fluid and Blood Loss for a 154-lb (70-kg) Male**

	Class I	Class II	Class III	Class IV
Blood loss (mL)	<750	750–1,500	1,500–2,000	>2,000
Blood loss (%)	<15	15–30	30–40	>40
Heart rate (beats/min)	<100	>100	>120	>140
Blood pressure	Within normal limits	Normal	Low	Low
Pulse pressure	Within normal limits	Narrow	Narrow	Very narrow
Capillary refill	Within normal limits	Delayed	Delayed	Absent
Respiratory rate (breaths/min)	14–20	20–30	30–40	>35
Central nervous system/mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
Skin condition	Cool, normal color	Cool, pale	Cold, pale, moist	Cold, cyanotic
Urine output (mL/h)	>30	20–30	5–15	Minimal or none
Fluid replacement	Crystalloids	Crystalloids	Crystalloids and blood	Crystalloids and blood

Modified from American College of Surgeons Committee on Trauma. *Advanced Trauma Life Support for Doctors: ATLS Student Course Manual*. 9th ed. Chicago, IL: American College of Surgeons; 2012.

Description

Treatment of hypovolemic shock revolves around treating the underlying condition, administering oxygen, and initiating volume replacement. Isotonic crystalloids—that is, normal saline and lactated Ringer solution—are the preferred solutions for fluid resuscitation, and are given in 250- to 500-mL increments to maintain BP in the low normal range. Another option is Plasma-Lyte, an isotonic, buffered intravenous crystalloid solution with a physiochemical composition (140 mmol/L sodium, 5 mmol/L potassium, 1.5 mmol/L magnesium, 98 mmol/L chloride) that more closely reflects human plasma than either lactated Ringer solution or normal saline. Many trauma surgeons prefer lactated Ringer solution or Plasma-Lyte over normal saline to avoid the development of hyperchloremic acidosis, which can occur in patients with severe hemorrhagic hypovolemia who are given large volumes of normal saline. Whether use of normal saline in this context impacts patient morbidity or mortality remains controversial, however, and all of these solutions will benefit the patient. Alternative solutions for fluid resuscitation, such as hypertonic saline and colloid solutions, have been explored, but have not shown any mortality benefit. For now, replenishment with isotonic fluid consisting of either normal saline, lactated Ringer solution, or Plasma-Lyte is the standard recommendation.

The American College of Surgeons recommends starting blood products in patients with class III hypovolemic shock and beginning a **massive transfusion protocol** for those with class IV hemorrhage. If massive transfusion (more than 10 units of RBCs in 24 hours) is to be initiated, current evidence supports maintaining a 1:1:1 ratio of packed red blood cells (PRBCs), fresh frozen plasma, and platelets. Of course, any classification system has inherent limitations, so providers must take into account all available clinical information with making decisions about blood product infusion. Some of the confounding factors in this system include patient age (older patients typically have less physiologic reserves), prior use of medications (eg, beta blockers may mask tachycardia), and the time lapse from injury to initiation of treatment.

The next section discusses distributive shock. **FIGURE 10-8** shows a conceptual illustration of distributive versus hypovolemic shock.

Description

Signs and Symptoms

Hypovolemic Shock

- Tachycardia
- Hypotension
- Signs of poor tissue perfusion (pallor and delayed capillary refill)
- Confusion
- Anxiety
- Cold, mottled, and pulseless extremities
- Decreased mentation

Differential Diagnosis

Hypovolemic Shock

- Fever
- Dehydration
- Hemorrhage
- Burns
- Excessive third spacing

Transport Management

Hypovolemic Shock

- Treat the underlying condition.
- Administer oxygen.
- Maintain the airway and ensure optimal ventilation.
- Initiate volume replacement (normal saline, lactated Ringer solution, or Plasma-Lyte in 250- to 500-mL increments).
- Administer blood products early if hemorrhage is suspected.

Distributive Shock

Distributive shock is a catch-all term used to describe several types of shock involving loss of vasomotor tone or increased vascular permeability; it includes neurogenic, anaphylactic, and septic shock. The human body has approximately 60,000 miles of blood vessels and 5 to 6 L of blood. Maintaining homeostasis requires constant regulation of vessel diameter and flow through capillary beds. When a disruption occurs in the vascular compartment causing widespread vasodilation and relative hypovolemia, distributive shock is present.

Neurogenic Shock

Neurogenic shock is a form of distributive shock caused by loss of sympathetic tone, which results in substantial peripheral vasodilation, bradycardia, and altered thermoregulation. Normally, the sympathetic nervous system maintains a baseline level of vasoconstriction within blood vessels, or “tone.” Trauma to the brain or spinal cord at the cervical or high thoracic level can disrupt this tone, as the bulk of the sympathetic ganglia reside in the sympathetic trunk running parallel to the thoracic vertebrae.

Neurogenic shock is not limited to trauma, however. Many pharmacologic agents, such as general and spinal anesthetics, opiates, and barbiturates; insulin shock; various toxins; and extreme parasympathetic stimulation may trigger the onset of neurogenic shock. It is important to differentiate neurogenic shock from spinal shock, which is a different entity. Spinal shock is a temporary loss of spinal function following trauma, which recovers after a variable amount of time; it is thought to represent a concussion injury to components of the spinal cord.

Neurogenic shock is characterized by relative hypovolemia as the result of vasodilation. In essence, the amount of fluid in the vasculature remains constant, but the container size is increased. As a result, there are significant drops in the SVR and BP. The signs and symptoms associated with neurogenic shock, however, can be very different from those found in hypovolemic shock **TABLE 10-8**. One profound difference is the presence of bradycardia in the face of hypotension; it is caused by the combination of loss of sympathetic tone and baroreceptor response. Nevertheless, neurogenic shock is a diagnosis of exclusion in the emergent setting, and all hypotensive trauma patients should initially be assumed to be bleeding.

TABLE 10-8 Hemodynamic Findings in Distributive Shock Compared With Hypovolemic Shock

	Hemodynamic Findings in Distributive Shock		
	Neurogenic Shock	**Anaphylactic Shock**	**Comparison With Hypovolemic Shock**
Heart rate	Decreased	Increased	Increased
Blood pressure	Decreased	Decreased	Within normal limits in the initial stage, then decreases as the patient decompensates
Pulse pressure	Normal	Narrow	Narrow
Central venous pressure/renal artery pressure	Decreased	Decreased	Decreased
Pulmonary capillary wedge pressure	Decreased	Decreased	Decreased
Cardiac output/cardiac index	Decreased	Decreased	Decreased
Systemic vascular resistance (SVR)/SVR index (SVRI)	Decreased	Decreased	Increased
Svo_2	Decreased	Decreased	Decreased
Urinary output	Decreased	Decreased	Decreased
Skin	Normal color, warm, dry	Flushed, warm to hot, pruritus, hives	Cool, pale, moist

Abbreviation: Svo_2, venous oxygen saturation

© Jones & Bartlett Learning.

Description

Treatment for neurogenic shock focuses on immediate correction of hypotension. The MAP should be maintained between 85 and 90 mm Hg for the first 7 days following injury if the cause of the neurogenic shock is incomplete spinal cord injury with potential for some recovery of function. Aggressive fluid therapy with isotonic crystalloids should be started, and a transition should be made to inotropes and vasopressors if needed.

Dopamine, norepinephrine (Levophed), and phenylephrine (Neo-Synephrine) are the vasopressor agents that are most commonly used in neurogenic shock. Norepinephrine and phenylephrine raise the BP by directly stimulating alpha adrenergic receptors in the smooth muscle of blood vessels, causing vasoconstriction. Dopamine, when given in moderate doses, stimulates beta-1 adrenergic receptors, increasing the force of contraction and, therefore, increasing CO. Higher dopamine doses stimulate alpha adrenergic receptors, mimicking the effects of norepinephrine.

Controlling the heart rate is also important in patients with neurogenic shock. Loss of sympathetic tone may result in profound bradycardia. Methods for increasing the heart rate include pacemaker therapy and administration of atropine. Atropine works by blocking acetylcholine (muscarinic) receptors, creating a temporary increase in heart rate.

Transport considerations for patients with neurogenic shock center on ensuring a patent airway, adequate ventilation, and oxygenation: Depending on the level of involvement, the patient may be unable to breathe without assistance or may have impaired ventilatory capabilities. Care also includes cardiac monitoring, administration of IV fluids and vasopressor medications as ordered, and maintenance of spinal motion restriction. The patient also requires placement of an indwelling urinary catheter.

Signs and Symptoms

Neurogenic Shock

- Relative hypovolemia as the result of vasodilation
- Bradycardia
- Significant drop in BP
- Normal pulse pressure
- Decreased CVP/RAP
- Decreased PCWP
- Decreased CO/cardiac index
- Significant drop in the SVR/SVRI
- Decreased SvO_2
- Decreased urinary output
- Normal color, warm, dry skin

Differential Diagnosis

Neurogenic Shock

- Spinal shock
- Hypovolemic shock
- Trauma to the brain or spinal cord
- Pharmacologic agents such as general and spinal anesthetics, opiates, and barbiturates
- Insulin shock
- Toxins
- Extreme parasympathetic stimulation

Transport Management

Neurogenic Shock

- Correct hypotension immediately.
- Maintain a MAP of 85 to 90 mm Hg for the first 7 days following injury.
- Consider administering vasopressors (dopamine, norepinephrine, phenylephrine). Administer inotropic agents and vasopressors if traditional fluid resuscitation is insufficient to maintain the MAP.
- Initiate fluid therapy with isotonic crystalloids.

- Maintain the heart rate (increase heart rate via pacemaker therapy or atropine administration).

Anaphylactic Shock

Anaphylactic shock is a severe, life-threatening allergic reaction producing systemic vasodilation in response to histamine release. The list of possible antigens in humans is extensive, including diagnostic agents, foods, bites, stings, chemical agents, and several classes of medications, such as antibiotics, immunologic agents, anesthetics, anti-inflammatory agents, narcotics, and hormones.

Two types of anaphylactic shock are distinguished: true and anaphylactoid. **True anaphylaxis** occurs when the allergen binds to immunoglobulin E (IgE) on the cell membranes of basophils and mast cells, stimulating the release of histamine from the cell. In contrast, an **anaphylactoid reaction** is a non–IgE-mediated response that causes the rupture of mast cells and basophils, which then release histamine and other defense mediators. Non–IgE-mediated responses can result in the same reactions as true shock without prior exposure to the antigen. Either reaction can be massive and can happen in minutes after exposure. Alternatively, the response may be delayed for hours or even days—a condition called a delayed hypersensitivity response.

Histamine, a cell mediator, is responsible for the widespread vasodilation and resultant relative hypovolemia, increased capillary membrane permeability, and smooth muscle constriction associated with anaphylactic shock. Increased capillary membrane permeability leads to oropharyngeal and laryngeal edema, and smooth muscle constriction contributes to bronchoconstriction; together, these effects can produce rapid life-threatening airway compromise.

Rapid treatment is necessary to limit the effects of anaphylaxis. Notably, standard oxygen therapy may not be enough to ensure adequate oxygenation. Some patients may need to be intubated, and some may require an emergency cricothyrotomy or tracheostomy to maintain an adequate airway.

Treatment focuses on removing the allergen that caused the severe reaction, including discontinuing the medication causing the reaction or simply removing a stinger after a bee sting. Drug therapy for anaphylaxis focuses on supporting the cardiovascular system and preventing further mediator release. Epinephrine is the drug of choice for anaphylactic shock because it acts as a physiologic antagonist to the **leukotrienes** and other cell mediators released in anaphylaxis. Epinephrine increases BP through stimulation of alpha-1 receptors, which leads to vasoconstriction. It also has bronchodilation effects owing to its activation of the beta-2 receptors. The initial dose of epinephrine is 0.3 to 0.5 mg (0.3 to 0.5 mL) of a 1 mg in 1 mL solution intramuscularly, given every 5 to 10 minutes as needed. If hypotension persists, initiating an epinephrine drip may be necessary. Epinephrine may not work effectively in patients taking beta blockers; in these cases, glucagon may be given IV at 5 to 15 µg/min. Glucagon mitigates anaphylaxis by increasing the heart rate and contractility via non–beta-receptor-mediated pathways.

Owing to the increased “container size” associated with anaphylactic shock, fluid therapy needs to be started early to maintain a MAP of greater than 65 mm Hg (or a SBP of greater than 90 mm Hg). Normal saline should be administered to sustain adequate preload volumes. Further vasopressor agents may be started if crystalloid therapy and epinephrine prove inadequate in maintaining CO.

Some other pharmacologic agents are also commonly given as treatments for anaphylactic shock; however, clinical data demonstrating their benefits are lacking, so they should be considered second-line agents, with epinephrine being the treatment of choice. Antihistamines such as diphenhydramine (Benadryl) are used to block histamine release from the H_1 receptors on smooth muscles, gland cells, and some nerve endings. The dose of diphenhydramine is 1 to 2 mg/kg IV, repeated every 4 to 8 hours, not to exceed 50 mg. Ranitidine (Zantac), an H_2 blocker, is sometimes used to treat severe allergic reactions because of its effects on the heart, along with its ability to decrease stimulation of acid secretion within the stomach. Bronchodilators are administered to relieve the shortness of breath associated with anaphylaxis. Albuterol is a beta-2 selective bronchodilator that works as a physiologic antagonist toward leukotrienes and other inflammatory mediators, thereby relaxing smooth muscle. Corticosteroids are often given to stabilize the capillary membrane, offsetting the inflammatory response in an effort to prevent a delayed reaction; however, this effect has never been proven.

While anaphylactic reactions following a biphasic course were previously believed to be highly common, newer studies have found that only 4% to 4.5% of such reactions are actually biphasic. The timing of the biphasic reaction has been shown to occur across a relatively wide range, between 1 and 72 hours after the initial reaction. While corticosteroids are often given to patients with anaphylaxis, there is no consensus on whether their administration has a role in preventing the biphasic reaction.

Signs and Symptoms

Anaphylactic Shock

- Increased heart rate
- Decreased BP
- Narrow pulse pressure
- Decreased CVP/RAP
- Decreased PCWP
- Decreased CO/cardiac index
- Decreased SVR/SVRI
- Decreased SvO_2
- Decreased urinary output
- Flushed skin that is warm to hot, with pruritus and hives
- Bronchoconstriction
- Laryngeal edema
- Angioedema
- Airway compromise

Differential Diagnosis

Anaphylactic Shock

- Allergic reaction
- Asthma attack
- Myocardial infection
- Choking
- Anxiety
- Neurogenic shock
- Septic shock
- Thyroid storm

Transport Management

Anaphylactic Shock

- Administer oxygen.
- Maintain an adequate airway.
- Remove the allergen that caused the reaction.
- Administer epinephrine.
- If the patient is taking beta blockers, administer glucagon if epinephrine is not effective.
- Initiate fluid therapy early with normal saline to maintain a MAP of greater than 65 mm Hg or a SBP of greater than 90 mm Hg.
- Administer vasopressor agents if crystalloid therapy is inadequate for maintaining CO.
- Consider other pharmacologic treatments: Antihistamines, ranitidine (Zantac, an H_2 blocker), bronchodilators (eg, albuterol, a beta-2 selective bronchodilator), and corticosteroids are other options.
- Perform cardiac monitoring.
- Observe for a possible second-phase reaction.

Other Forms of Distributive Shock

Additional forms of distributive shock include endocrine causes such as addisonian crisis from mineralocorticoid deficiency, myxedema crisis from hypothyroidism, and thyrotoxicosis such as in thyroid storm. These conditions are covered in Chapter 18, *Endocrine*

Emergencies. The most common cause of distributive shock is sepsis, which is a progressive disease that typically results from an infection.

Sepsis

Sepsis is life-threatening organ dysfunction caused by a dysregulated host response to infection. It is part of a spectrum of disease culminating in septic shock, whose distinct classifications and treatment approaches have been outlined by a joint task force sponsored by the European Society of Intensive Care Medicine and the Society of Critical Care Medicine. Initially released in 1991, sepsis definitions and guidelines have been updated several times, most recently in 2016. This section describes the continuum of the disease and then provides a detailed discussion of the pathophysiology, assessment, and management of sepsis.

Types of Sepsis

Systemic inflammatory response syndrome (SIRS) is a widespread inflammatory process with both infectious and noninfectious causes. Acute respiratory distress syndrome (ARDS), burns, pancreatitis, intestinal endotoxins, and major trauma are the most commonly identified triggers for the development of SIRS when no microorganism is involved.

Four variables—temperature, heart rate, respiratory rate, and white blood cell (WBC) count—are used to identify SIRS **TABLE 10-9**. In the past, sepsis was defined as the presence of two or more markers of sepsis in the setting of a suspected infection. However, the 2016 revision acknowledged that SIRS criteria can be met in noninfected people or not met in infected people, and the presence of these markers is often simply reflective of the body's normal response to infection.

TABLE 10-9 Systemic Inflammatory Response Syndrome Criteria[a]

Criteria	Marker
Temperature	>38°C (100.4°F) <36°C (96.8°F)
Respiratory rate	>20 breaths/min PaO_2 <32 mm Hg
Pulse rate	>90 beats/min
White blood cell (WBC) count	>12,000/µL <4,000/µL >10% immature band forms

[a] Criteria from the American College of Chest Physicians, 1992.

Data from Levy MM, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. *Intens Care Med*. 2003;29(4):530-538.

The current diagnosis of sepsis includes the presence of organ dysfunction in the setting of infection. Organ dysfunction is defined by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score of 2 points or more, which is associated with an in-hospital mortality greater than 10% **TABLE 10-10**. Recognizing that the SOFA score variables are rarely obtained outside of the intensive care unit (ICU), the 2016 guidelines introduced the quick SOFA (qSOFA) score to rapidly identify a patient with sepsis at the bedside. In this setting, sepsis is diagnosed if two of the following three signs are present: respiratory rate of 22 breaths/min or greater, altered mentation, or SBP of 100 mm Hg or less. Subsequent studies have challenged the qSOFA's utility as a screening tool, however, demonstrating that this score has reduced sensitivity in detecting sepsis in comparison to the SIRS criteria, with the highest sensitivity found with the use of the National Early Warning Score (NEWS) **TABLE 10-11**. The NEWS is a scoring system derived from six physiologic parameters: respiratory rate, oxygen saturation, SBP, pulse rate, level of consciousness or new confusion, and temperature.

TABLE 10-10 | Sequential [Sepsis-Related] Organ Failure Assessment (SOFA) Score

	Score				
System	**0**	**1**	**2**	**3**	**4**
Respiration Pao_2/Fio_2, mm Hg (kPa)	≥400 (53.3)	≤400 (53.3)	<300 (40)	>200 (26.7) with respiratory support	<100 (13.3) with respiratory support
Coagulation Platelets $\times 10^3/\mu L$	≥150	<150	<100	<50	<20
Liver Bilirubin, mg/dL (μmol/L)	<1.2 (20)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	>12.0 (204)
Cardiovascular	MAP ≥70 mm Hg	MAP <70 mm Hg	Dopamine <5 or dobutamine (any dose)	Dopamine 5.1–15 or epinephrine ≤0.1 or norepinephrine ≤0.1[a]	Dopamine > 15 or epinephrine >0.1 or norepinephrine >0.1[a]
Central nervous system Glasgow Coma Scale score[b]	15	13–14	10–12	6–9	<6
Renal Creatinine, mg/dL (μmol/L) Urine output, mL/d	<1.2 (110)	1.2–1.9 (110–170)	2.0–3.4 (171–299)	3.5–4.9 (300–440) <500	>5.0 (440) <200

Abbreviations: Fio_2, fraction of inspired oxygen; MAP, mean arterial pressure; Pao_2, partial pressure of oxygen

[a] Catecholamine doses are given as µg/kg/min for at least 1 hour.

[b] Glasgow Coma Scale scores range from 3 to 15; higher scores indicate better neurologic function.

Description

Septic shock is defined as fluid-unresponsive hypotension requiring a vasopressor to maintain a MAP of 65 mm Hg or greater and a serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia. These patients are critically ill and have a mortality rate exceeding 40%.

Epidemiology

Determining the exact number of sepsis cases per year is difficult, as definitions have varied over the years. Nevertheless, all reports agree on one point: The incidence of sepsis-related infections is increasing. An estimated 1.7 million cases of sepsis occur each year in the United States, according to the Centers for Disease Control and Prevention. As this trend continues, CCTPs will likely encounter more cases of sepsis.

Although sepsis affects all populations and age groups, the majority of cases occur in people older than 65 years. This condition is most prevalent in nonwhite males between the ages of 57 and 70 years. A number of coexisting medical conditions have been closely associated with sepsis, including diabetes, hypertension, congestive heart failure, chronic obstructive pulmonary disease (COPD), cirrhosis, human immunodeficiency virus (HIV) infection, cancer, and pregnancy.

The mortality rate for sepsis is roughly 20%, but it increases significantly as the severity of sepsis increases. Septic shock has a reported mortality rate of more than 40% and is a leading cause of death in ICUs.

Despite the development of sophisticated technologies and advancements in medical therapies, sepsis remains a challenge to the medical community. Mortality rates have been decreasing, though, likely due to aggressive management of this condition. Health care professionals must be aware of the many risk factors associated with sepsis to keep mortality rates low. The conditions that place people at greatest risk for developing sepsis are listed in **TABLE 10-12**. Prolonged hospitalization is also a risk factor for sepsis for any person. The longer a patient remains in the ICU (especially) or the hospital, the greater the risk for sepsis becomes. Invasive procedures, comorbidities, and use of immunosuppressants increase this risk even further.

TABLE 10-12 Risk Factors for Sepsis

Patients with a compromised immune system	Extremes of age: infants and older patients Patients with cancer Transplant recipients Patients with HIV/AIDS Patients with immunosuppressed systems Patients with alcoholism Pregnancy
Chronic and coexisting diseases	Diabetes Chronic obstructive pulmonary disease Cirrhosis Heart failure Renal failure
Infections and exposures	Meningitis Community-acquired pneumonia Cellulitis Urinary tract infections Organisms with antimicrobial resistance
Patients who are critically ill	Increased use of invasive catheters and prosthetic devices Postoperative abdominal surgery

Pathophysiology

To understand the pathophysiology of sepsis, it is necessary to review some basic anatomy and physiology of the immune system. The immune response is typically classified into innate and adaptive arms.

The **innate immune system** is the first line of defense, including what is commonly referred to as the inflammatory response. It represents a generalized, fast-acting response to antigen recognition and is accomplished through the actions of neutrophils, macrophages, natural killer (NK) cells, and complement.

The **adaptive immune system** employs lymphocytes, antibodies, and memory cells; it offers a more precise response to specific antigens, but requires time to mobilize its defense if the pathogen is unknown. This aspect of the immune response is called "adaptive" because it creates a targeted response to an invading pathogen based on its exposed antigenic signatures. Memory cells remember specific antigens with which they have previously come in contact, so when an antigen tries to invade again, the adaptive immune system can mount a faster response to it.

Taken together, the innate and adaptive immune systems provide a robust immune response that protects the human body from disease. However, prolonged and extensive activation of this system is responsible for many of the problems that arise in patients with sepsis.

Pathogens

The microorganisms that activate the immune system are referred to as **pathogens**. Sepsis can occur as a result of infection at any body site, including the lungs, abdomen, skin, soft tissue, urinary tract, bloodstream, and central nervous system. Bacteria are the pathogens most commonly associated with the development of sepsis, although fungi, viruses, and parasites can cause this condition as well. Each pathogen has identifiers on it called **antigens** that can elicit an immune response within the body. A pathogen is recognized in the body when its antigen binds to special cells within the immune system known as antigen-presenting cells (APC); they include B cells, dendritic cells, and macrophages. An APC will engulf, digest, and finally "present" the antigen on its own surface, where T cells can encounter and develop a targeted immune response to the antigen.

This powerful response system must be prevented from attacking the normal body structures and, therefore, must be capable of classifying antigens as "self" or "nonself." Problems with this system can lead to various autoimmune conditions, with its overreaction being responsible for allergies and anaphylaxis.

In addition to the infectious agents just described, the human body is colonized by symbiotic bacterial flora, which assist in digestion and several other functions. The immune system keeps the flora in balance; disruptions of this balance can lead to overgrowth and undergrowth, both of which have negative consequences such as gastrointestinal (GI) upset and yeast infections.

Infectious agents may produce endotoxins and exotoxins that alter the living cells and ultimately destroy them. This action is the primary way that bacteria affect the immune system stimulus response and cause cell death. **Endotoxins** are lipopolysaccharides that coat the outer surface of gram-negative bacteria and elicit strong immune responses in humans while providing a layer of protection for the bacterium. The bacterial cell can also secrete endotoxins and release them en masse when cell death occurs. **Exotoxins** are proteins secreted by some bacteria that can directly cause significant damage to host cells while also triggering an immune response.

Gram-negative and gram-positive bacteria are the two types of organisms most commonly responsible for sepsis. A large study of infection among ICU patients showed that positive isolates consisted of 62% gram negative, 47% gram positive, and 17% fungal organisms (with some patients growing multiple organisms). Approximately one-third of patients with sepsis will have negative cultures.

Infection

Infection is the invasion of normally sterile tissue by a pathogen, and **bacteremia** is the presence of viable bacteria in the bloodstream. The body's first lines of defense against pathogens are its natural barriers—for example, the skin, mucous membranes, and GI tract. Typically, when an infection develops, it is because a pathogen was able to penetrate these natural barriers. Normally, these barriers mitigate infection by inhibiting the entry of nonself pathogens into the body and by keeping a careful watch over self antigens.

Isolated infections are confined to a small area, with the invading organisms being destroyed by immune cells within that location. Components of the innate system recognize foreign antigens through the pattern recognition receptors that activate them and similar cells in the area, initiating the inflammatory process. Characteristic changes in the microcirculation (arterioles, capillaries, and venules) occur near the site of injury secondary to inflammation:

- Blood vessels dilate, increasing blood flow to the area.
- Vascular permeability increases, facilitating an influx of fluid and plasma cells (exudate) into the area.
- Certain WBCs (**neutrophils**) adhere to the inner walls of vessels and then migrate through the vessel walls to the site of injury. While destroying the pathogen, these phagocytic cells cause the release of lytic enzymes, which are potent enough to damage healthy cells near the area of injury.

Numerous chemical mediators, called **cytokines**, are released from injured cells (the endothelium of the microcirculation) in response to tissue insult. Some of these cytokines include interleukins, **tumor necrosis factor (TNF)**, histamine, prostaglandins, and bradykinins. These chemicals cause vasodilation, smooth muscle contraction, increased tissue permeability, and pain **TABLE 10-13**. Inflammation is an important process because it helps contain the injury, allowing phagocytes and the complement system to clean up the area. Cytokine communicators also send out distress signals informing the body of the injury. These signals attract neutrophils to the site of infection. There, these WBCs move through the endothelial wall to the site of injury, where they begin their phagocytic role.

TABLE 10-13 The Body's Response to Inflammatory Chemical Mediators

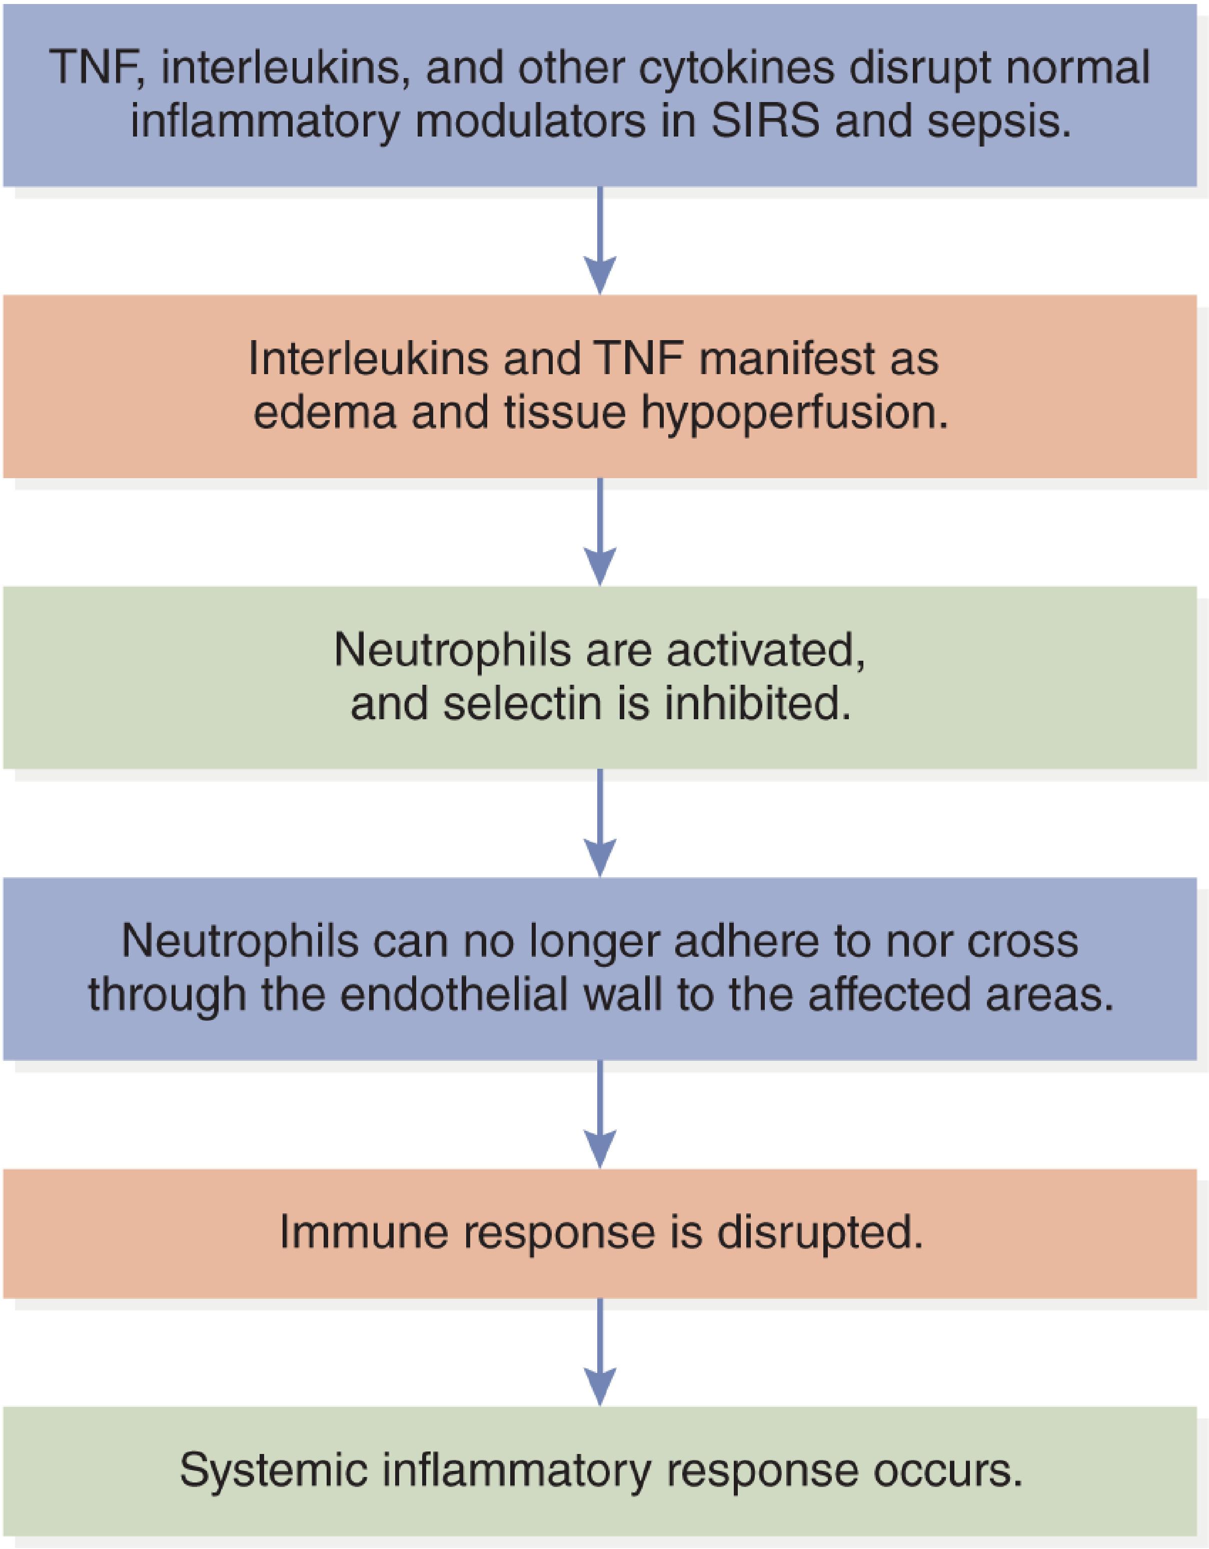
Inflammatory Chemical Mediator Action	Body Response
Vasodilation	Redness and heat production
Smooth muscle contraction	Difficulty breathing
Increased capillary permeability	Edema and swelling
Stimulation of pain receptors	Pain

© Jones & Bartlett Learning.

Vasodilation and increased capillary permeability also activate the clotting pathways. Tissue factor is released, leading to the production of thrombin, a pro-inflammatory substance that initiates fibrin clot formation in the microvasculature. Fibrin is the final product of the coagulation cascade and is responsible for preventing the spread of infection by building a fibrin clot barrier wall.

Systemic Infection

Systemic infections activate a widespread inflammatory response throughout the body, completely overwhelming and theoretically confusing the immune system **FIGURE 10-9**. SIRS, sepsis, and septic shock are part of a dynamic hypermetabolic, hyperinflammatory response to an infection that leads to a loss of control of the immune response. Left unchecked, the vasodilation and permeability that are initially helpful in fighting an infection may progress to distributive shock.



TNF, interleukins, and other cytokines disrupt normal inflammatory modulators in SIRS and sepsis.
Interleukins and TNF manifest as edema and tissue hypoperfusion.
Neutrophils are activated, and selectin is inhibited.
Neutrophils can no longer adhere to nor cross through the endothelial wall to the affected areas.
Immune response is disrupted.
Systemic inflammatory response occurs.

FIGURE 10-9 Summary of the process leading to a systemic inflammatory response. *Abbreviations*: SIRS, systemic inflammatory response syndrome; TNF, tumor necrosis factor

© Jones & Bartlett Learning.

Description

Sepsis disrupts normal inflammatory modulators. This is an area of intense research, and many mediators that participate in this process have already been identified. Interleukins, TNF, and other cytokines whose release leads to fever, edema, and tissue hypoperfusion are produced rapidly after insult or injury, and they continue to proliferate as the inflammatory process continues. These chemical mediators lead to activation of neutrophils while simultaneously inhibiting selectin, the protein that adheres neutrophils to the endothelium, allowing these WBCs to move into tissue to fight infection.

The inflammatory process, in association with the complement cascade, damages the endothelium, causing small clots to form in the capillaries. These microemboli can lead to DIC, as described earlier (see Figure 10-6). The progression of DIC is difficult to control and has been the focus of significant research looking for therapeutic modalities.

In summary, microvascular disruption and injury are responsible for hypoperfusion and the shunting of oxygen, resulting in decreased oxygen delivery to the tissues. The profound imbalance between oxygen delivery and consumption causes hypoxia within the cell and tissue. This complex cascade of events is the primary cause of sepsis and its progression to organ dysfunction and failure.

Assessment

Distributive shock caused by sepsis differs from other shock states in that it has two phases. Phase 1 is the **hyperdynamic state**, commonly referred to as warm shock. Phase 2 is the **hypodynamic state**, commonly referred to as cold shock. A high-CO state, which may last for hours or days, characterizes the hyperdynamic (warm) phase. This phase may progress to hypodynamic (cold) shock when the patient’s condition deteriorates rapidly and a sudden drop in CO occurs. The prognosis is much better for patients in hyperdynamic shock than for those in hypodynamic shock.

To recognize sepsis while it is still in its early stages, the provider must maintain a high index of suspicion for this disorder. A thorough patient history correlated with the patient presentation can ensure early identification and allow for rapid interventions to break the progression of the sepsis process. Do not withhold treatment while searching for the source: In many cases, an infectious cause is never identified. Specimen cultures are obtained from the blood, urine, sputum, and any drainage site to assist in identifying the causative organism. If the pathogen is bacterial, the WBC count is typically elevated and testing will identify immature neutrophils or bands. Once the pathogen is identified, more direct antimicrobial therapy can be initiated.

Many health care providers associate infection with fever. Although fever is certainly one clinical sign of infection, it may not be present in geriatric, newborn, and infant populations; patients with chronic renal failure; and patients receiving steroids or other anti-inflammatory drugs. Hypothermia is present in about 10% of patients with sepsis and is associated with a poor prognosis.

The cardiovascular and respiratory organs are the hardest hit in sepsis and septic shock. The cardiovascular changes seen in sepsis result from its inflammatory process. The massive vasodilation significantly lowers the SVR, so the heart increases CO. Cardiac output is extremely elevated in sepsis states. To produce this high-output state, the heart rate becomes tachycardic, and the stroke volume increases. Initially, normal to low-normal BP is maintained. Skin color and mucous membranes appear normal because of the vasodilation with associated high CO. However, the skin typically feels warm to the touch as the result of fever.

Once hypotension ensues, the patient is considered to be in septic shock. Because septic shock is refractory to fluid challenges, vasoactive agents must be initiated. This pathway is also the means by which progression from hyperdynamic shock to hypodynamic shock occurs. Hypodynamic shock gets its name from the low-CO state observed in these patients. Patients are unable to compensate for the relative hypovolemia in this phase, and their condition deteriorates rapidly, as evidenced by low BP, decreased pulse pressure, and low CO. Skin color and temperature change as blood is shunted to critical organs. The patient becomes cold and clammy, with pallor or cyanosis. In patients with DIC, petechiae may appear, and blood may ooze from mucous membranes, including the nose and mouth, and from any place where invasive procedures were necessary, including IV sites, indwelling urinary catheters, and chest tubes. Diagnostic patterns at this stage can include low hemoglobin and hematocrit reflecting anemia and low platelets and fibrinogen if DIC is occurring. A rising lactate level is perhaps the most ominous sign and can be used as a marker of disease severity.

The respiratory system also manifests changes. In hyperdynamic septic shock, the respiratory rate increases along with the depth of respiration, leading to respiratory alkalosis. As shock progresses, pulmonary edema and ARDS can develop. While pulmonary edema generally results from aggressive fluid resuscitation as well as cardiac pump insufficiency, ARDS—a complication of SIRS—evolves through an intricate process related to unchecked inflammation and alveolar membrane leakiness.

Mechanical ventilatory support is generally needed in patients with sepsis states associated with ARDS and should follow the ARDSNET protocol. A lung-protective strategy should be initiated, with low tidal volumes at 6 mL/kg, while keeping end-inspiratory plateau pressures lower than 30 cm H_2O. End-inspiratory plateau pressures should also be monitored closely. Mild **hypercapnia** can be permitted in patients with sepsis plus ARDS to allow for low tidal volumes and pressures. Ideally, the FIO_2 should be titrated to less than 60%. Therapy goals should be an SpO_2 of greater than 92%. (Treatment of ARDS is discussed in Chapter 6, *Respiratory Emergencies and Airway Management*.)

ARDS is described using the Berlin definition:

- Acute onset of respiratory failure within 1 week of a known clinical insult
- Diffuse bilateral infiltrates evident on chest radiography, not fully explained by effusion, lobar/lung collapse, or nodules
- Respiratory failure not fully explained by cardiac failure or fluid overload
- Hypoxemia, defined on a minimum positive end-expiratory pressure (PEEP) of 5 cm H_2O or greater, as $\text{Pa}\textsc{o}_2/\text{F}\textsc{io}_2$ of 300 or less for mild ARDS, $\text{Pa}\textsc{o}_2/\text{F}\textsc{io}_2$ of 200 or less for moderate ARDS, and $\text{Pa}\textsc{o}_2/\text{F}\textsc{io}_2$ of 100 or less for severe ARDS

TABLE 10-14 lists lab abnormalities seen in patients with sepsis.

TABLE 10-14 Lab Abnormalities in Sepsis

Specimen cultures obtained from the blood, urine, sputum, and any drainage site to identify the causative organism
Elevated WBC count (if the pathogen is bacterial) associated with immature neutrophils or bands
Low hemoglobin level and hematocrit value
Low fibrinogen levels
Thrombocytopenia
Prolonged prothrombin time
Elevated D-dimer level
Elevated lactate level (>4 mmol/L)

Management

Early recognition and early management of sepsis are vital for a positive patient outcome. The primary goal of sepsis treatment is to maintain organ perfusion while enhancing tissue oxygenation. Achieving this goal requires balancing preload, afterload, and contractility to achieve an optimal level of homeostasis. The most current recommendations from the Surviving Sepsis Campaign are outlined in the Hour-1 bundle:

- Measure lactate level. (Remeasure lactate level if the initial level is elevated to >2 mmol/L.)
- Obtain blood cultures before administering antibiotics.

- Administer broad-spectrum antibiotics.
- Begin rapid administration of 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L.
- Apply vasopressors if the patient remains hypotensive during or after fluid resuscitation, to maintain a MAP of 65 mm Hg or higher.

While all of the bundle elements may not be completed within the first hour, it is ideal for all of them to have begun within this time frame.

Fluid Resuscitation

The determinants of CO are preload, afterload, heart rate, and contractility. Initial resuscitation includes volume expansion to optimize preload. Isotonic crystalloids should be given in an initial fluid challenge as a 30 mL/kg (2,000 to 3,000 mL of fluid) bolus. The goal is to achieve a MAP of greater than 65 mm Hg. If the patient shows signs of fluid overload, intubation or administration of diuretics may be necessary. There is no evidence that the use of colloids produces any significant improvement in outcomes when compared with the use of crystalloids. Consider the infusion of PRBCs if the hemoglobin level drops below 7.0 g/dL.

Lactate trending can be a useful guide when assessing treatment response. Point-of-care lactate meters have become increasingly available either as stand-alone devices or as part of a blood gas panel. Recent evidence has shown that usual, aggressive care for patients with sepsis is equivalent to the protocolized goal-directed therapy proposed in 2001. Central venous catheters are no longer routinely recommended unless they are specifically indicated by the need to administer vasoactive medications or the need for additional access. Research has shown that using central venous oxygenation to guide treatment response is no better than lactate trending, and the latter approach is far less invasive. Use of CVP as a treatment parameter has become increasingly controversial and is no longer recommended as the sole value to guide fluid resuscitation. However, arterial lines are still recommended whenever vasoactive medications will be infused.

Vasopressor and Inotropic Support

Fluid therapy is not always sufficient to maintain BP in patients with sepsis. If the 30 mL/kg fluid challenge proves inadequate to maintain BP, vasopressors should be started. Detailed profiles of the vasoactive agents used for this purpose—norepinephrine, dopamine, phenylephrine, vasopressin, epinephrine, dobutamine, nitroglycerin, and angiotensin II—are presented in Chapter 8, *Critical Care Pharmacology*.

Norepinephrine is the vasopressor of choice in hypotensive patients with sepsis. This sympathomimetic agent acts directly on alpha adrenergic receptors in the smooth muscle of blood vessels to rapidly increase BP, while also stimulating beta adrenergic receptors that work to increase CO by enhancing contractility.

Norepinephrine produces a minimal increase in the heart rate as compared with dopamine; hence, it has emerged as the first-line treatment for sepsis. Norepinephrine is typically started at 2 μg/min and titrated to a desired MAP of greater than 65 mm Hg. In some cases, the initial dose may be as high as 10 μg/min until the BP stabilizes, and max doses vary locally, often ranging from 20 to 40 μg/min.

Dopamine is no longer recommended for routine use in septic shock, as it has been shown to increase arrhythmias and mortality as compared to norepinephrine. Further, there is no evidence that use of low-dose dopamine stimulates renal output, so it is not used for this purpose.

Vasopressin or epinephrine may be administered as a secondary pressor if the patient's hypotension proves refractory to norepinephrine. Vasopressin works as a vasoconstrictor but has no inotropic or chronotropic effects. Therefore, CO may decrease when it is administered, resulting in a decreased blood supply to the spleen. Vasopressin is used in lower doses when complementing another pressor, beginning at 0.01 unit/min and being titrated up to 0.04 unit/min.

Epinephrine is a nonselective adrenergic activator, meaning it stimulates alpha-1, beta-1, and beta-2 receptors. It increases MAP by increasing the cardiac index, stroke volume, SVR, and heart rate.

Other vasopressors such as phenylephrine and dopamine may also be used in sepsis, but only in carefully selected populations or as last-resort efforts. Phenylephrine has pure alpha adrenergic properties that increase BP significantly without affecting the heart rate. However, the vasoconstriction it produces within the visceral tissue and mesentery may increase lactic acidosis, exacerbating the hypoxic state associated with sepsis. Dopamine can cause increased arrhythmias but may be helpful in patients with bradycardia.

Dobutamine is an inotropic agent that has proved very beneficial in treating cardiac depression associated with sepsis. This inotropic agent increases cardiac contractility through its selective beta-1 adrenergic properties. Dobutamine is especially useful when given in conjunction with norepinephrine. An IV infusion typically starts at 2 μg/kg/min and may be titrated to as high as 20 μg/kg/min. When titrating dobutamine, it is important to monitor MAP, Svo_2, and the CO or cardiac index to establish whether the treatment is adequate.

Infection Control

Cultures of all potential infection sources (eg, blood, urine, sputum, wounds) should be obtained as soon as possible and ideally before any antibiotic administration; however, inability to obtain cultures should not delay antibiotic treatment. In addition to cultures, viral test panels should be obtained. The goal of initial therapy with broad-spectrum antibiotics is to cover all likely possible infectious agents. When cultures identify specific microorganisms, antibiotic therapy can be narrowed to be more specific to the pathogen. Administer antibiotics within the first hour of suspecting sepsis to minimize mortality, because every hour of delay in antibiotic administration increases mortality.

Infection control also requires therapy to remove potential infection sources, such as special interventions for wound debridement, abscess drainage, or device removal. Identifying and removing the potential source of infection is key to treating and lowering mortality in sepsis.

Immune-Specific Therapy

Corticosteroids

In sepsis, corticosteroid production drops and a relative adrenocortical insufficiency can develop. Nevertheless, studies on steroid administration have demonstrated mixed outcomes on mortality, and there is currently no consensus opinion on how they should be used. The 2016 Surviving Sepsis guidelines recommend their use in septic shock only when hypotension is refractory to fluid challenges and vasopressors. A recent Cochrane review also concluded that glucocorticoid steroids appear to improve patient-centered outcomes, such as reducing total days in the ICU. When used in the treatment of septic shock, intravenous hydrocortisone should be given at 200 mg/d.

Signs and Symptoms

Sepsis

- Distributive shock (beginning with hyperdynamic [warm] shock, progressing to hypodynamic [cold] shock)
- Infection, either confirmed or highly suspicious
- Fever may or may not be present
- Hypothermia may be present in later stages
- Cardiovascular changes
- Significantly lowered SVR
- Tachycardia
- Normal to low-normal BP initially; hypotension once in septic shock
- Normal skin color, normal mucous membrane color, but warm skin initially
- Cold, clammy skin with pallor or cyanosis when sepsis is more progressed
- Petechiae
- Blood oozing from mucous membranes and procedure sites
- Decreased pulse pressure
- Increased respiratory rate
- Increased respiratory depth
- Respiratory alkalosis
- ARDS

Postresuscitation Management

Once a patient's condition is stabilized, ongoing management must be active. Fluid resuscitation and vasopressors should be continued to maintain a goal urine output and lactate clearance.

Specifically, following a cardiac arrest, a 12-lead ECG should be performed immediately to evaluate for new evidence of ischemia or ST-segment elevation myocardial infarction and to determine if the patient requires the cardiac catheterization laboratory. It is currently recommended that targeted temperature management be initiated for all comatose patients following cardiac arrest, regardless of whether the initial cardiac rhythm is deemed shockable or nonshockable. This principle was formerly known as therapeutic hypothermia; however, there is ongoing debate over whether the neurologic benefits observed in studies of this treatment are attributable to the mild hypothermia or simply to the avoidance of fever. Cooling the patient's body to a core temperature between 32°C and 36°C (89.6°F to 96.8°F) is advised, with specific temperature targets varying based on institution protocols and depending on patient characteristics. Protocols related to postresuscitation care are generally closely tied to American Heart Association (AHA) guidelines **TABLE 10-15**. CCTPs should always refer to both their local protocols and current AHA guidelines.

Transport Management

Sepsis

- Maintain the following:
  - MAP greater than 65 mm Hg or SBP greater than 90 mm Hg
  - Urine output greater than 0.5 mL/kg/h
  - SpO_2 greater than 92% with administration of supplemental oxygen as needed
- Provide fluid resuscitation (30 mL/kg isotonic crystalloid bolus to stabilize filling pressures).
- Administer vasoactive agents if isotonic fluid bolus is inadequate to maintain BP.
- Monitor D-dimer level.
- Provide mechanical ventilatory support if the patient has ARDS.
  - Maintain low tidal volumes at 6 mL/kg.
  - Provide high PEEP at ranges of 5 to 14 cm H_2O. Increase the PEEP as the need arises to maintain oxygen saturation.
  - Make FIO_2 adjustments for oxygen saturation as needed.
  - Maintain PaO_2 between 55 and 80 mm Hg or SpO_2 between 88% and 95%.
  - Keep end-inspiratory plateau pressures lower than 30 cm H_2O.
  - Monitor $PaCO_2$ closely.
  - Sedation, if needed, must be monitored closely.
- Initiate broad-spectrum antibiotic therapy as ordered.
- Remove potential sources of infection: wound debridement, abscess drainage, and device removal.
- Consider administration of a corticosteroid or recombinant human APCs.

TABLE 10-15 Shock Resuscitation

Common Initial Treatment

- Oxygen
- IV access
- Monitoring

Cardiogenic Shock

- ECG for signs of STEMI
- Aspirin
- Nitroglycerin unless hypotensive
- Inotropic support (dobutamine)
- Consider diuresis for volume overload
- Emergent echocardiogram for structural issue
- Catheter lab for STEMI
- Obstructive shock evaluation:
    - Tension pneumothorax: needle decompression and chest tube
    - Pericardial tamponade: pericardiocentesis

Hypovolemic Shock

- Identify and control bleeding
- Large-bore IV access
- IV fluid bolus and blood transfusion
- Operating room

Distributive Shock (Neurogenic, Anaphylactic, Septic)

- Volume resuscitation with crystalloids
- Vasopressor support
- Evidence of anaphylaxis:
    - Epinephrine IM and gtt as needed
    - Airway control
    - H_1 and H_2 blockers
    - Steroids
- Evidence of sepsis:
    - Broad-spectrum antibiotics
    - Ongoing evaluation with lactate
    - Source control

Common Initial Treatment

Postresuscitation Management

- ECG to evaluate for STEMI
- Crystalloid bolus and vasopressors to maintain MAP >65 mm Hg
- Consider targeted temperature management in hospital

Abbreviations: ECG, electrocardiogram; H_1 and H_2, histamine; IV, intravenous; MAP, mean arterial pressure; STEMI, ST-segment elevation myocardial infarction

Blood Administration

Blood administration can be part of the management of shock, as discussed in the previous section. The decision to give a transfusion to a patient during a critical care transport is more complex than the administration of blood in the hospital setting. The urgency of the transfusion, the out-of-hospital time, the availability of the blood products, **type-and-crossmatch** information, and the appropriate transport and care of the blood product must be considered. A risk-benefit analysis of the "right treatment for the right patient at the right time" must be conducted as well.

Blood administration may be required to restore circulating blood volume, improve the blood's oxygen-carrying ability, or correct specific coagulation components. Blood products for transfusion can take the form of whole blood, RBCs, WBCs, platelets, cryoprecipitate, or other blood products. It is currently less common to transfuse whole blood owing to the expense, uncommon availability, and possibility of volume overload during its administration. Conditions for which blood administration may be considered include hemorrhagic blood loss as a result of trauma, internal hemorrhage, perioperative and postoperative complications, specific disease entities such as leukemia or other cancers, anemia due to illness, and coagulation disorders.

Many CCT programs carry type O blood for field pickups or will take matched blood with the patient from outlying hospitals; however, the availability of blood products in rural health care settings can be a critical issue when blood administration is contemplated. Rural hospitals may have a limited supply of banked blood products, especially of certain blood types and specific blood products required by a critically ill patient. Such limitations alter the desired treatment of the patient.

Time becomes a factor in the transport decisions surrounding a critically ill or injured patient. Awaiting the availability of certain blood products may lengthen the time to definitive care at a tertiary care center; it may be more important to transport the patient urgently than to perform the transfusion. In particular, the out-of-hospital time for the patient must be taken into account. For example, if it would take 15 minutes to obtain the needed blood products but the total transport time would be 20 minutes, it would likely be prudent to transport the patient and forgo the transfusion until the patient reaches the receiving facility. If the patient can tolerate the transport without the en route transfusion, the decision to defer blood administration until arrival at the receiving hospital may be in the patient’s best interest.

Blood administration can result in undesirable complications such as transfusion reactions. Complications of this nature are best handled in the controlled environment of a hospital setting and may be difficult to address adequately during transport. Management of transfusion reactions is covered later in this section.

The transfusion of blood or blood products is considered to be a form of human tissue transplantation. For this reason, some states regulate who may initiate blood transfusions. Many state or institutional blood bank regulations require two licensed personnel to check blood and ensure a proper match of the blood unit to the patient. Each unit is treated as a new transfusion, rather than as a continuation of the previous unit.

Care of the blood products must be considered if the transfusion is not initiated before transport. The specific container and ice provided by the sending facility’s blood bank must be used to ensure that the quality of the blood product is maintained. The blood products must remain cold throughout transport. For this reason, bags of ice are placed in an insulated icebox with ice beneath and on top of the blood products when transporting whole blood, PRBCs, or platelets. Care must be taken to prevent the ice from melting, including steps such as placing the icebox in a cool area and away from direct sunlight during transport.

The blood bank thaws fresh-frozen plasma and cryoprecipitate under specific guidelines. After thawing, fresh-frozen plasma must be transfused within a 24-hour period and cryoprecipitate must be transfused within a 6-hour period. Blood products are best stored in a refrigerator specially designed to store blood, which includes strict temperature regulations and consistently monitored temperature-recording systems, along with required alarm systems in case the refrigerator fails to maintain the temperature settings.

The extensive requirements for proper storage of banked blood products allow for little tolerance of deviations when blood administration occurs outside the hospital setting. Consequently, an inability to adhere to the stringent care, storage, and temperature monitoring of blood products during transport will result in refusal and waste of transferred blood products by the receiving facility's blood bank. If the patient may need blood products during transport, but it is not certain whether they will be administered, the decision to transport the blood should be made with caution. Most likely, the receiving facility's blood bank will destroy unused blood products from another blood bank. In fact, policies in many institutions forbid the acceptance of transferred blood products from outside blood banks. The possible wasting of a scarce resource, such as blood products, may be important in the decision to transport blood products that may not be absolutely necessary for a patient during transport.

Another key consideration is that blood transfusion requires a skilled health care provider with knowledge and experience in blood product administrations. Therefore, the expertise of the CCTP, medical direction, and prevailing medical protocol may further influence the decision to transfuse blood products during transport.

Once the decision to administer blood products has been made, the steps to provide for proper blood administration must be followed. These include appropriate typing and crossmatching through laboratory analysis. An exception to the required crossmatching of the patient before transfusion may be made during emergency resuscitation for hemorrhagic shock, when type O, Rh-negative blood (the universal donor type) may be administered owing to the urgent need for blood replacement and the critical delay associated with typing and crossmatching the patient before transfusion. In such a case, requirements for the transfusion procedure include appropriate IV access, blood tubing administration sets, priming of the tubing with normal saline, validation of the blood product's match with the specific patient before administration, and continued supervision by a skilled health care provider **FIGURE 10-10**.

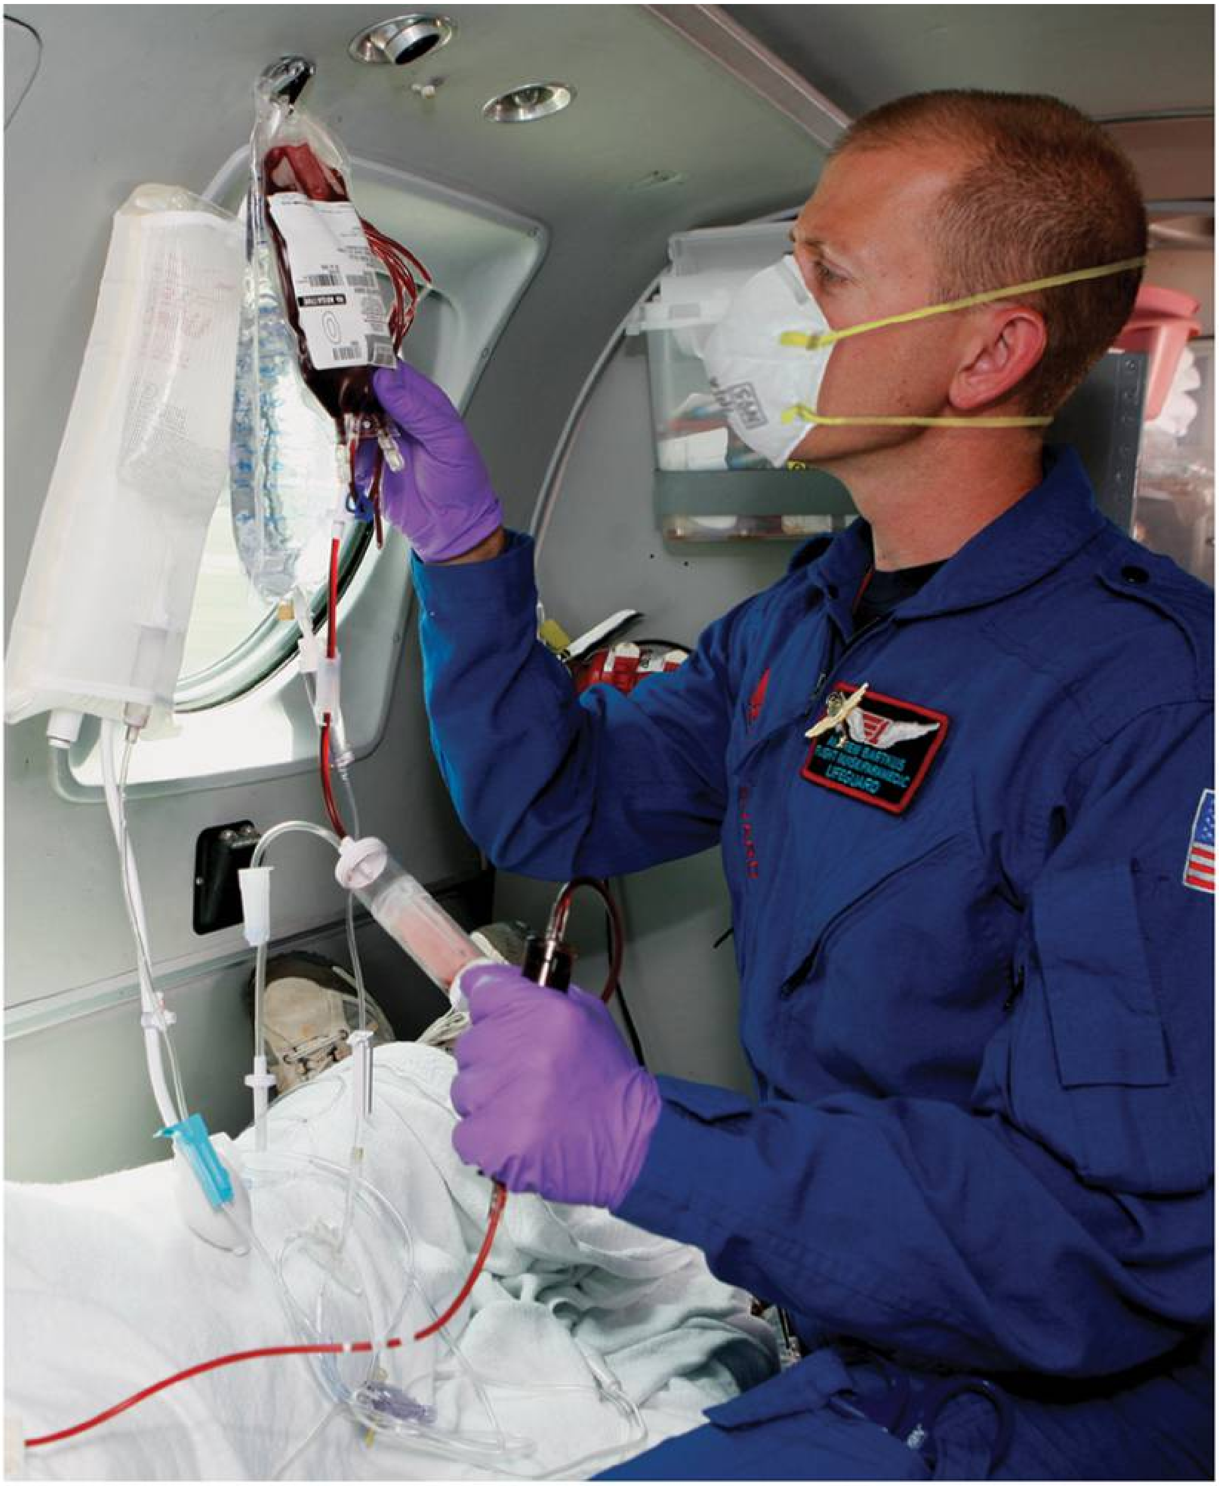

FIGURE 10-10 Proper procedures for blood administration include appropriate IV access, appropriate blood tubing administration sets, validation of the blood product's match with the specific patient before administration, and continued supervision by a skilled health care provider.

© Jones & Bartlett Learning.

When preparing for a potential large-volume resuscitation, the CCTP must understand the fundamental factors that impact flow rate through a cylinder, as defined by Poiseuille's law:

$$Q = \frac{\pi P r^4}{8 \eta l}$$

According to this principle, the flow (Q) of a fluid through a tube is directly proportional to the fourth power of the radius (r) of the tube and the pressure (P) being applied, and is inversely proportional to the length (l) of the tube and the viscosity(η) of the fluid. Practically speaking, a larger, shorter IV line under pressure will maximize flow rate. When measuring the length of the system, remember that it includes any IV extension tubing that is attached to the infusion set. IV connection tubing is used almost ubiquitously for its convenience and for the advantages it provides against blood loss and exposure, infection, and air embolism. If the objective is large-volume transfusion, however, providers should avoid a needleless IV connector, which can negate the improved flow intended by placing a larger-gauge IV access point. If necessary, use multiple large-bore (14- or 16-gauge) catheters to administer multiple units of blood simultaneously.

Pressure bags or rapid infusion devices can also be used to enhance the flow of the transfusion under emergent resuscitation conditions. In addition to higher flow rates, rapid infusion devices can rapidly warm refrigerated fluids to physiologic temperatures before their infusion **FIGURE 10-11**. This warming helps to avoid hypothermia—one of the three components of the lethal triad of trauma (hypothermia, acidosis, coagulopathy) that has been shown to contribute to worsening coagulopathy, cardiovascular function, and hepatocellular function. If neither a pressure bag nor a rapid infusion device is available in the field, manually squeezing the bag of fluid can significantly improve the flow rate in comparison to gravity alone.

ABO System

Blood contains a variety of antigens, with more than 400 RBC antigens having been identified to date. These antigens influence the compatibility of blood between people. Three types of blood antigens are generally considered important in the setting of blood transfusion—namely, the ABO blood group, Rh factor, and the human leukocyte antigen blood group. The type and crossmatch process focuses on identifying these antigen group characteristics through laboratory testing and ensuring compatibility of blood donor–recipient ABO grouping. Incompatibility at this step may cause the most severe type of transfusion reaction, known as acute hemolysis.

The ABO method of blood typing identifies two antigens on a RBC, known as A and B. If a person has only an A antigen identified, that person is type A. A person who has only a B antigen identified is type B. If both A and B antigens are present, the person is type AB. When neither an A nor B antigen is present, the blood type is O. The most common blood types in the United States are A and O, with 85% of the population having one of these two blood types. Type O is the most common blood type. Type B is found in 10% of the US population, whereas only 5% of the population has type AB blood.

A blood transfusion reaction may occur when a patient possesses antigens to a blood type and receives that blood type. Human error resulting in the misidentification of crossmatch samples or recipients is the most common cause of **ABO-incompatible transfusion reactions**. These reactions have caused an average of two deaths per year over the past decade in the United States. Patients with A antigens in their blood also have anti-B antibodies in their plasma; similarly, patients with B antigens in their blood also have anti-A antibodies in their plasma. Transfusion reactions may occur if patients receive a blood type for which they have antibodies.

People who have type AB blood do not have antibodies and are known as **universal recipients**. They can receive blood types A, B, AB, and O without the threat of an ABO reaction. People who have type O blood are considered **universal donors** because their blood can be transfused into patients with types A, B, and AB blood. However, people with type O blood have antibodies to blood types A and B and, therefore, can receive only type O blood.

Patients should receive transfusions of their own blood type to minimize possible transfusion reactions. In an emergency situation in which the time necessary for crossmatching of blood cannot be taken, type O, Rh-negative blood or plasma can be transfused until crossmatched blood becomes available.

Rh factors are antigens found on the cell membrane of RBCs. These antigens are present in approximately 85% of the US population, who are known as “Rh positive.” People lacking the Rh antigen are termed “Rh negative.” There are no natural Rh antibodies. Instead, an Rh-negative person may develop an Rh antibody if exposed to Rh-positive blood. This first exposure to Rh-positive blood allows a person to become sensitized. A second Rh-positive exposure could result in a fatal hemolytic reaction. This type of reaction may occur during a transfusion or pregnancy.

Human leukocyte antigen (HLA) is present on the surfaces of the cell membranes of circulating platelets, WBCs, and most tissue cells. Patients receiving platelets from multiple donors may experience febrile transfusion reactions from the infusion of HLAs. The ensuing antigen-antibody reaction destroys the platelets, reducing the benefits derived from the transfusion. HLA-matched platelet transfusions dramatically diminish this antigen-antibody reaction and are optimal for patients receiving multiple transfusions.

Blood Products

Blood component therapy has become common in the United States, with nearly 21 million of these transfusions taking place each year. Many of these transfusions occur in surgical and obstetric patients. Such transfusions provide benefits including increased tissue oxygenation, decreased blood loss, and improved clinical outcomes. The risks and costs of transfusions must always be considered, however. Transfusion reactions and the risk of transmission of multiple infectious diseases must be factored into any decision to transfuse blood products.

Blood Components and Derivatives

Blood transfusions became possible in the early 1900s after discovery of the A, B, O, and AB blood types. The first blood bank was founded in the United States in 1937. During World War II, the use of whole blood and plasma was widespread. Subsequently, the introduction of plastic blood storage containers and apheresis instruments allowed for the use of blood components as therapy. By the 1970s, blood component therapy had gained acceptance and its use surpassed the use of whole blood. Recently, however, whole blood has been regaining its popularity as a treatment for patients in hemorrhagic shock.

Whole Blood

Whole blood contains all blood components, including RBCs, WBCs, platelets, plasma, and electrolytes. The usual volume is approximately 450 to 500 mL/U. Transfusion of whole blood is indicated only in cases of acute massive blood loss, where its effects of blood volume expansion and increased oxygen-carrying capacity are urgently needed. Whole-blood transfusions should be considered only in patients who have lost at least 25% of their total blood volume. Whenever possible, loss of blood should be treated with options other than whole blood, such as blood components, crystalloids, or colloid solutions. Administration of whole blood may cause fluid volume overload in patients with cardiac compromise.

CONTROVERSIES

Retrospective study of soldiers with combat injuries in the Middle East who required large volumes of blood transfusion demonstrated improved survival when they were given plasma in a roughly equal ratio to red blood cells. Since then, civilian trauma studies have demonstrated that in patients who required activation of massive transfusion protocols, outcomes were improved when these patients received a more balanced resuscitation of RBCs, plasma, and platelets in a 1:1:1 ratio. This balanced resuscitation approach is seen as an approximation of whole blood and has prompted protocol shifts in the US military and a small number of civilian trauma centers to recommend whole blood as the preferred prehospital fluid for the resuscitation of patients with hemorrhagic shock.

Proponents of whole-blood resuscitation point to the fact that 1 unit of whole blood is more concentrated than the equivalent component products, which contain additive solutions; therefore, patients may require fewer transfusions and be exposed to fewer foreign donor antigens. Moreover, proponents for whole blood use argue that transfusing 1 unit of whole blood is easier than keeping track of a 1:1:1 ratio in the midst of a massive transfusion. Thus far, however, meta-analysis comparing whole blood to balanced resuscitation of components has not demonstrated a difference in outcomes, and blood component therapy remains the most common transfusion option.

Whole blood is stored at a temperature between 34°F and 43°F (1°C and 6°C). The expiration date depends on the anticoagulant preservative, but most commonly a citrate phosphate-dextrose solution is used that can allow for refrigerated storage up to 21 days. If not treated with a preservative solution, whole blood will begin to degrade after 24 hours of storage. This cell breakdown causes elevated potassium levels, the formation of microaggregates, damaged platelets and granulocytes, and decreased clotting factors.

Whole-blood transfusions must be ABO matched with the recipient because of the presence of antibodies. Hemoglobin levels should rise 1 g/dL per infusion of each unit of whole blood. Administer whole-blood transfusions as rapidly as possible while maintaining hemodynamic stability. Whole blood may be administered through an IV catheter as small as 20 gauge, with normal saline solution, and within a 4-hour period. The patient must be closely monitored during the infusion for possible fluid volume overload and transfusion reactions.

Packed Red Blood Cells

Packed red blood cells (PRBCs) retain all of the characteristics of whole blood, with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood. This constitutes the removal of nearly 90% of the fluid around the RBCs.

An anticoagulant preservative is then added that can allow RBCs to last for up to 42 days. Each unit of PRBCs retains the same concentration of RBCs as a unit of whole blood and is approximately 250 mL in volume.

PRBCs are indicated for the restoration and maintenance of blood's oxygen-carrying ability. Anemia and blood loss are possible indications for PRBC administration. A patient's hemoglobin level is expected to rise 1 g/dL per unit of administered PRBCs.

Nearly 70% of the leukocytes are removed from each unit of PRBCs, which reduces the risk for febrile, nonhemolytic reactions. Proper ABO compatibility and Rh factor matching are required before administration of these blood products.

Special Populations

Pediatric patients have proportionately higher blood and plasma volumes compared to adults. Transfusion of PRBCs is calculated by weight. Children younger than 4 months are initially given 10 mL/kg of PRBCs, whereas children 4 months of age or older can be transfused with 10 to 20 mL/kg depending on their lab values and clinical condition. Increased attention to volume overload during blood product administration is particularly important in the pediatric population.

Washed blood products are RBC or platelet products in which the small amount of noncellular fluid has been replaced, typically with saline. This process removes all of the plasma proteins—for example, antibodies, cytokines, electrolytes, and preservative solution. The removal of the plasma proteins can decrease the risk of severe allergic reactions. In pediatric patients, the removal of potassium in particular reduces the risk of hyperkalemia.

In **leuko-reduced blood products**, the WBCs and platelet fragments have been filtered from donated blood products. While in some countries this filtering is done universally, in the United States leuko-reduction of donated blood is performed in approximately 95% of platelets and only 75% of RBCs. The use of leuko-reduced blood products can reduce the risk of febrile nonhemolytic transfusion reactions in patients with a history of prior reactions or chronic transfusions, and the risk of HLA alloimmunization in patients awaiting organ transplantation.

In **irradiated blood products**, lymphocyte DNA has been exposed to radiation, which damages the DNA and thereby limits its ability to replicate. The resulting blood products are given to severely immunocompromised patients, in an effort to avoid the rare but often fatal condition of transfusion-associated graft-versus-host disease (ta-GVHD). This disease is estimated to occur in less than 1% of at-risk populations. Such populations include but are not limited to patients with congenital immunodeficiency syndromes, acute leukemia, or lymphoma; patients who have received organ transplants; and oncology patients undergoing chemotherapy. While they likely reduce this risk as well, leuko-reduced blood products are not considered to be an effective protective mechanism against the development of ta-GVHD.

Platelets

Platelets are blood components that are manufactured in the bone marrow; they consist of cytoplasmic fragments containing enzymes necessary for normal clotting response. In the United States, nearly 7,000 units of platelets are transfused daily. These products can be frozen and kept for up to 2 years, but are most commonly stored at room temperature and kept under constant agitation to prevent aggregation and clumping, resulting in a shelf life of 5 days. Indications for platelet transfusions include patients who are bleeding because of thrombocytopenia or, in rare cases, the presence of abnormally functioning platelets. Patients experiencing low platelet counts (less than 5,000 to 10,000 cells/µL) may benefit from platelet transfusions on a prophylactic basis. Platelet therapy may also be considered before surgery or extensive invasive procedures in those patients with platelet levels of less than 50,000 cells/µL. Patients who are receiving chemotherapy, have disseminated intravascular coagulation, or need massive transfusions may be candidates for platelet therapy as well.

ABO-identical platelets are ideal whenever available, with Rh-negative platelets matched to Rh-negative patients as frequently as possible for transfusion. If a patient must receive multiple transfusions of platelets, single-donor platelets should be administered.

Each bag of platelet concentrate contains 5.5×10^{10} of platelets in 50 to 70 mL of plasma. A single unit raises the platelet count by 5,000 cells/μL. The calculation for dosing of platelet therapy is based on 6 to 10 U and 1 U/10 kg of body weight.

Administration of platelets requires a filtered component IV drip set with normal saline solution. Premedication of the patient before transfusion may include antihistamines or acetaminophen to reduce or prevent chills, fever, and allergic reactions.

Fresh-Frozen Plasma

Fresh-frozen plasma (FFP) consists of uncoagulated plasma that has been separated from the RBCs. This plasma is primarily composed of water, proteins, salts, and metabolites, and is rich in clotting factors. As the name implies, FFP is kept frozen, so it must be thawed before use; after thawing, it can be kept refrigerated for up to 24 hours. Indications for the administration of FFP may include blood loss, coagulation deficiencies, warfarin reversal, and thrombotic thrombocytopenic purpura.

Transfusions of FFP must be ABO compatible; Rh matching is not required. Blood administration sets and normal saline solution are required for rapid infusion. Because the citric acid preservative in FFP may bind with calcium during transfusion and can lead to hypocalcemia, close patient monitoring for hypocalcemia is required during transfusion. FFP must be infused within 24 hours of being thawed.

Cryoprecipitate

Cryoprecipitate is a frozen blood product created from the plasma of a donor. It contains factor VIII, fibrinogen, von Willebrand factor, and factor XIII; it follows that indications for administering cryoprecipitate include hemophilia A, fibrinogen deficiency, von Willebrand disease, and factor XIII deficiency. Cryoprecipitate is useful in treating patients with clotting disorders, because it replaces fibrinogen. It is typically given to patients with fibrinogen levels of less than 50 to 60 mg/dL. Each bag contains 80 to 100 U of factor VIII. A patient may need as much as 10 U of cryoprecipitate to restore the fibrinogen level to 100 mg/dL.

Administration of cryoprecipitate does not require compatibility testing, but ABO compatibility is preferred. An Rh match is not necessary.

A blood administration set can be used for infusion, and cryoprecipitate should be administered as rapidly as tolerated. Cryoprecipitate must be administered within 6 hours of thawing. Whole-blood donor requirements and the preparation of cryoprecipitate are the same as those for platelets and FFP.

Albumin

Albumin is prepared by the fractionation of pooled plasma. This product is available as a 5% or 25% solution and is used for volume replacement in patients with conditions such as burns, trauma, surgery, or infections. However, large studies have failed to find a comparative benefit when using albumin instead of crystalloid fluids; consequently, its use remains controversial. The 25% solution will expand to five times its volume in extravascular water and move into the vascular space. Thus, it is important that patients receiving 25% albumin have adequate extravascular water and the compensatory abilities to handle this blood volume expansion.

ABO and Rh compatibility are not a consideration with albumin products. The manufacturer-provided tubing should be used for albumin administration, and the infusion rate should be set in accordance with the patient’s condition and response. Patients with cardiac and pulmonary disease must be monitored closely during albumin administration because of the risk of heart failure from volume overload.

Plasma Protein Fractions

Plasma protein fraction contains 83% albumin and 17% globulins. This blood product is available in a 5% preparation and is indicated for volume expansion in patients with hypovolemia and hypoproteinemia. Clinical indications for its administration include shock and burns. Plasma protein fraction is available in 250-mL containers and can be stored for 5 years at 35.6°F to 50°F (2°C to 10°C).

Synthetic Blood Substitutes

The quest for synthetic substitutes for blood transfusions continues to move forward despite several setbacks and disappointments. The most studied product thus far has been the Hb-based oxygen carrier, Hemopure (HBOC-211), which is made from purified bovine hemoglobin. Clinical trials of HBOC-211 have raised concerns about patient tolerance of the volume associated with its infusion, as well as increased methemoglobin levels. Several other products have been developed or are in active trials, but none of these agents is FDA approved for clinical use in the United States. Under compassionate use authorization, HBOC-211 can be used at some centers for patients with critical anemia who are unable to receive blood products.

Tranexamic Acid

Tranexamic acid is a synthetic antifibrinolytic agent that has several uses in medicine, most notably for patients undergoing elective surgery and for trauma patients with hypovolemic shock. It works by inhibiting plasminogen activation, thereby preventing fibrin clot breakdown and promoting clotting. A large European study demonstrated a mortality reduction in trauma patients receiving tranexamic acid when compared to placebo, particularly when those patients received tranexamic acid early, within 3 hours of injury onset. Further, there was no increase in the number of adverse events such as pulmonary embolism or stroke. EMS systems are beginning to adopt this new therapy, and CCTPs may encounter patients who have received tranexamic acid before transport.

For trauma patients, tranexamic acid is dosed as a 1-g bolus given over 10 minutes, followed by infusion of 1 g over 8 hours. Aside from its use in trauma indications, tranexamic acid has been demonstrated to have benefits in controlling bleeding from epistaxis, hemoptysis, and postpartum hemorrhage. In contrast, a recent randomized controlled trial of tranexamic acid in patients with an acute GI bleed showed no improvement in outcomes, and its use is not recommended in this group.

Anticoagulants

For many years, warfarin (Coumadin) and heparin were the mainstays of anticoagulation; however, since the first direct-acting oral anticoagulant (DOAC) was approved in 2010, use of DOACs has become increasingly prevalent in daily practice. These medications are generally administered for thromboembolic prophylaxis in patients with atrial fibrillation or a mechanical heart valve, as well as in postsurgical patients or patients confined to bed. They are used therapeutically to treat deep vein thrombosis, pulmonary embolism, and other thromboembolic diseases.

Warfarin works by inhibiting the vitamin K–dependent clotting factors (II, VII, IX, and X) and requires frequent checks of the patient’s international normalized ratio to maintain the goal therapeutic level. A variety of medications, such as certain antibiotics, can increase or decrease its effectiveness.

Heparin can be used in its natural, unfractionated form, or as a fractionated low-molecular-weight version (Enoxaparin or Lovenox). Both types are injectable medications that work by indirectly inhibiting factor Xa.

DOACs work by directly inhibiting either thrombin itself (dabigatran [Pradaxa]) or factor Xa (rivaroxaban [Xarelto], apixaban [Eliquis]). While these medications offer significant advantages over warfarin, such as higher dosing reliability and fewer lab checks, their effects can be more challenging to reverse. Warfarin and heparin have well-established reversal protocols that can be implemented in the setting of a traumatic bleeding event. A four-factor prothrombin complex concentrate (PCC) containing high dosages of factors II, VII, IX, and X (Kcentra) is FDA approved for the emergent reversal of warfarin, and protamine can be used to bind to unfractionated heparin to inactivate it. For patients on dabigatran who require emergent reversal, the monoclonal antibody idarucizumab (Praxbind) can be administered to inactivate its anticoagulant effects. If idarucizumab is not available, dialysis is another option to remove dabigatran from the patient's system. For patients taking rivaroxaban or apixaban, andexanet alfa (Andexxa) can be used to reverse life-threatening bleeds. Andexanet alfa is a compound that binds directly to factor Xa inhibitors to inactivate them; however, a randomized controlled trial has not been conducted to determine its superiority to four-factor PCC. Further, andexanet alfa is significantly more expensive than four-factor PCC. Thus, both techniques of Xa inhibitor reversal are in use currently, depending on facility resources.

Procedure

The procedure for administering blood is discussed in this section.

Indications

Indications for administering blood include the following:

- Significant hypovolemia as the result of acute blood loss
- Symptomatic anemia
- Decreasing hemoglobin level
- Decreasing hematocrit value
- Increase oxygen-carrying ability
- Decreased clotting factors
- Presurgical care in selected cases

Equipment/Materials

Upon receiving a physician's orders to administer blood, the CCTP needs to prepare the following equipment and materials:

- Physician's orders
- Blood product, typed and crossmatched (in some cases may be cryoprecipitate, platelets, or plasma)
- Dedicated venous access line (18-gauge or larger needle)
- Filtered administration set

- Thermometer

Complications

Potential complications of administering blood include the following:

- Anaphylaxis
- Hemolytic reaction
- DIC
- Transfusion reaction
- Infection

Signs of complications include the following:

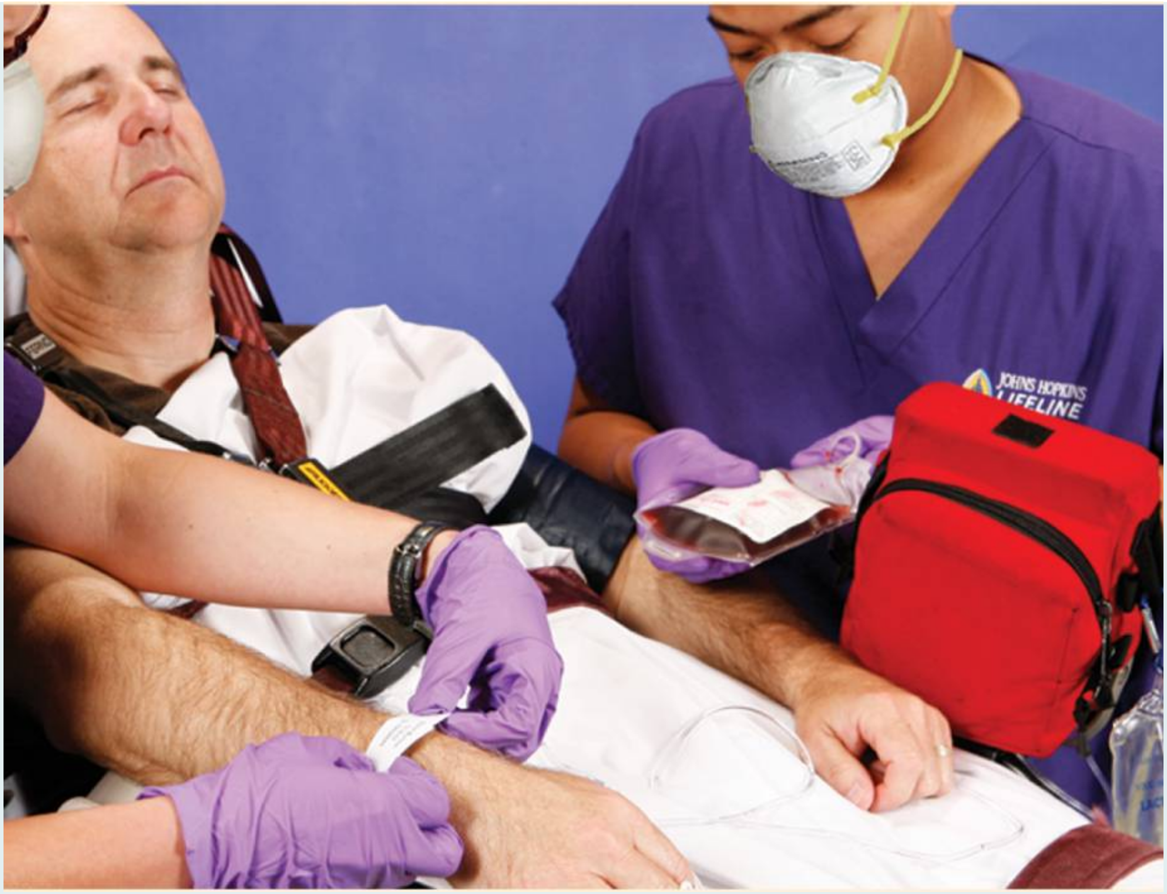
- Body temperature of 2°F (1°C) or more above the baseline temperature
- Hives, itching, or skin symptoms
- Swelling, soreness, or hematoma at the venous site
- Flank pain
- Tachycardia
- Respiratory distress (wheezing and dyspnea)
- Hypotension
- Bleeding from widely varied sites or previously clotted wounds
- Blood in the urine
- Anaphylaxis
- Nausea and vomiting

Steps

Skill Drill 10-1 shows the steps for administering blood products. These steps are also described here:

SKILL DRILL 10-1 Administering Blood Products

Step 1
Confirm the order or protocol.

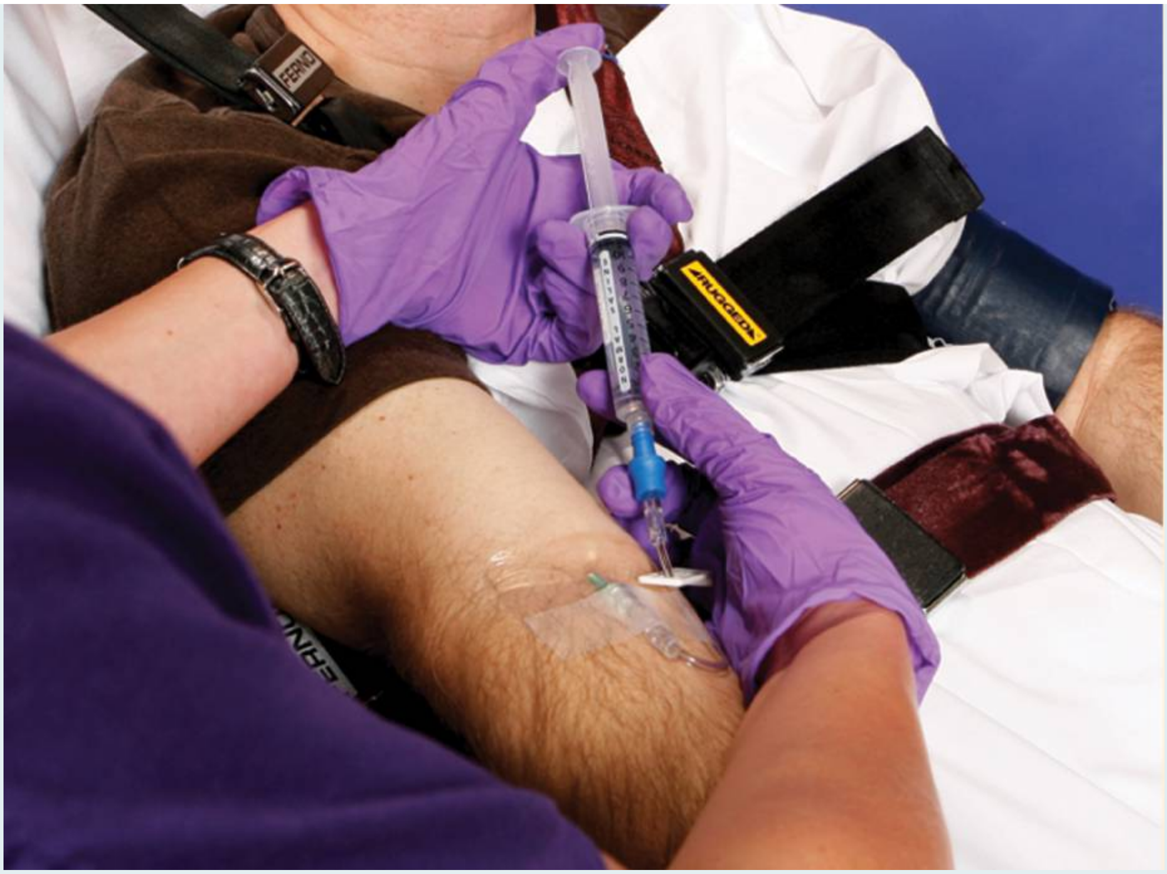


JOHNS HOPKINS
LIFELINE

Step 2
Check the patient for the following: right patient, right blood product, and right type. Have a second provider confirm steps 1 and 2 with you.

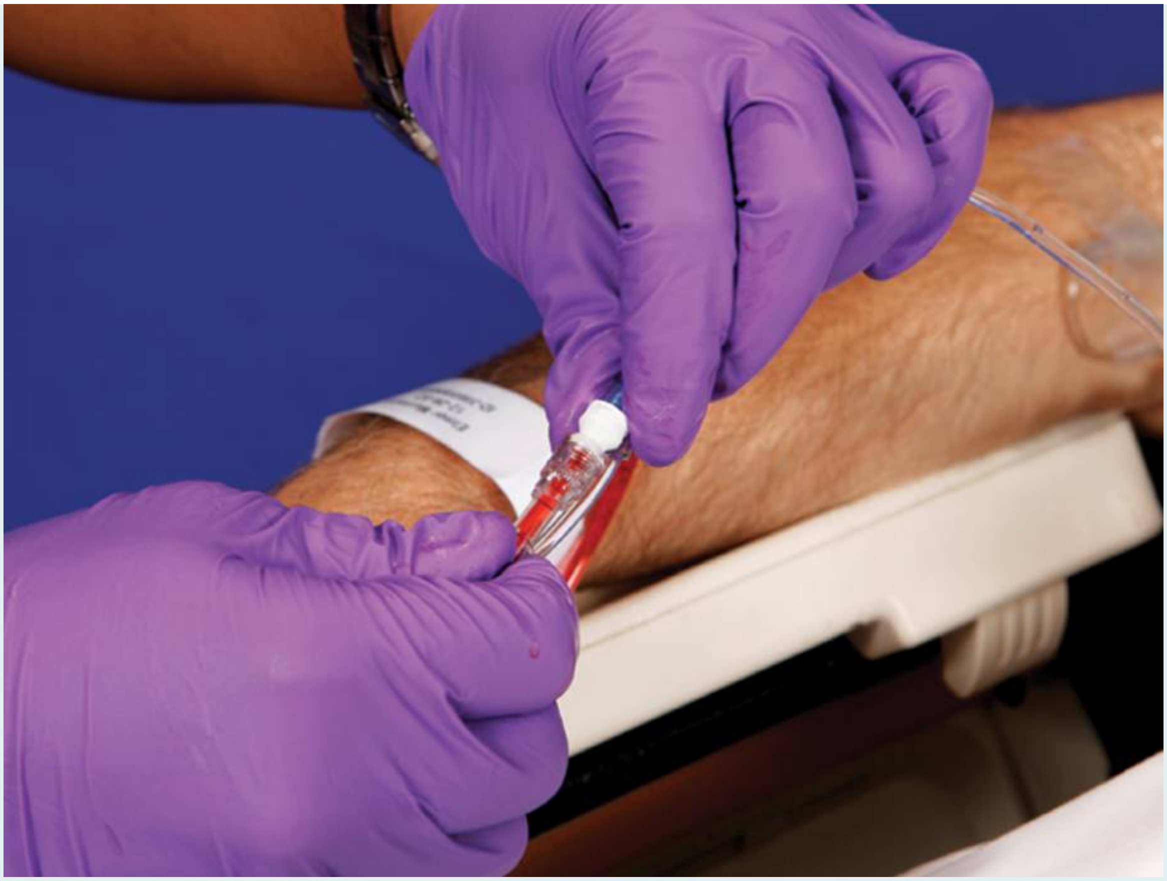
Step 3
Assess the patient’s baseline vital signs and temperature.

Step 4
Ensure suitable venous access. Check the blood for the following: right patient, right blood product, right type, and expiration date. Assess the patient for the possibility of a transfusion reaction, and consider prophylactic administration of medications. Maintain the temperature of the blood product.

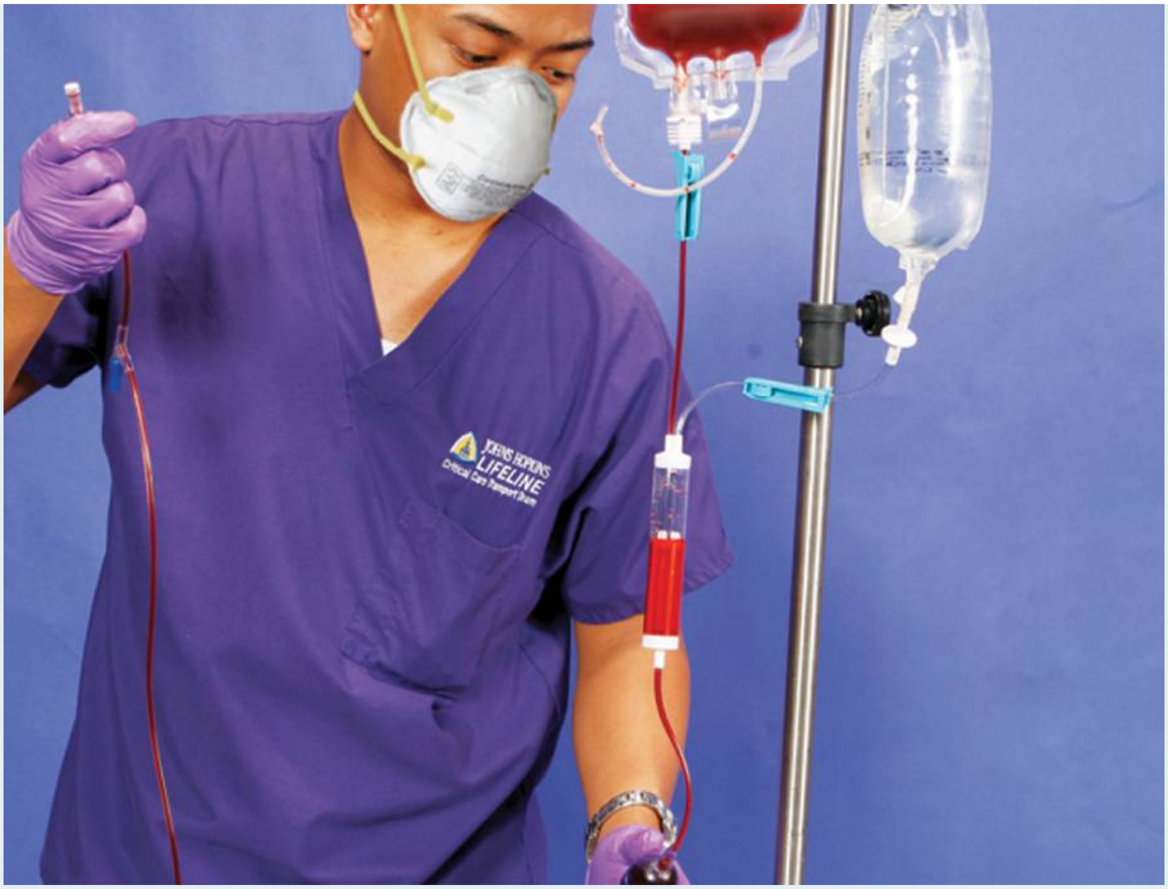


FERNO
RUGGED

Step 5
Flush the tubing with normal saline. Cover the administration filter with blood.



Step 6
Connect the blood to the tubing.



JOHNS HOPKINS
LIFELINE
Critical Care Transport System

Step 7
Piggyback into the IV line of normal saline.

Step 8
Start the transfusion slowly. Monitor for adverse reactions.

© Jones & Bartlett Learning.

1. Prepare the patient by following these steps:
   a. Confirm the order or protocol **STEP 1**.
   b. Check the patient for the following “rights”: right patient, right blood product, and right type. Have a second provider confirm steps a and b with you **STEP 2**.
   c. Assess the patient’s baseline vital signs and temperature **STEP 3**.
   d. Ensure suitable venous access (usually requires 18-gauge or larger needle) **STEP 4**. At this point, patient preparation is complete and the transfusion procedure begins.

2. Check the blood for the following “rights”: right patient, right blood product, and right type. Also check the blood’s expiration date.
3. Assess the patient for the possibility of a transfusion reaction, and consider the prophylactic administration of ibuprofen or acetaminophen and diphenhydramine.
4. Maintain the temperature of the blood product.
5. Flush the tubing with normal saline **STEP 5**.
6. Connect the blood to the tubing **STEP 6**.
7. Saturate the administration filter with the blood.
8. Piggyback into the IV line of normal saline **STEP 7**.
9. Start the transfusion slowly **STEP 8**.
10. Monitor every 5 minutes for adverse reactions.

It is important to follow these transfusion precautions:

- Do not mix blood with 5% dextrose in water (causes hemolysis).
- Do not mix blood with lactated Ringer solution (causes clotting).
- Do not mix blood with medications (may react).
- Have a second venous access available.

Transfusion Reactions

Transfusion reactions are of great concern and play a significant role in the decision to administer blood products. These reactions can be as mild as chills or as catastrophic as death. Reactions can include both endogenous reactions caused by an antigen-antibody reaction in the recipient and exogenous reactions caused by external factors related to the transfused blood.

Allergic Reactions

Allergic reactions are caused by allergens in the donated blood and are evidenced by symptoms of anaphylaxis, including chills, facial and laryngeal edema, pruritus, urticaria, and wheezing, as well as fever, nausea, and vomiting. Management includes the use of antihistamines and careful patient monitoring and assessment. Additionally, providers should consider the indications for epinephrine and corticosteroid administration.

Isolated reactions such as urticaria or hives may occur during transfusion without additional signs or symptoms of anaphylaxis and without further sequelae. The transfusion does not need to be discontinued in such a case; treatment with an antihistamine is usually sufficient. When a patient has a known history of this type of allergic reaction, premedicate the patient with an antihistamine before beginning the transfusion.

Bacterial Contamination

Bacterial contamination of blood components usually occurs during one of the following phases of blood administration: during phlebotomy, during the component preparation or processing, or during thawing of the blood components.

The incidence of bacterial contamination of blood products is low. When it does occur, the ensuing infection may have a rapid onset and lead to death. Platelets present a particularly high risk of infection. Report all cases of suspected bacterial contamination of blood products to the local department of public health.

Bacterial contamination usually results from endotoxins produced by organisms capable of surviving the cold, such as *Pseudomonas*, *Staphylococcus*, and *Yersinia enterocolitica*. Presenting symptoms may occur rapidly or within 30 minutes after transfusion and include chills, fever, vomiting, abdominal cramping, bloody diarrhea, hemoglobinuria, shock, renal failure, and DIC. It is essential to rapidly recognize sepsis caused by blood products contaminated by bacteria. Stop the transfusion immediately upon the onset of symptoms. Keep the IV line open, and implement the protocol for transfusion reactions. Send the blood component unit, any associated fluids, and the transfusion equipment to the blood bank immediately for thorough inspection, Gram staining, and culture. Draw blood cultures from the patient as soon as possible to identify the presence of aerobic or anaerobic organisms. Consider the administration of broad-spectrum antibiotics, corticosteroids, and vasopressors;

treatment for shock; fluid support; respiratory ventilation; and maintenance of renal function in the management of these patients.

Febrile Transfusion Reactions

Febrile transfusion reactions are caused by bacterial lipopolysaccharides or antileukocyte recipient antibodies directed against donor WBCs. Patients may experience temperatures as high as 104°F (40°C), chills, headache, facial flushing, palpitations, cough, chest tightness, increased pulse rate, and flank pain. Treatment of these patients includes administration of antipyretics and antihistamines. Consider modifications if future blood transfusions are anticipated in these patients, including the administration of frozen RBCs and the use of leukocyte filters as modifiers.

Hemolytic Transfusion Reactions

Hemolytic transfusion reactions may be caused by ABO or Rh incompatibility, intradonor incompatibility, improper crossmatching, or improper blood storage.

Immediate hemolytic transfusion reactions usually occur soon after the transfusion of incompatible RBCs. The RBCs are quickly destroyed, resulting in the release of hemoglobin and cell remnants into the bloodstream. This process leads to the onset of hemoglobinuria and abnormal bleeding from open sites, accompanied by hypotension. The reaction time varies between 1 hour and 2 hours, with the onset of symptoms occurring within minutes after the blood transfusion begins. Symptoms include chest pain, facial flushing, shortness of breath, chills, fever, hypotension, flank pain, hemoglobinuria, oliguria, bloody oozing at the infusion site, burning along the vein receiving the blood, shock, signs of renal failure, and DIC. These reactions are relatively rare, representing only 0.41% of all reported adverse effects to transfusion.

Treatment of immediate hemolytic transfusion reactions focuses on prevention and supportive management. If a hemolytic transfusion reaction is suspected, immediately stop the transfusion. The use of diuretics to augment renal diuresis in an effort to prevent renal failure is recommended. The patient must be closely monitored for the risk factors related to DIC and hypotension is required. Hypotension is managed with fluid resuscitation and vasoactive agents. Consider the use of blood component therapy, including FFP, cryoprecipitate, and platelets, in patients with bleeding complications or significant coagulation abnormalities.

Human error is the cause of most cases of immediate hemolytic transfusion reactions; therefore, these reactions are considered preventable. The extensive policies and procedures necessary to ensure proper patient identification, sample collection and labeling, unit identification, patient testing, handling, and correct transfusion must be strictly enforced.

Delayed hemolytic transfusion reactions most often occur in patients who have been sensitized through a previous transfusion, pregnancy, or transplant and who possess an antibody undetectable by standard pretransfusion testing. In cases of delayed hemolytic transfusion reactions caused by secondary response, the onset of symptoms does not occur until 1 to 30 days after transfusion. The production of antibodies sufficient to generate the signs and symptoms of delayed hemolytic transfusion reactions occurs during this time period. Clinical signs and symptoms usually consist of mild fever, chills, and moderate jaundice. Generally, the reaction is mild; severe cases and death are rare. Treatment focuses on the prevention and treatment of severe complications should they arise. Support of renal function includes IV fluids to maintain adequate fluid status.

Plasma Protein Incompatibility

Plasma protein incompatibility results from immunoglobulin A incompatibility. Clinical presentations include abdominal pain, diarrhea, shortness of breath, chills, fever, flushing, and hypotension. Management of this form of incompatibility includes oxygen administration, fluids, epinephrine, and corticosteroids as indicated.

Other Causes

Other exogenous transfusion reactions include bleeding tendencies, circulatory overload, hypocalcemia, hypothermia, and potassium intoxication **TABLE 10-16**. Bleeding tendencies may be caused by low platelet counts in banked blood, which then cause thrombocytopenia in patients who receive these products. Clinical presentations include abnormal bleeding and oozing from breaks in the skin or gums, abnormal bruising, and petechiae. Management involves the consideration of transfusion of platelets, FFP, or cryoprecipitate as needed.

Blood Transfusion Management Considerations

Transfusion-associated circulatory overload (TACO) is a potential complication during blood administration. As noted earlier, administering whole blood has the possible disadvantage of infusing an increased total volume of blood product, which may be poorly tolerated by certain patients. Caution should be exercised with the administration of whole blood in patients with cardiac and pulmonary disease, who are at higher risk for experiencing congestive heart failure. The use of PRBCs in lieu of whole blood administration is recommended in this patient group. The use of diuretics should be considered if circulatory overload is suspected.

Transfusion-related acute lung injury (TRALI) is another recognized complication of blood administration. In this condition, neutrophil activation in the lung parenchyma leads to an ARDS-like presentation.

Hypocalcemia may result from citrate toxicity during blood transfusions when blood products containing citrate are infused too quickly and bind to calcium. The ensuing depletion of circulating calcium results in calcium deficiency in the patient. This calcium deficit may lead to arrhythmias, hypotension, muscle cramping, nausea, vomiting, seizure activity, or a tingling sensation in the fingers. Should such symptoms occur, it may be necessary to slow or stop the transfusion. These reactions may be more severe in patients with hypothermia and in those with elevated potassium levels. Management considerations include the slow infusion of calcium gluconate.

High potassium levels in stored plasma caused by the hemolysis of RBCs may result in hyperkalemia during blood administration. Clinical manifestations of this electrolyte imbalance may include diarrhea, intestinal colic, flaccidity, muscle twitching, oliguria, signs of renal failure, bradycardia, ECG changes with visible tall peaked T waves, and cardiac arrest. Treat the patient for hyperkalemia according to standard protocols. See Chapter 17, *Gastrointestinal and Genitourinary Emergencies*, for further discussion of hyperkalemia treatment.

The induction of hypothermia is possible when large amounts of cold blood products are infused too rapidly. Hypothermia symptoms may include chills, shivering, hypotension, arrhythmias, bradycardia, or cardiac arrest if the body temperature falls below 86°F (30°C). Treatment considerations may include stopping the transfusion, warming the patient, obtaining a diagnostic 12-lead ECG, and warming the blood if the transfusion is resumed.

The risk-benefit analysis of blood administration must be approached with caution. Blood transfusion can be a life-saving intervention, but the many complications and adverse reactions that are possible with administration of blood products require the thoughtful care of highly skilled providers and vigilance in the health care setting.

Flight Considerations

In the transport environment, a patient in shock or with sepsis or MODS will most likely be in a very labile state, requiring diligence by CCTPs in monitoring and adjusting therapy to maintain adequate oxygenation and hemodynamic status. It is important to pay close attention and ensure that all infusions are dosed properly and are compatible. Ventilator transfers and settings must also be managed carefully because oxygen desaturation may occur easily. In addition, movement and agitation can have a negative effect on these patients.

Transport of patients with sepsis over long distances by fixed-wing transport is an infrequent event. However, when it does occur, altitude and cabin pressure require ventilator adjustments to compensate for the pressures at altitude.

Summary

In the transport environment, a patient with sepsis will often be critically ill, and the therapeutic regimen will include use of multiple support devices and treatments. The referring facility may have exhausted its ability to care for the patient. CCTPs must be well versed in the many aspects of the management of shock, sepsis, SIRS, and MODS. Multiple therapies may be needed concurrently in the care of patients in critical condition because of these disorders.

CASE STUDY

You are called to a regional hospital ICU for emergency ground transfer of a male patient to a tertiary facility. Three days earlier, the patient fell, sustained splenic trauma, and underwent emergency repair of a splenic tear. Transport time by ground will be 1 hour.

Upon your arrival, the staff reports that 3 days ago EMS providers brought the patient, a 35-year-old, 170-pound (77-kg) man who fell from a scaffold, to the emergency department. He has no medical history, smokes half a pack of cigarettes per day, and is an occasional drinker. He was diagnosed with a splenic tear and underwent surgical repair. He was admitted to the ICU after surgery, has had worsening hemodynamic status, and is being referred to a tertiary facility for ongoing care. During his stay, the patient received PRBCs, normal saline, and FFP for surgery and stabilization. A PA catheter was inserted, and norepinephrine was initiated to maintain hemodynamic status. He was given cefazolin (Ancef) as surgical prophylaxis. He continues to need a ventilator as well.

This patient is currently mildly responsive, with a Glasgow Coma Scale score of 7T (“T” indicates that the patient is intubated). He is intubated with a 9.0 endotracheal tube and ventilated with synchronized intermittent mandatory ventilation. The tidal volume is 700 mL, the rate is 10 breaths/min, FIO_2 is 50%, and PEEP is 5 cm H_2O. Occasional suctioning is required. Two peripheral lines are in place, with normal saline running at 100 mL/h. Norepinephrine is infusing at 6 µg/min. The patient is receiving enteral nutrition via a nasally inserted duodenal tube. His PA catheter reveals lowered PCWP, decreased SVR, and increased CO. An available chest radiograph reveals bilateral diffuse infiltrates. Current monitoring reveals the following: heart rate, 133 beats/min; BP, 84/43 mm Hg; temperature, 102°F (38.9°C); MAP, 55 mm Hg; CVP, 3 mm Hg; PA pressure, 20/10 mm Hg; PCWP, 7 mm Hg; SpO_2, 89%; and end-tidal carbon dioxide, 35 mm Hg. Current lab values are as follows: hemoglobin, 11.0 g/dL; hematocrit, 33.1%; WBC count, 24, 100/µL; platelet count, 51×10^3/µL; BUN, 61 mg/dL; creatinine, 2.1 mg/dL; Na^+, 146 mEq/L; K^+, 4.8 mEq/L; Cl^-, 111 mEq/L; glucose, 225 mg/dL; pH, 7.29; PCO_2, 52 mm Hg; PaO_2, 47 mm Hg; and HCO_3^-, 14 mEq/L. Urine output has been scant, at less than 50 mL/h.

Your assessment confirms the preceding information. The patient feels febrile to the touch. The examination reveals equal and reactive pupils at 5 mm. The enteral feeding tube is placed nasally and secured. The endotracheal tube is secured at 23 cm at the lip line. The trachea is midline. Other portions of the head, eye, ear, nose, and throat exam have normal findings. The chest has equal rise and fall with ventilations. A PA catheter is placed in the right side and is secure. Lung sounds reveal bilateral, diffuse, light crackles. The abdomen reveals a splenic surgical incision that is intact and dressed; no exudate is noted. An indwelling urinary catheter is noted with a pelvic exam. The lower extremities are cool and pale. Pedal pulses can be detected by Doppler ultrasonography only. Faint radial pulses are noted. Capillary refill is delayed.

You transfer the patient's IV lines to your pumps, then transfer the ECG and hemodynamic lines and calibrate them to your monitors. You move the patient to your litter and duplicate his ventilator settings on your portable ventilator, increasing the FIO_2 to 80%. You discharge the patient from the ICU, obtain all records, and move to your mobile ICU. The patient is placed in the mobile ICU, all oxygen and power needs are transferred to onboard systems, and transport is begun.

En route, no change in the patient's hemodynamic status is noted, and the patient continues to be hypoxic, with an oxygen saturation of 89%. You contact medical control, and standing protocols are initiated.

Immediate attention is given to increasing the oxygenation and perfusion. Norepinephrine is increased to 10 µg/min, and epinephrine is considered as another pressor agent to increase the BP and SVR. The ventilator FIO_2 is increased to 100% and PEEP to 10 cm H_2O. Only slight improvements of oxygenation (90%) and hemodynamics (BP, 88/46 mm Hg) are noted. Hydrocortisone is also considered. Further discussions are held to maintain current patient status, and further therapy will ensue on admission to the tertiary facility. No further changes are noted during the transport course, and the patient is delivered to the tertiary facility ICU without further incident.

1. What is your differential diagnosis?
2. Which other treatment may be beneficial to this patient?
3. Is this an appropriate transfer based on the patient's condition?

Analysis

This patient is most likely experiencing sepsis and SIRS. MODS should be considered a possible diagnosis because of the patient's respiratory failure and renal insufficiency. The infection could have occurred secondary to the surgical exploration, or it might be the result of the mechanical ventilation (pneumonia) or perhaps an invasive line or catheter (intravascular or urinary).

Treatments en route to the receiving facility may include the following:

- Further increasing ventilator support by increasing FIO_2, minute volume, and PEEP. Tidal volume should not be increased.
- Administering chemical paralytics to facilitate ventilation. Sedatives must be used with paralytics, and the hypotensive effects may require increased pressor doses.

- Performing adequate fluid resuscitation *before* increasing any vasopressor doses; 4 to 6 L may be required. Blood products would be considered if the hematocrit value is less than 21%.
- Adding an infusion of another vasopressor agent, such as epinephrine or vasopressin, *after* adequate fluid resuscitation.
- Instituting dobutamine therapy, which may enhance tissue oxygen delivery, only *after* adequate fluids and vasopressor support.

This is an appropriate transfer because the patient will benefit from further treatment at a tertiary facility, such as the following:

- Further ventilator support
- Studies and determination of appropriate antibiotic therapy
- Possible surgical consult and intervention
- Anticoagulation and inflammatory therapies

Sepsis and MODS present complex challenges to CCTPs. Despite recent advances in the critical care arena, these conditions continue to have high mortality and morbidity rates. New therapies are helpful, but early detection and intervention remain the cornerstones of positive outcomes. Identification of risk factors and subtle changes in the patient’s condition are required to identify early onset of these disorders and to initiate aggressive therapy to reverse the process and obtain a favorable outcome. Although CCTPs are limited in terms of the therapeutic options they may implement to reverse the process, such care still serves a vital role in supporting these extremely ill patients. Transport staff members have sufficient resources to address these patients’ challenges and must remain vigilant in providing support for failing organ systems, restoring intravascular volume, and ensuring adequate oxygenation to meet the body’s metabolic demands.

PREP KIT

Ready for Review

- All cells require energy, a continuous supply of oxygen, and nutrients. From those nutrients, mitochondria manufacture energy in the form of adenosine triphosphate (ATP), in a process called cellular respiration.
- Cellular respiration has three parts: glycolysis, the Krebs cycle, and the electron transport chain (oxidative phosphorylation). Unlike the other two parts of cellular respiration, which require oxygen, glycolysis can occur in an anaerobic environment as well as the usual aerobic environment. Nevertheless, such a solo attempt to support cellular respiration reduces the amount of ATP produced and increases lactic acid production, which can result in cell damage, impaired tissue function, and a cascade of injurious effects.
- To get oxygen to the body's cells, the respiratory system must allow oxygen and carbon dioxide exchange across the alveolar-capillary membrane. Once this transfer occurs, arterial blood transports oxygen to the tissues; in this blood, the oxygen is either dissolved in plasma (3%) or bound to hemoglobin (97%).
- Various factors can affect the delivery of oxygen-rich blood to the tissues, including blood volume, viscosity, and arterial elasticity. However, the primary determinants of adequate transport are BP (it must be stable) and cardiac output (it must be adequate).
- Under normal conditions, the cells extract only 25% of the oxygen delivered to the tissues of the body. This allows the body a buffer zone for periods of low oxygen delivery, during which the cells must extract more oxygen.
- Shock is a progressive, whole-body response to an inadequate supply of oxygen within cells, tissues, and organs, from one or multiple causes. It is commonly organized into stages, and the mortality rate increases with progression through these stages:

  - In the compensatory stage of shock, neural, hormonal, and chemical mechanisms attempt to compensate for the severely reduced delivery of oxygen. In effect, they cover up for low circulatory volumes, poor stroke volume, and falling cardiac output, especially in children and healthy young adults. Common signs and symptoms may be as subtle as mild tachypnea and tachycardia. Mean arterial pressure (MAP) may decrease 10 to 15 mm Hg from baseline, and cardiac output may drop slightly.
  - In the decompensatory stage, multifaceted systemic responses to cell breakdown affect nearly every organ of the body. Compensatory mechanisms begin to fail, such that patients demonstrate more pronounced signs of shock, including altered mental status, tachycardia, and a drop in MAP from baseline. Laboratory analysis shows a progression of acidosis, hyperkalemia, and climbing lactate levels. This life-threatening emergency requires immediate treatment.
  - In the refractory stage, compensatory mechanisms have failed. The patient is unresponsive to verbal stimuli, BP is inadequate, the heart rate is increased, the respiratory rate is increased, and respirations are shallow. The skin is cold, cyanotic, and/or mottled, and peripheral pulses are weak and thready to absent. Urinary output decreases and bowel sounds are absent. Anaerobic metabolism progresses to permanent organ dysfunction, and treatment can no longer reverse the mass effects. Multiple organ failure ensues and the risk of mortality is at its highest.
- Management of shock focuses on maximizing oxygen consumption by maintaining an adequate oxygen supply, providing hemoglobin through administration of blood products, and optimizing cardiac output. If a breakdown in one or more of these components occurs, a loss of homeostasis will occur.
- Multiple organ dysfunction syndrome (MODS) is diagnosed when two or more organs stop functioning. The organs affected early in

MODS are the brain, kidneys, liver, adrenal glands, and heart. Sepsis is the leading cause of MODS.

- Shock traditionally is classified by cause. More than one type of shock may be present at the same time.
- Cardiogenic shock results when the ventricles are unable to pump blood forward, ultimately decreasing cardiac output. Manifestations vary depending on the underlying cause, but common signs and symptoms are low BP; altered mental status; cool, pale, diaphoretic skin; decreased urine output; weak and thready pulses; distant or abnormal S_3 or S_4 heart sounds; fluid accumulation in the lungs or limbs; and tachypnea. Management focuses on enhancing cardiac output while decreasing the left ventricular workload.
- In hypovolemic shock, too little circulating blood volume is present within the vascular system, which results in hypotension. Manifestations include tachycardia; hypotension; signs of poor tissue perfusion; altered mental status; and cold, mottled, and pulseless extremities. Management revolves around treating the underlying condition, administering oxygen, and initiating volume replacement.
- Distributive shock encompasses several types of shock involving loss of vasomotor tone or increased vascular permeability—namely, neurogenic shock, anaphylactic shock, and septic shock.
- Neurogenic shock results from conditions that impede the sympathetic nervous system's ability to control the constriction and dilation of vessel walls, such as trauma to the brain or spinal cord. The signs and symptoms associated with neurogenic shock can be very different from those found in hypovolemic shock; most profound is the presence of bradycardia in the face of hypotension. It is vital to piece together all possible causes of hypotension to determine the best treatment, which generally focuses on maintaining MAP at greater than 85 mm Hg.
- Anaphylactic shock is a severe, life-threatening allergic reaction producing systemic vasodilation in response to histamine release.

The reaction can be massive, and it can occur minutes after exposure, or hours or days later. Manifestations include bronchoconstriction, laryngeal edema, and angioedema resulting in airway compromise, which requires rapid treatment to limit its effects. Standard oxygen therapy may not be enough to maintain adequate oxygenation; patients may require intubation, an emergency cricothyrotomy, or tracheostomy to maintain an adequate airway.

- Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection. Septic shock is a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than is noted with sepsis alone.
- Septic shock is a progressive disease that typically stems from an infection. It usually starts as a localized infection and then develops into a widespread inflammatory process, referred to as systemic inflammatory response syndrome (SIRS). When hypotension develops, septic shock is diagnosed.
- Infection is the leading cause of SIRS and septic shock. However, any shock state can trigger SIRS and lead to sepsis, and ultimately to multiple organ failure. The minimum criteria for early recognition of SIRS relate to temperature, heart rate, respiratory rate, and WBC count.
- The prevalence of sepsis-related infections is increasing. Such infections, which affect all populations and age groups, are especially associated with diabetes, hypertension, congestive heart failure, chronic obstructive pulmonary disease, cirrhosis, HIV infection, cancer, and pregnancy. Prolonged hospitalization is a risk factor, as are invasive procedures, comorbidities, and use of immunosuppressants. The mortality rate for sepsis increases with its severity.
- Bacteria are the pathogens most commonly associated with the development of sepsis, although fungi, viruses, and parasites can also cause this condition. Infection can occur at any body site,

including the lungs, abdomen, skin, and urinary tract; it can also be a primary bloodstream infection. Gram-negative and gram-positive bacteria are the two types of organisms most commonly responsible for sepsis.

- Sepsis is part of a dynamic hypermetabolic, hyperinflammatory response to an infection that leads to a loss of control of the immune response. Left unchecked, the vasodilation and permeability that are initially helpful in fighting an infection may progress to distributive shock.
- Microvascular disruption and injury are responsible for hypoperfusion and the shunting of oxygen, which result in decreased oxygen delivery to the tissues. The profound imbalance between oxygen delivery and consumption causes hypoxia within the cells and tissues. This complex cascade of events is a primary cause of sepsis and its progression to organ dysfunction and failure.
- The first priority in recognizing sepsis is to maintain a high index of suspicion for the two phases of distributive shock: hyperdynamic (warm shock) and hypodynamic (cold shock). High cardiac output lasting hours or days characterizes the hyperdynamic phase. It can progress to the hypodynamic phase, which features a rapid deterioration of the patient’s condition accompanied by a sudden drop in cardiac output. Other manifestations of sepsis may include fever, hypothermia (in later stages), tachycardia, normal-to-low BP progressing to hypotension, normal skin progressing to cold and clammy skin with pallor or cyanosis, petechiae and blood oozing from mucous membranes and procedure sites, decreased pulse pressure, increased respiratory rate and depth, respiratory alkalosis, and acute respiratory distress syndrome.
- Management of sepsis aims to maintain organ perfusion while enhancing tissue oxygenation. It requires balancing preload, afterload, and contractility to achieve the targeted criteria for an optimal level of homeostasis.

- Fluid resuscitation is a key component of sepsis treatment, but it is not always sufficient to maintain BP. When it proves inadequate, vasopressors and inotropic agents may be administered in an effort to interrupt the septic cascade. Infection control and immune-specific therapy are other components of the multipronged sepsis treatment algorithm.
- Blood administration is sometimes performed to manage shock and should be considered when patients have hemorrhagic blood loss as a result of trauma, internal hemorrhage, perioperative and postoperative complications, specific disease entities, anemia due to illness, or coagulation disorders.
- The decision to give a transfusion during transport is complex. Factors to consider include the urgency of the transfusion, the amount of time out of the hospital, the availability of blood products, type and crossmatch information, and appropriate transport and care of the blood product.
- Steps for proper blood administration include appropriate typing and crossmatching, obtaining appropriate IV access, securing the appropriate blood tubing administration sets, priming the tubing with normal saline, validating the blood product's match with the specific patient before administration, and continued supervision by a skilled health care provider.
- In an emergency situation in which there is not enough time for crossmatching, type O, Rh-negative (universal donor type) blood or plasma can be transfused until crossmatched blood becomes available.
- Blood contains a variety of antigens that influence the blood's compatibility in various persons. Three types of blood antigens are the ABO blood group, Rh factor, and the HLA blood group; they are all considered during the crossmatching process.
- A person with only an A antigen is type A; a person with only a B antigen is type B. If both A and B antigens are identified, the person is type AB. When neither A nor B antigens are identified, the person's blood type is O.

- People with type AB blood are universal recipients; they can receive blood types A, B, AB, and O without the threat of an ABO reaction. People with type O blood are universal donors; their blood can be transfused into patients with type A, B, and AB blood.
- Rh factors are antigens found on the cell membrane of RBCs. An Rh-negative person may develop an Rh antibody if exposed to Rh-positive blood. A second Rh-positive exposure could then result in a fatal hemolytic reaction.
- Human leukocyte antigens (HLAs) are present on the cell membrane surfaces of circulating platelets, WBCs, and most tissue cells. Patients receiving platelets from multiple donors may experience febrile transfusion reactions due to an HLA reaction. This type of reaction destroys the platelets, reducing the benefits obtained from the transfusion.
- Blood can be administered in many different forms: whole blood, packed red blood cells (PRBCs), platelets, fresh-frozen plasma (FFP), cryoprecipitate, albumin, plasma protein fractions, and synthetic blood substitutes. Specific groups of immunocompromised patients may require blood products that have been irradiated, leuko-reduced, or washed prior to transfusion.
- Whole blood contains all blood components (RBCs, WBCs, platelets, plasma, and electrolytes). Transfusion with whole blood is indicated only in acute massive blood loss for blood volume expansion and increased oxygen-carrying capacity. This type of transfusion has some significant disadvantages, including fluid volume overload in patients with cardiac compromise and degradation of the stored whole blood after 24 hours of storage.
- PRBCs retain all of the characteristics of whole blood, with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood. Anemia and blood loss are possible indications for PRBC administration.

- Platelet therapy may be considered for patients with extremely low platelet levels, those who are bleeding due to thrombocytopenia, and those with abnormally functioning platelets. If a patient must receive multiple transfusions of platelets, the platelets should come from a single donor.
- FFP is uncoagulated plasma that has been separated from the RBCs. Indications for its administration include blood loss, coagulation deficiencies, warfarin reversal, and thrombotic thrombocytopenia purpura. Patients must be closely monitored for hypocalcemia during FFP transfusions.
- Cryoprecipitate is a frozen blood product created from the plasma of a donor. It contains factor VIII, fibrinogen, von Willebrand factor, and factor XIII, and is useful in treating patients with clotting disorders. Administration of cryoprecipitate does not require compatibility testing.
- Albumin is prepared by the fractionation of pooled plasma. It can be used for volume replacement in patients with conditions such as burns, trauma, surgery, or infections. Patients with cardiac and pulmonary disease must be monitored closely during albumin administration.
- Plasma protein fraction contains 83% albumin and 17% globulins. It is indicated for volume expansion in patients with hypovolemia and hypoproteinemia. Clinical indications for the administration of plasma protein fraction may include shock and burns.
- Other types of blood products include synthetic blood substitutes, which have proved disappointing in clinical use to date; tranexamic acid, a synthetic antifibrinolytic agent that may be used in trauma patients with hypovolemic shock; and direct-acting oral anticoagulants.
- When performing blood administration, it is important to follow transfusion precautions:
  - Do not mix blood with 5% dextrose in water (causes hemolysis).

  - Do not mix blood with lactated Ringer solution (causes clotting).
  - Do not mix blood with medications (may react).
  - Have a second venous access line available.
- Blood administration can result in transfusion reactions, which can be as mild as chills or as catastrophic as death. Signs of such a reaction include body temperature that is 2°F (1°C) or more above the baseline temperature; hives, itching, or skin symptoms; swelling, soreness, or hematoma at the venous site; flank pain; tachycardia; respiratory distress (wheezing and dyspnea); hypotension; bleeding from widely varied sites or previously clotted wounds; blood in the urine; anaphylaxis; and nausea and vomiting.
- The main types of transfusion reactions include allergic reactions, bacterial contamination, febrile transfusion reactions, hemolytic transfusion reactions, and plasma protein incompatibility.
- Allergic reactions caused by allergens in the donated blood may produce symptoms of anaphylaxis (ie, chills, facial and laryngeal edema, pruritus, urticaria, and wheezing) as well as fever, nausea, and vomiting. Management includes the use of antihistamines, careful patient monitoring and assessment, and possibly epinephrine and corticosteroid administration.
- Bacterial contamination of blood components usually occurs during phlebotomy, component preparation or processing, or thawing of the blood components. Presenting symptoms may occur within 30 minutes after the transfusion begins and include chills, fever, vomiting, abdominal cramping, bloody diarrhea, hemoglobinuria, shock, renal failure, and DIC. It is essential to rapidly recognize these symptoms, stop the transfusion immediately, and implement the protocol for transfusion reactions.
- In febrile transfusion reactions, symptoms include a temperature as high as 104°F (40°C), chills, headache, facial flushing, palpitations, cough, chest tightness, increased pulse rate, and

flank pain. Treatment includes the administration of antipyretics and antihistamines.

- Hemolytic transfusion reactions are caused by ABO or Rh incompatibility, intradonor incompatibility, improper crossmatching, or improper blood storage.
- Immediate hemolytic transfusion reactions may occur during the transfusion or within the first 24 hours after transfusion. Such reactions destroy RBCs, such that hemoglobin and cell remnants are released into the bloodstream. Symptoms include chest pain, facial flushing, shortness of breath, chills, fever, hypotension, flank pain, hemoglobinuria, oliguria, bloody oozing at the infusion site, burning along the vein receiving the blood, shock, signs of renal failure, and DIC. Treatment of immediate hemolytic transfusion reactions focuses on prevention and supportive management.
- Delayed hemolytic transfusion reactions occur 1 to 30 days after transfusion. Signs and symptoms are usually mild, including mild fever, chills, and moderate jaundice. Treatment focuses on the prevention and treatment of severe complications should they arise.
- Plasma protein incompatibility is caused by immunoglobulin A incompatibility. Clinical presentations include abdominal pain, diarrhea, shortness of breath, chills, fever, flushing, and hypotension. Management includes oxygen administration, fluids, epinephrine, and corticosteroids as indicated.
- Hypocalcemia may occur when blood products containing citrate are infused too quickly and bind to calcium, causing calcium deficiency and leading to arrhythmias, hypotension, muscle cramping, nausea, vomiting, seizure activity, or a tingling sensation in the fingers. Slowing or stopping the transfusion may be indicated. Management considerations include the slow infusion of calcium gluconate.
- High potassium levels in stored plasma may result in potassium intoxication during blood administration. Clinical manifestations may include diarrhea, intestinal colic, flaccidity, muscle twitching,

oliguria, signs of renal failure, bradycardia, ECG changes with visible tall peaked T waves, and cardiac arrest.

- Hypothermia may result from a rapid infusion of large amounts of cold blood products. Symptoms may include chills, shivering, hypotension, arrhythmias, bradycardia, or cardiac arrest. Treatment may include stopping the transfusion, warming the patient, obtaining a diagnostic 12-lead ECG, and warming the blood if the transfusion is resumed.
- Patients with sepsis are rarely transported over long distances by fixed-wing transport; when they are, altitude and cabin pressure require ventilator adjustments to compensate for the pressures at altitude.

Vital Vocabulary

ABO-incompatible transfusion reactions Transfusion reactions in which the patient possesses antigens to a blood type and receives that blood type.

adaptive immune system The secondary mechanism that protects the host by reacting with and eliminating specific antigens, but that requires more time than the innate immune system to mobilize its defenses against unknown pathogens.

aerobic metabolism A form of energy production in which mitochondria use glucose, amino acids, and fatty acids combined with oxygen and ADP to produce ATP, carbon dioxide, water, and heat.

albumin A blood product containing this specific protein found in the blood, which is prepared by the fractionation of pooled plasma; used for volume replacement in certain conditions.

anaerobic metabolism A less efficient form of energy production in which an alternative pathway converts glucose to pyruvic acid with the simultaneous production of ATP; it also results in the production of lactate.

anaphylactic shock A severe hypersensitivity reaction that involves bronchoconstriction and cardiovascular collapse.

anaphylactoid reaction A non–IgE-mediated response that causes the rupture of mast cells and basophils, which then release histamine and other defense mediators.

antigens Substances that can create an immune response in the body.

arterial oxygen content (CaO_2) The total amount of oxygen in the arterial blood.

bacteremia The presence of viable bacteria in the bloodstream.

cardiac index A hemodynamic value that adjusts a patient’s cardiac output to take into account the total body surface area.

cardiac output (CO) The amount of blood pumped by the heart per minute, calculated by multiplying the stroke volume by the heart rate per minute.

cardiogenic shock A condition caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery.

cryoprecipitate A blood product created from plasma and in which clotting factors, especially factor VIII, are concentrated; it is used to treat patients with coagulation disorders.

cytokines Chemical messengers that enhance cell growth, promote cell activation, direct cellular traffic, stimulate macrophage function, and destroy antigens. Interleukins are a type of cytokine.

delayed hemolytic transfusion reactions Transfusion reactions that do not occur until 3 to 30 days after transfusion.

disseminated intravascular coagulation (DIC) A complex condition arising from different causes that activate coagulation mechanisms, resulting in obstructed blood flow as a result of microclots as well as fibrinolysis, while the body attempts to reopen the microcirculation. Bleeding, thrombosis, and, potentially, organ dysfunction result.

distributive shock A condition characterized by widespread dilation of the resistance vessels, the capacitance vessels, or both.

ejection fraction The portion of the blood ejected from the ventricle during systole.

endotoxins Lipopolysaccharides that coat the outer surface of gram-negative bacteria and elicit strong immune responses in humans while providing a layer of protection for the bacterium; they can also be secreted from the cell and are released en masse when cell death occurs.

exotoxins Proteins that are secreted by some bacteria and can directly cause significant damage to host cells while also triggering an immune response.

fresh-frozen plasma (FFP) A blood product in which uncoagulated plasma has been separated from the red blood cells; it is primarily composed of water, proteins, salts, metabolites, and clotting factors.

hemolysis The destruction of red blood cells, which results in the release of hemoglobin and cell remnants into the bloodstream.

hemolytic transfusion reactions Transfusion reactions caused by ABO or Rh incompatibility, intradonor incompatibility, improper crossmatching, or improper blood storage.

human leukocyte antigen (HLA) An antigen present on the cell membrane surfaces of circulating platelets, white blood cells, and most tissue cells.

hypercapnia Greater than normal amounts of carbon dioxide in the blood.

hyperdynamic state The first stage of distributive shock, which is characterized primarily by high cardiac output and low peripheral vascular resistance; also known as warm shock.

hypodynamic state The second stage of distributive shock, which is characterized primarily by a subnormal temperature, a low white blood cell count, profound hypotension and hypoperfusion, and a sudden drop in cardiac output; also known as cold shock.

hypovolemic shock A condition in which the circulating blood volume is inadequate for delivering sufficient oxygen and nutrients to the body.

immediate hemolytic transfusion reactions Transfusion reactions that usually occur soon (between 1 and 2 hours) after the transfusion of incompatible red blood cells.

infection The invasion of normally sterile tissue by a pathogen.

innate immune system The primary nonspecific antigen and immunogen defense mechanism that protects the host by eliminating microbes and other antigens in an effort to prevent infection and allergic reactions.

irradiated blood products Blood products in which lymphocyte DNA has been exposed to radiation to damage it, and thereby limit the cells’ ability to replicate and cause the rare but often fatal condition of transfusion-associated graft-versus-host disease.

leuko-reduced blood products Blood products in which the white blood cells and platelet fragments have been filtered from donated blood products.

leukotrienes A class of biologically active compounds that occur naturally in leukocytes and that produce allergic and inflammatory reactions.

massive transfusion protocol The rapid administration of large amounts of blood products in fixed ratios (usually 1:1:1) for the management of hemorrhagic shock.

mean arterial pressure (MAP) The average (or mean) pressure against the arterial wall during a cardiac cycle.

microcirculation Circulation that occurs in the microvasculature, the body’s smallest vessels (arterioles, capillaries, and venules).

multiple organ dysfunction syndrome (MODS) Altered organ function in acutely ill patients, which is diagnosed when two or more organs stop functioning.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, leading to widespread dilation; it is seen in spinal cord injuries.

neutrophils A type of leukocyte (white blood cell); these numerous phagocytic microphages usually are the first of the mobile phagocytic cells to arrive at the site of injury or infection.

oxygen consumption ($\dot{V}o_2$) The amount of oxygen used by the cells and tissues.

oxygen delivery (DO_2) The amount of oxygen delivered to the tissues each minute.

oxygen extraction ratio (ERO_2) The relationship between oxygen consumption and oxygen delivery; a measure of the cells’ ability to use oxygen.

packed red blood cells (PRBCs) A blood product that retains all of the characteristics of whole blood, with the exception of the extraction of approximately 250 mL of platelet-rich plasma from each unit of whole blood.

pathogens Microorganisms that activate the immune system and cause disease; they include viruses, parasites, fungi, and bacteria.

plasma protein fraction A blood product that contains 83% albumin and 17% globulins.

primary MODS Multiple organ dysfunction syndrome that results from a direct insult such as trauma.

refractory stage The stage of shock characterized by persistently low mean arterial blood pressure despite vasopressor therapy and adequate fluid resuscitation.

Rh factors Antigens found on the cell membrane of red blood cells.

secondary MODS Multiple organ dysfunction syndrome that presents a slower, more progressive insult to organs and frequently results from the sepsis cascade.

sepsis A condition of life-threatening organ dysfunction caused by a dysregulated host response to infection.

septic shock A subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than occurs with sepsis alone.

systemic inflammatory response syndrome (SIRS) A widespread inflammatory process associated with infectious and noninfectious causes, without end-organ damage.

transfusion reactions Reactions resulting from an endogenous or exogenous factor related to transfused blood.

true anaphylaxis An anaphylactic reaction that occurs when the allergen binds to immunoglobulin E on the cell membranes of basophils and when mast cells stimulate the release of histamine from the cell.

tumor necrosis factor (TNF) A protein mediator that is released primarily by macrophages and T lymphocytes, and that helps regulate the immune response.

type-and-crossmatch The test to determine compatibility between patient serum and donor red blood cells prior to transfusion.

universal donors Persons who have type O blood.

universal recipients Persons who have type AB blood.

washed blood products Red blood cell or platelet products in which the small amount of noncellular fluid has been replaced, typically with saline.

CHAPTER 11

Trauma

Christopher McLaughlin, MD, MBA

OBJECTIVES

After completing this chapter, you will be able to:

1. Understand the critical care transport professional's impact on preventing trauma deaths by performing proper prehospital care and transporting patients to the appropriate trauma center (p 466).
2. Explain the significance of trauma management for morbidity and mortality (pp 466–467).
3. Understand Newton's first, second, and third laws of motion, and explain how they relate to patterns of injury (p 467).
4. Discuss the types of trauma (pp 467–468).
5. Describe the various trauma scoring systems, including the Glasgow Coma Scale, the trauma score, the revised trauma score, the Abbreviated Injury Scale, the Injury Severity Score, and the trauma injury severity score, and explain how they are used (pp 468–472).
6. Discuss the classifications of trauma centers defined by the American College of Surgeons' Committee on Trauma, including Level I, II, III, and IV trauma centers (pp 472–473).
7. Understand how to assess a patient in a hospital setting prior to initiating interfacility transport (pp 473–474).
8. Describe the elements of the hypothermia–acidosis–coagulopathy triad, including how to manage them (pp 474–475).
9. Understand how and when diagnostic imaging, including standard radiographs, computed tomography, ultrasonography, transthoracic echocardiography, transesophageal echocardiography, magnetic resonance imaging, and intra-abdominal pressure monitoring, are used and their implications (pp 475–480).
10. Explain how to recognize, assess, and manage the most common thoracic trauma injuries, including pneumothorax (open, simple, and tension), hemothorax, flail chest, pericardial tamponade, aortic dissection, myocardial contusion, diaphragmatic rupture, tracheobronchial disruption, pulmonary contusion, esophageal perforation, and traumatic asphyxia (pp 481–504).
11. Explain how to insert and manage a chest tube, including pigtail catheters (pp 488–495).

12. Describe how to recognize, assess, and manage ear, eye, neck, and tracheal trauma injuries (pp 505–511).
13. Identify the signs and symptoms of abdominal and pelvic injuries, including both hollow and solid organ injuries, and describe how to manage them (pp 511–514).
14. Understand the indications for and use of resuscitative endovascular balloon occlusion of the aorta (REBOA) (pp 514–516).
15. Identify the most commonly encountered types of fractures, and describe how to manage them (pp 520–524).
16. Explain how to recognize, monitor, and manage compartment syndrome, rhabdomyolysis, and crush syndrome (pp 524–527).
17. Discuss specific trauma considerations for special populations (pp 527–528).

Introduction

Trauma poses a significant threat to life. Since emergency medical services (EMS) began to evolve in the 1960s, more emphasis has been placed on rapidly identifying injuries and transporting patients to an appropriate trauma center for definitive care. The severity of the injuries in a traumatic incident may range from minor to life threatening. All trauma patients need a trauma assessment to determine if they have serious injuries. Most local community hospitals should be able to manage and treat patients with minor injuries.

The ability of the critical care transport professional (CCTP) to provide appropriate care for trauma patients en route to the trauma center can help decrease the incidence of morbidity and mortality related to their injuries. The emphasis on identifying life-threatening illnesses and injuries as soon as possible and transporting the patient to an appropriate facility has certainly improved patient outcomes. Unfortunately, trauma remains the leading cause of death in persons younger than 45 years. According to the Centers for Disease Control and Prevention, traumatic injuries accounted for more than 170,000 deaths in the United States in 2019. Many preventable trauma deaths occur in the prehospital environment, further highlighting the importance of proper prehospital care.

Renewed emphasis on education has helped to focus prehospital care providers’ priorities at the scene of a trauma incident. These priorities include scene safety, rapid motion restriction/stabilization, and transport.

Scenarios Involving Trauma Patients

CCTPs may encounter trauma patients in two very different situations. The first scenario is the scene call, in which CCTPs usually back up field basic life support (BLS) and/or advanced life support (ALS) providers. In these cases, the CCTP will be working in more austere and less controlled conditions with less sophisticated assessment tools than are available in an interfacility transport. During a scene call, the CCTP may be asked to provide care that is outside the scope of the standard field responder, such as rapid sequence intubation (RSI), or to provide a speedy transport of the patient to a facility for immediate surgery or blood transfusion, such as by rotor-wing aircraft.

In the second scenario, the CCTP is involved in transferring critical patients, usually from smaller facilities to trauma centers. In this situation, the CCTP will be able to review laboratory results, imaging, and other sophisticated assessment findings prior to beginning the transport. The CCTP may also be able to enlist the assistance of the transferring physician or other house staff to help with stabilization efforts prior to transport. These steps may include securing difficult airways, inserting chest tubes, and hanging blood or other treatments that may be better performed in the referring hospital than in a moving transport vehicle. Diplomatically enlisting this aid and advocating for the patient are other jobs of the CCTP in this situation.

In both types of calls, the time it takes to stabilize the patient’s condition for transport must be balanced against the need to transport an unstable patient immediately for definitive care that cannot be provided in the field. A top priority of the CCTP is to determine the treatment that needs to be provided before transport versus what can be done en route.

Morbidity and Mortality

Managers and practitioners in trauma systems in the United States spend considerable time and effort in researching ways to decrease morbidity and mortality rates. The terms *morbidity* and *mortality* are often used synonymously with *disability* and *death*, because these outcomes are ultimately what advanced trauma systems are working to prevent. **Morbidity** refers to nonfatal injury and disability, whereas **mortality** refers to deaths caused by injury and disease. Reducing their incidences is an area of concern for all trauma systems in the United States, because trauma is the leading cause of death in the pediatric population and a leading cause of death overall. One-half of all deaths of children result from trauma, and this cause accounts for more than 14,000 deaths annually.

Prevention and quality trauma care are two major factors that contribute to decreasing morbidity and mortality rates. High-quality prevention programs keep the trauma system and its patients from the effect of life-threatening and life-altering injuries related to trauma. This role is especially significant because a vast majority of trauma deaths are related to motor vehicle crashes (MVCs). Such crashes are often caused by factors such as alcohol, excessive speed, lack of physical restraints, and poor judgment. Most of these factors can be easily addressed with an established and efficiently functioning prevention program.

An alarming statistic related to MVCs is the number of people who survive the crash but sustain a debilitating injury that leaves them incapacitated. Many of these injuries involve the head and the spinal cord. To prevent these kinds of negative outcomes, the CCTP must realize the importance of avoiding secondary injury caused by improper handling of the patient. Patients with long-term debilitating injuries will spend the rest of their lives dependent on others for basic everyday needs and may require advanced nursing care, resulting in a huge cost to society and to the patients and their families, both financially and emotionally.

Overview of Trauma

Newton’s Laws of Motion

By far one of the foremost scientific intellects of all time, Sir Isaac Newton discovered three laws of motion. These laws factor into the mechanism of injury for trauma patients, which in turn affects the care that EMS responders provide to these patients. We review them here.

Newton’s First Law

Newton’s first law of motion deals with force and velocity, both of which play key roles in MVCs. Essentially, Newton says, “A body in motion remains in motion in a straight line unless acted upon by an outside force.” The CCTP must understand this concept to predict patterns of injuries. For example, suppose a vehicle traveling at 50 mph hits a tree head on and comes to an abrupt stop. The chain of events during the collision includes the vehicle striking the tree, the patient’s chest striking the steering wheel, and the patient’s internal organs striking the rib cage. During this sequence, the exchange of energy within the body causes many different types of damage. A solid understanding of Newton’s first law of motion better prepares the CCTP to deliver the appropriate standard of care to patients with traumatic injuries.

Newton’s Second Law

Newton’s second law of motion refers to an object’s behavior when an outside force is applied. According to this law, acceleration depends on two variables—the mass of the object and the force upon the object. In essence, if force is increased, so is acceleration. If mass is increased, the acceleration is decreased. Essentially, an object accelerates in the direction in which it is pushed. If you push the object twice as hard, it accelerates twice as much. Conversely, if the mass of an object increases, the acceleration must decrease proportionally if force is to remain constant as F (force) = m (mass) × a (acceleration).

Newton's Third Law

Newton's third law of motion is most commonly paraphrased as "To every action, there is an equal and opposite reaction." In other words, if a motor vehicle strikes a wall at 70 mph, the wall pushes back at 70 mph. A solid understanding of the third law is of particular importance to the CCTP when evaluating the mechanism of injury and understanding the predictability of injuries. For example, the CCTP would have a higher index of suspicion of a chest injury if the patient is a passenger in a motor vehicle that was traveling at 70 mph when it hit a tree head on than if the vehicle had been traveling at 5 mph.

Types of Trauma

Traumatic injuries are generally classified into one of two categories: blunt or penetrating. Patients may have injuries that fit into both classifications at the same time. For example, an individual who is stabbed in the back (penetrating injury) and then falls down a flight of steps (blunt injury) could experience both types of injuries. Blunt injuries result from an energy exchange between an object and the body, without intrusion through the skin **FIGURE 11-1**. Examples include rapid forward decelerations (crashes), rapid vertical decelerations (falls), and energy transferred from blunt instruments such as a stick or bat. Penetrating injuries refer to injuries caused by external forces in which the skin is penetrated by an object. Examples include projectiles, such as bullets, knives, and fragments from explosions and falls upon fixed objects.

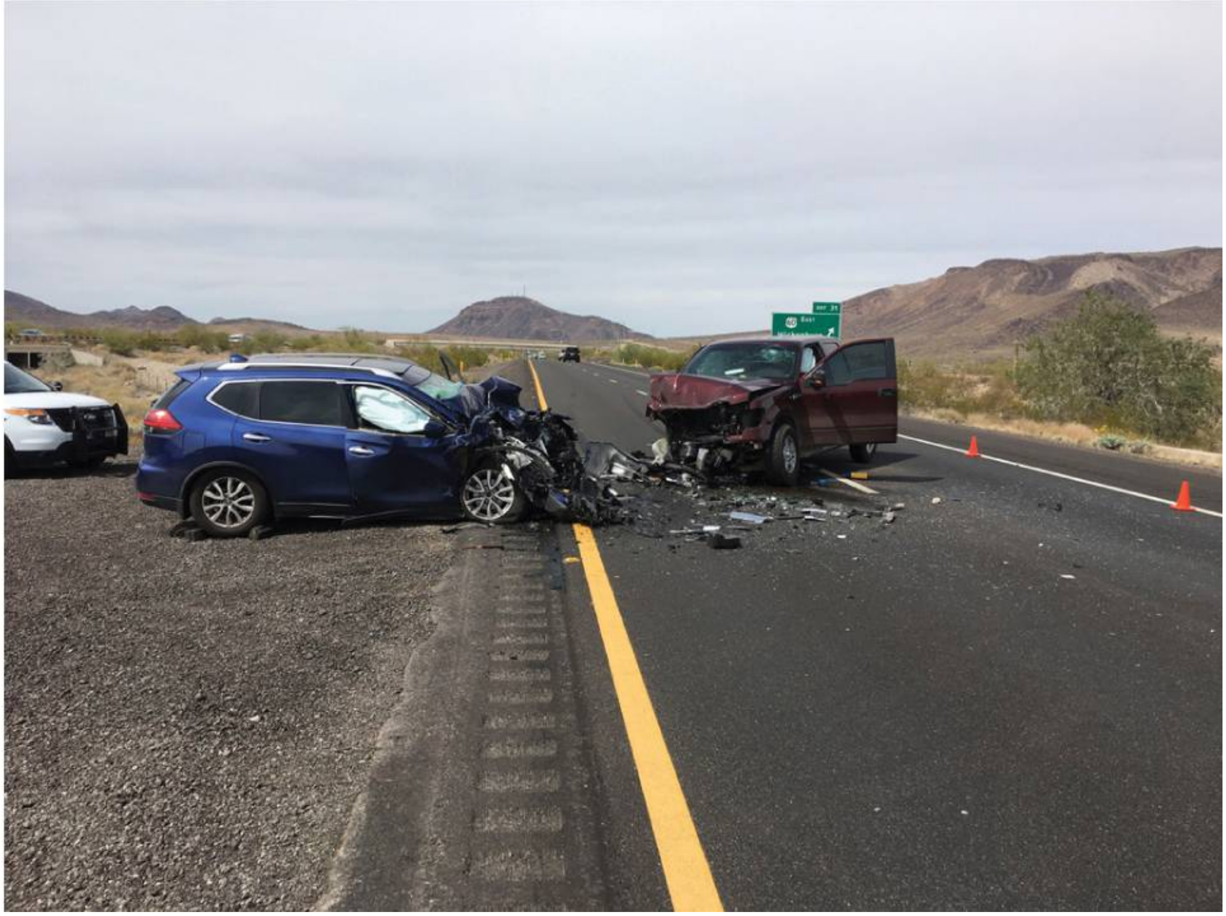

FIGURE 11-1 A front-end collision should prompt the CCTP to suspect potential head, neck, and chest injuries.

© Uncredited/AP/Shutterstock.

Deceleration injuries are caused by a sudden stop of the body's forward motion. These blunt injuries can result from falls, MVCs, or abuse such as shaken baby syndrome. Common injuries involve shearing, avulsing, or rupturing of body organs, fascia, nerves, and other soft tissue. Often these types of injuries are not visible to the CCTP, so a thorough understanding of the types of mechanisms of injury and effective assessment skills is imperative.

Forces that disrupt or damage the tissues of the body cause external force injuries. These injuries can result from gunshot wounds, stabbings, and projectiles. The severity of the injury depends on the anatomic area involved, the mass, and, most importantly, the velocity of the foreign object that enters the body. The kinetic energy (KE) of an object is the energy associated with that object in motion. It reflects the relationship between the weight (mass) of the object and the velocity at which it is traveling, and is expressed mathematically as follows (m = mass, v = velocity):

$$\mathrm{KE} = \frac{1}{2} mv^2$$

External force injuries require the CCTP to use excellent patient assessment skills to prioritize the patient’s injuries and the treatments for them. When doing so, the CCTP must be careful not to develop tunnel vision. Tunnel vision occurs when people devote all of their attention to what is immediately in front of them, ignoring their peripheral vision. For example, the CCTP with tunnel vision might focus on a visible injury, which may or may not be life threatening, yet ignore other injuries to the patient that may well be life threatening **FIGURE 11-2**. Maintaining a calm, professional demeanor and using a systematic approach will allow the CCTP to maintain a high index of suspicion and keen attention to detail.

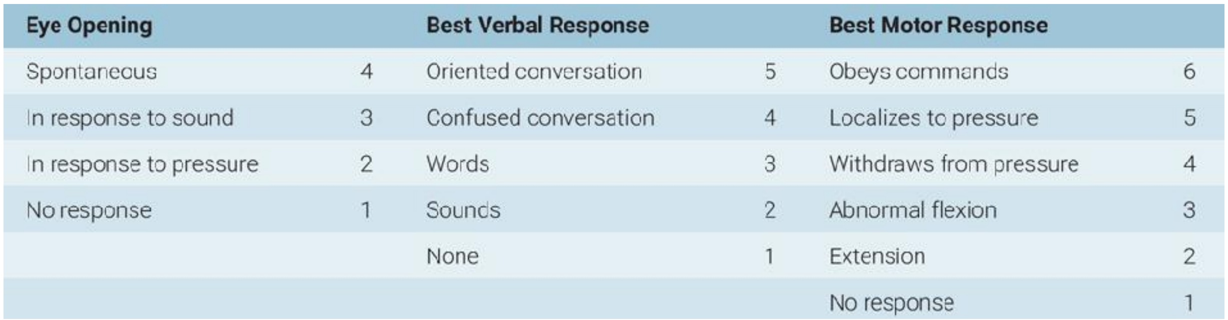
Trauma Scoring Systems

Several trauma scoring systems are used in the critical care transport environment to provide assessment information and as indicators of patient survivability. Trauma scoring systems are an important tool for regional trauma centers, which use them in conjunction with their quality assurance programs.

Glasgow Coma Scale

The **Glasgow Coma Scale (GCS)** is a validated tool that is widely used by health care professionals to assess the neurologic status of a wide variety of patients. This scoring system is used to determine a patient's level of consciousness by measuring and assigning point values, or scores, for three basic indicators of neurologic function: eye opening, verbal response, and motor response. The highest score is 15; the lowest score is 3. The lower the score, the more severe the extent of brain injury. **TABLE 11-1** shows how the numerical values are determined.

TABLE 11-1 **Glasgow Coma Scale**



Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to sound	3	Confused conversation	4	Localizes to pressure	5
In response to pressure	2	Words	3	Withdraws from pressure	4
No response	1	Sounds	2	Abnormal flexion	3
		None	1	Extension	2
				No response	1

[a] Some systems assign a "Not testable" (NT) score for any element that cannot be tested. Eye opening cannot be tested in a patient whose eyes are closed due to a local factor, such as swelling; verbal response cannot be tested in a patient who has a preexisting factor interfering with communication, such as mutism; and motor response cannot be tested in a patient who has preexisting paralysis or other limiting factor.

Scoring:
13–15 may indicate mild dysfunction, although 15 is the score a person without neurologic impairment would receive.
9–12 may indicate moderate dysfunction.
8 or less is indicative of severe dysfunction.
© Jones & Bartlett Learning.

Description

The GCS score is an important tool when caring for trauma patients and can be used for numerous other types of patients. Many medical emergencies, such as drug overdoses, metabolic disorders, and neurologic emergencies, will benefit from frequent patient evaluation using the GCS. Ongoing assessments assist CCTPs in rapidly identifying treatable conditions.

Patients who present with a GCS score of less than 8 warrant immediate consideration for intubation or further advanced airway intervention, as they likely have significant neurologic impairment. While not without its critics, the GCS score is one of the most frequently used means of objectively assessing the central nervous system when invasive monitoring devices are not available. Even in an intubated patient, the GCS score provides useful information; the CCTP merely needs to note when a patient’s inability to verbalize may be impaired by a device in their airway, rather than a decrease in neurologic function. Always give detailed explanations of abnormal GCS findings in the narrative section of your patient care record.

In many situations, successful management of the unresponsive patient with a head injury depends on ongoing examinations. Neurologic changes can occur in a matter of minutes, which may necessitate obtaining a GCS score as often as every 5 minutes. Ongoing GCS assessment scores must always be compared to the baseline score. It is important to look for changes that signal deterioration, as well as any improvements. Any changes must be reported to the receiving facility.

Special Populations

It is just as important to obtain an accurate neurologic exam in children as it is in adults, although doing so may be more difficult with pediatric patients. Depending on the age of the child, modifications may be necessary to accurately identify any neurologic deficits. These modifications are made based on the child's age and stage of pediatric development.

Just as in adults, a poor GCS score in a pediatric patient usually indicates the patient requires some type of immediate intervention, such as airway control or aggressive resuscitation. Chapter 24, *Pediatric Emergencies,* discusses the pediatric GCS score and its application in the management of pediatric patients.

Trauma Score

The **trauma score** is a predictor of the likelihood of patient survival. The score ranges from 1 to 16, with 16 being the best possible score, and takes into account the GCS score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill. The trauma score, however, does not accurately predict survivability in patients with severe head injuries. Therefore, the revised trauma score (discussed next) has replaced the trauma score as a means of assessment.

Special Populations

The pediatric trauma score takes into account the child's weight, systolic blood pressure, airway status, central nervous system status, the presence of an open wound, and the presence of musculoskeletal trauma. Chapter 24, *Pediatric Emergencies*, discusses the pediatric trauma score and its application in the management of pediatric patients.

Revised Trauma Score

The numeric scoring of trauma patients as a means of determining the severity of their injuries is common practice. Several different trauma scoring systems have been developed, with the most commonly used system being the **revised trauma score**.

The revised trauma score measures three physiologic parameters: respiratory rate, systolic blood pressure, and GCS score **TABLE 11-2**. Total scores range from 0 to 13, with more seriously injured patients receiving lower scores. The score can also be weighted; the result then ranges from 1.0 to 7.8408. When the scores are weighted, the GCS score is given more weight to account for a patient's compensatory mechanisms that could prevent vital signs from accurately reflecting the patient's condition. The weighted score is not practical for use in clinical care but is a helpful research tool when studying mortality among trauma patients. Much time and effort are spent researching ways to decrease morbidity and mortality in trauma patients, and extensive research has shown that low revised trauma scores are correlated with high mortality rates **FIGURE 11-3**. This relationship simply reinforces the effectiveness of the various trauma scores.

TABLE 11-2 Components of the Revised Trauma Score

Revised Trauma Score	Components
4	GCS score: 13–15 Systolic blood pressure: >89 mm Hg Respiratory rate: 10–29 breaths/min
3	GCS score: 9–12 Systolic blood pressure: 76–89 mm Hg Respiratory rate: >29 breaths/min
2	GCS score: 6–8 Systolic blood pressure: 50–75 mm Hg Respiratory rate: 6–9 breaths/min
1	GCS score: 4–5 Systolic blood pressure: 1–49 mm Hg Respiratory rate: 1–5 breaths/min
0	GCS score: 3 Systolic blood pressure: 0 mm Hg Respiratory rate: 0 breaths/min

Abbreviation: GCS, Glasgow Coma Scale
© Jones & Bartlett Learning.

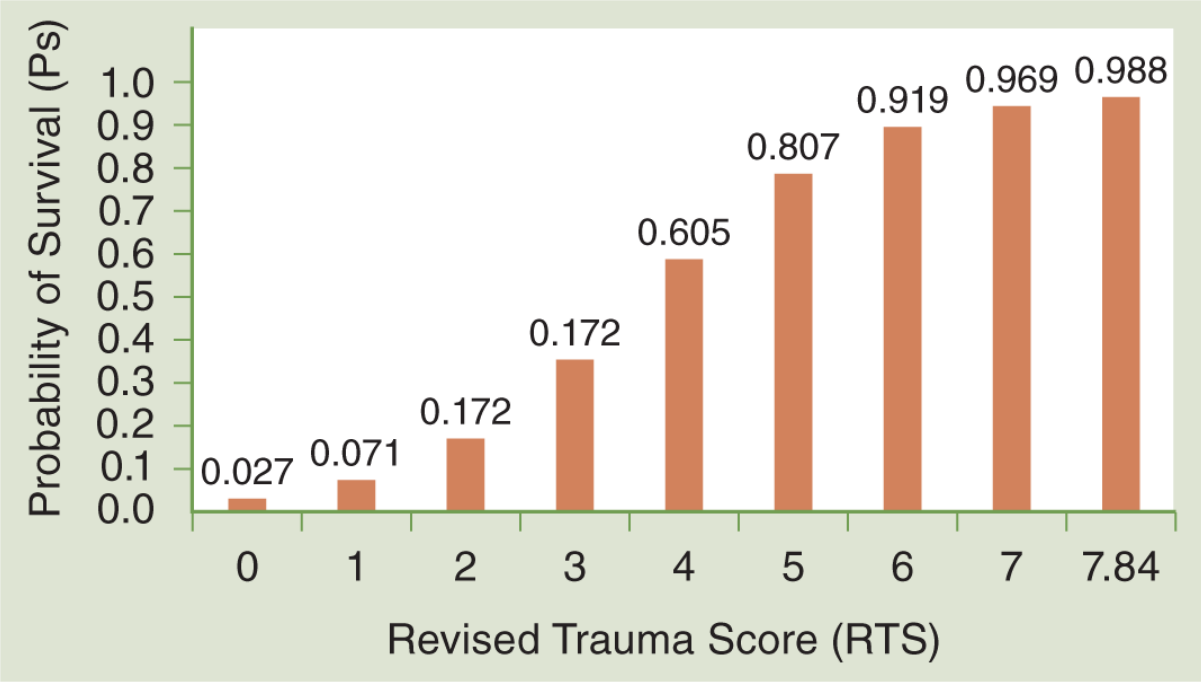


FIGURE 11-3 Survival probability by revised trauma score.

Modified from Survival Probability by Revised Trauma Score. © Trauma.org.

The revised trauma score does not readily identify the small percentage of severely injured trauma patients whose vital signs, because of compensatory mechanisms, do not accurately represent their conditions. For example, a patient with severe trauma who is in compensated shock may not present with abnormal vital signs (eg, low systolic blood pressure and increased respiratory rate) because the body is compensating for the blood loss. The body's ability to compensate for this blood loss may last for only a brief period. When the patient begins to decompensate, the vital signs will begin to deteriorate. Importantly, aggressive resuscitation should begin *before* the patient's vital signs deteriorate. Regardless of the revised trauma score calculated at a particular moment, the CCTP needs to be prepared for each trauma patient's condition to deteriorate with time, once the body becomes unable to compensate for the injury. For patients with a revised trauma score of less than 11, the American College of Surgeons recommends transfer to a Level I or II trauma center. *A high index of suspicion for potential decompensation should be maintained in all trauma patients.*

Abbreviated Injury Scale

Developed in 1969, the **Abbreviated Injury Scale (AIS)** is an anatomic scoring system that is designed to provide a reasonably accurate means of ranking the severity of injury. This scale categorizes injuries into six body regions—head, neck, thorax, abdomen, spine, and extremities—and assigns an individual score to each injury. Injuries are ranked on a scale of 1 to 6 in the AIS system:

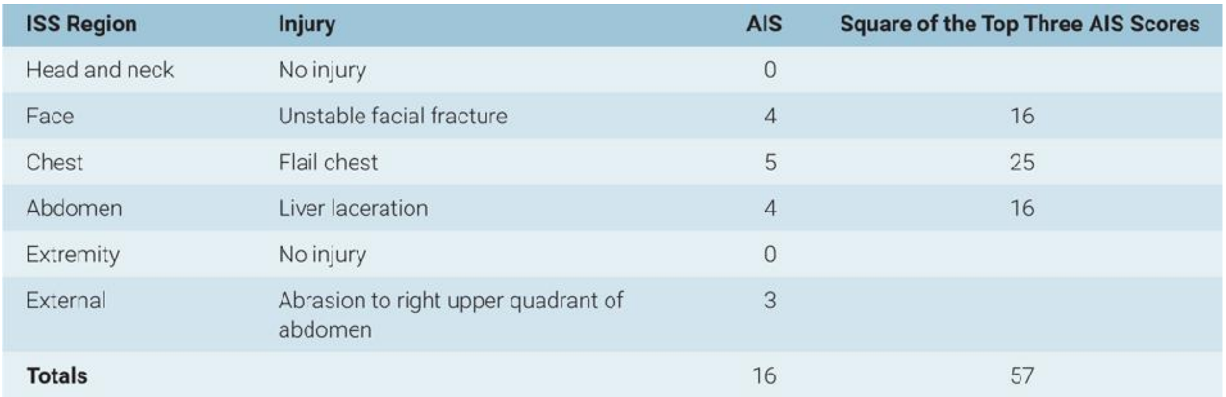
- Minor injury: 1
- Moderate injury: 2
- Serious injury: 3
- Severe injury: 4
- Critical condition: 5
- Unsurvivable: 6

Areas that are not injured are typically given a score of 0 or not recorded. The AIS allows for the determination of the severity of an individual injury but does not take into account multisystem injuries. Such scores are typically calculated for research purposes and in conjunction with trauma center outcome reporting. The AIS scoring system is not used in the clinical setting but is important for identifying injury patterns.

Injury Severity Score

The **Injury Severity Score (ISS)** is an anatomic scoring system that provides a single overall score for patients with multiple injuries. It quantifies multisystem injuries through the use of AIS scores. The ISS is determined by adding the squares of the three highest AIS scores. The ISS is a number between 0 and 75, with 1 being an isolated minor injury and 75 being severe multisystem injury. Any ISS body region that is assigned an AIS score of 6 (nonsurvivable) equates to an ISS of 75. **TABLE 11-3** shows an example of the ISS calculation.

TABLE 11-3 **Sample ISS Calculation**



ISS Region	Injury	AIS	Square of the Top Three AIS Scores
Head and neck	No injury	0	
Face	Unstable facial fracture	4	16
Chest	Flail chest	5	25
Abdomen	Liver laceration	4	16
Extremity	No injury	0	
External	Abrasion to right upper quadrant of abdomen	3	
Totals		16	57

Abbreviations: AIS, Abbreviated Injury Score; ISS, Injury Severity Score
Reproduced from Injury Severity Score. Trauma.org.
http://www.trauma.org/archive/scores/iss.html.

Description

As with AIS scores, trauma registry personnel often use the ISS for data collection and research purposes. Generally, an ISS greater than 15 is associated with major trauma requiring care at a Level I facility. Once data such as ISS scores are collected, some variances can occur with this scoring system. For example, any error made in AIS scoring will increase the likelihood of errors with the ISS.

Trauma Injury Severity Score

The **trauma injury severity score (TRISS)** is another scoring system that calculates the survival probability of the critically ill or injured patient. This scoring system uses the results of the ISS and the revised trauma score along with the patient’s age, so it incorporates the patient’s physiologic and anatomic indicators. This score is rarely used in the transport setting.

It is important for CCTPs to use their triage skills in the field when determining where to transport a patient. Ultimately, the various trauma scoring systems are not as useful as expert triage skills, because a full description of the patient injuries is not known.

Trauma Systems

Levels of Trauma Care

The CCTP is often called to incident scenes and outlying facilities to transport critically injured trauma patients to more definitive care. For this reason, it is important to be familiar with how the American College of Surgeons' Committee on Trauma (ACS-COT) classifies echelons of trauma care. Trauma centers are classified into Levels I through IV, with Level I having the most resources, followed by Levels II, III, and IV, respectively.

A Level I facility is a comprehensive resource center that serves as the major referral hospital in a mature trauma system. Level I facilities must be capable of providing every aspect of trauma care from prevention through rehabilitation; therefore, the facility must have adequate personnel and resources to support that care. Because of the extensive requirements, most Level I facilities are large, university-based teaching hospitals that serve larger cities or heavily populated areas. These centers have subspecialty care, such as neurosurgery, orthopedic surgery, and intensive care units, readily available, in addition to dedicated surgery department access.

Level II centers are expected to provide definitive care during the initial trauma hospitalization, regardless of injury severity. These facilities are usually academic institutions or public/private community facilities located in less densely populated areas and may not have all the subspecialties of a Level I facility. Because of its location and resource limitations, the Level II trauma center may not be able to provide the same comprehensive care as a Level I trauma center.

Level III facilities typically serve communities that do not have access to Level I or II facilities. These facilities provide assessment, resuscitation, stabilization, and transfer when necessary. Level III facilities must have transfer agreements with a Level I or II trauma center and must have protocols in place to transfer patients whose needs exceed the facility's resources.

Level IV facilities are typically found in remote, outlying areas where no higher level of care is available. They provide advanced trauma life support (ATLS) prior to transfer. Such a facility may be a clinic or urgent care facility, and may or may not be staffed with a physician.

A mature and inclusive trauma system will leave no facility without a direct link to a Level I or II facility. All facilities, no matter the level, are expected to provide the same high quality of initial stabilization regardless of the trauma center's level.

Trauma centers can be either adult trauma centers or pediatric trauma centers, but are not necessarily both. Pediatric trauma centers are not as common as adult trauma centers. When transporting a pediatric trauma patient, you must be certain to transport the patient to the closest appropriate facility—a pediatric trauma center, if that is the closest option.

Since 1987, the ACS-COT has provided a consultation and verification program through which hospitals can be evaluated to see if they are meeting ACS-COT criteria. In addition, it provides consultation on developing and evolving trauma systems to states, regions, counties, and cities.

Classification of Trauma Patients

Trauma centers often have multiple tiers of trauma activations. The ACS-COT provides minimum criteria for Level I (full trauma team) activation. When one or more of the following criteria are present in the trauma patient, the full trauma team should be available and ready to provide ALS:

- Confirmed blood pressure less than 90 mm Hg at any time in adults and age-specific hypotension in children
- Gunshot wounds to the neck, chest, or abdomen or extremities proximal to the elbow/knee
- Glasgow Coma Scale score less than 9, with a mechanism of injury attributed to trauma

- Patients transferred from other hospitals who are receiving blood to maintain vital signs
- Patients requiring advanced airways who are transferred from the scene
- Patients who have respiratory compromise or are in need of an emergent airway
  - Includes intubated patients who are transferred from another facility with ongoing respiratory compromise
  - Does not include patients intubated at another facility who are now stable from a respiratory standpoint
- Emergency physician's discretion

The ACS-COT has also developed criteria to consider transfer of a trauma patient from a Level III facility to a Level I or II facility. These criteria, which are listed in **TABLE 11-4**, represent some of the more common reasons for trauma patient transfer. The CCTP should be familiar with the presentation and management of these conditions.

TABLE 11-4 **Criteria for Consideration of Transfer From Level III Centers to Level I or II Centers**

1. Carotid or vertebral artery injury
2. Torn thoracic aorta or great vessel
3. Cardiac rupture
4. Bilateral pulmonary contusion with PaO_2:FIO_2 ratio <200
5. Major abdominal vascular injury
6. Grade IV or V liver injuries requiring transfusion of more than 6 units of red blood cells in 6 hours
7. Unstable pelvic fracture requiring transfusion of more than 6 units of red blood cells in 6 hours
8. Fracture or dislocation with loss of distal pulses
9. Penetrating injuries or open fracture of the skull
10. Glasgow Coma Scale of less than 14 or lateralizing
11. Spinal fracture or spinal cord deficit
12. Complex pelvis/acetabulum fractures

13. More than two unilateral rib fractures or bilateral rib fractures with pulmonary contusion (if no critical care consultation is available at the referring facility)
14. Significant torso injury with advanced comorbid disease (such as coronary artery disease, chronic obstructive pulmonary disease)

Abbreviations: F_{IO_2}, fraction of inspired oxygen; Pa_{O_2}, partial pressure of arterial oxygen

Interfacility Transport Trauma Management

Paramedics are already well versed in prehospital management of trauma. Interfacility management of trauma patients will often involve patients who are severely injured and in need of close assessment and continued monitoring. Some of these patients may undergo damage-control surgery prior to transfer. This treatment involves surgical correction of life-threatening injuries and initiation of resuscitation, followed by transfer to a critical care unit or tertiary hospital for longer-term stabilization and monitoring. Definitive surgery, in contrast, is performed after the patient's life-threatening injuries have been stabilized. For patients who meet certain criteria, injuries may be managed without surgery. Regardless of the approach taken, management after the patient's initial arrival at a hospital should follow ATLS guidelines.

Just as in the prehospital setting, the ABCs are addressed first during an interfacility transport call. On arrival at the facility, the CCTP should ensure the ABCs have been assessed and managed before initiating transfer. In addition, the CCTP should assess the placement of the endotracheal tube (if present), presence of breath sounds, and capnography waveform. If any doubt exists about the endotracheal tube's proper placement, transport should not be initiated until the airway status is stabilized. Cardiovascular status should be assessed, including the patency of all vascular access devices and the total volume of fluids infused since the patient presented at the receiving facility. A thorough neurologic exam, including GCS score, should be performed and documented. Although this effort might seem to duplicate earlier care, it is imperative to assess the patient from head to toe for external injuries prior to initiating transfer and in collaboration with the initial trauma team if possible. Previously unseen injuries can prove fatal during interfacility transport if they are not discovered and addressed prior to departure. Repeated head-to-

toe assessments will decrease the possibility of missed injuries, which occur more often in patients with multisystem trauma.

Elicit as much medical history as possible from the patient or hospital staff. Consider whether the patient might have drug or alcohol intoxication; as many as one-third of all trauma patients are drug or alcohol dependent. The CCTP must also be prepared to detect and treat complications on initial evaluation and treatment, including fluid overload, transfusion reactions, contrast-induced renal issues, abdominal compartment syndrome, bleeding, and shock.

The Hypothermia–Acidosis–Coagulopathy Triad

The lethal triad of hypothermia, acidosis, and coagulopathy is often described in the trauma literature as the cornerstone of understanding proper resuscitation of the bleeding trauma patient. Each element of the lethal triad exacerbates the effect of the other two, and can accelerate patient decompensation without timely intervention.

Hypothermia

Hypothermia, defined as a core body temperature less than 35°C (95°F), is commonly encountered in trauma patients. In fact, studies have shown that the incidence of hypothermia in trauma patients can be as high as 50%. Moreover, hypothermia in trauma is associated with higher mortality rates.

Hypothermia can generally be attributed to either the environment or the treatment provided. Extended time in the field during an extrication process can contribute to hypothermia in trauma patients. Even on a warm day, loss of blood and thermoregulation in trauma can result in this condition. Additionally, a major component of ATLS is complete exposure and assessment, which often means removing clothing and blankets that could cover up injuries. Hypothermia can also be induced or exacerbated by the CCTP by exposing the patient for an exam, failing to increase the ambient temperature in patient care areas, and infusing fluids. Administration of nonwarmed infusions requires the body to warm up the fluid internally, resulting in further decreases in core temperature, energy expenditure, and further stress to thermoregulation mechanisms.

The CCTP must diligently prevent hypothermia and work to reverse it if it does occur before and during transport. Limit exposure of the patient as much as possible. Increase the ambient temperature by using warm blankets and raising the temperature in the patient compartment of the transport vehicle. This increase in temperature may be needed even on a warm day. Use of warmed fluids may be helpful, although fluids stored in a warmer have not been shown to maintain significant warmth when infused. To administer truly warm fluids, it is necessary to use a device that actively warms fluids while they are infusing. Warmed and humidified oxygen may be beneficial as well. For critically injured patients, esophageal temperature probes can provide continuous monitoring of core body temperature during their transfer. The CCTP should also be cognizant of the multiple other side effects of hypothermia, such as reduced drug clearance **TABLE 11-5**.

TABLE 11-5 Effects of Hypothermia on Trauma Patients

Impaired Cardiorespiratory Function
Cardiac depression Myocardial ischemia Arrhythmias Peripheral vasoconstriction Impaired tissue oxygen delivery Elevated oxygen consumption during rewarming Blunted response to catecholamines Increased blood viscosity Metabolic acidosis
Bleeding Diathesis
Decreased kinetics of coagulation factors Reduced platelet function
Reduced Clearance of Drugs
Decreased hepatic blood flow Decreased hepatic metabolism Decreased renal blood flow
Increased Risk of Infection
Decreased white blood cell number and function Impaired cellular immune response

Wound infection

- Thermoregulatory vasoconstriction
- Decreased subcutaneous oxygen tension
- Impaired oxidative killing by neutrophils
- Decreased collagen deposition

Acidosis

Hypothermia can directly lead to acidosis, as can administration of large volumes of acidic crystalloid solutions during resuscitation efforts. Normal saline, which has a pH of 5.5 and a very high level of chloride, can worsen underlying acidosis. The acidotic pH and tendency to induce a hyperchloremic metabolic acidosis, in addition to the existing lactic acidosis, make large volumes of normal saline a potentially harmful resuscitation fluid. Lactated Ringer solution, with a pH of 6.5, is an imperfect alternative because of the lactate content and incompatibility with other fluids, medications, and blood products. More recently, Plasma-Lyte A and Plasma-Lyte 148 have made their way into critical care as balanced-pH, multiple-electrolyte fluids of choice for large-volume crystalloid resuscitation. The patient’s respiratory status, such as acidosis from hypoventilation, should be taken into consideration as well.

Coagulopathy

Coagulopathy, which is seen in 25% of severely injured patients, can be precipitated by hypothermia and acidosis, or by acute blood loss. Dilutional coagulopathy occurs when providers resuscitate a bleeding trauma patient with fluid or blood products that do not contain the same clotting factors lost in the whole blood. Aggressively managing hemorrhage, including early replacement of both clotting factors and packed blood cells, is important to reverse or prevent progressive coagulopathy. New trauma recommendations call for a 1:1:1 ratio of plasma, platelets, and packed red blood cells for replacement, especially in the context of massive transfusion protocols, while minimizing crystalloid infusions. The CCTP should be familiar with the different types of blood products and the goals of administration for each type.

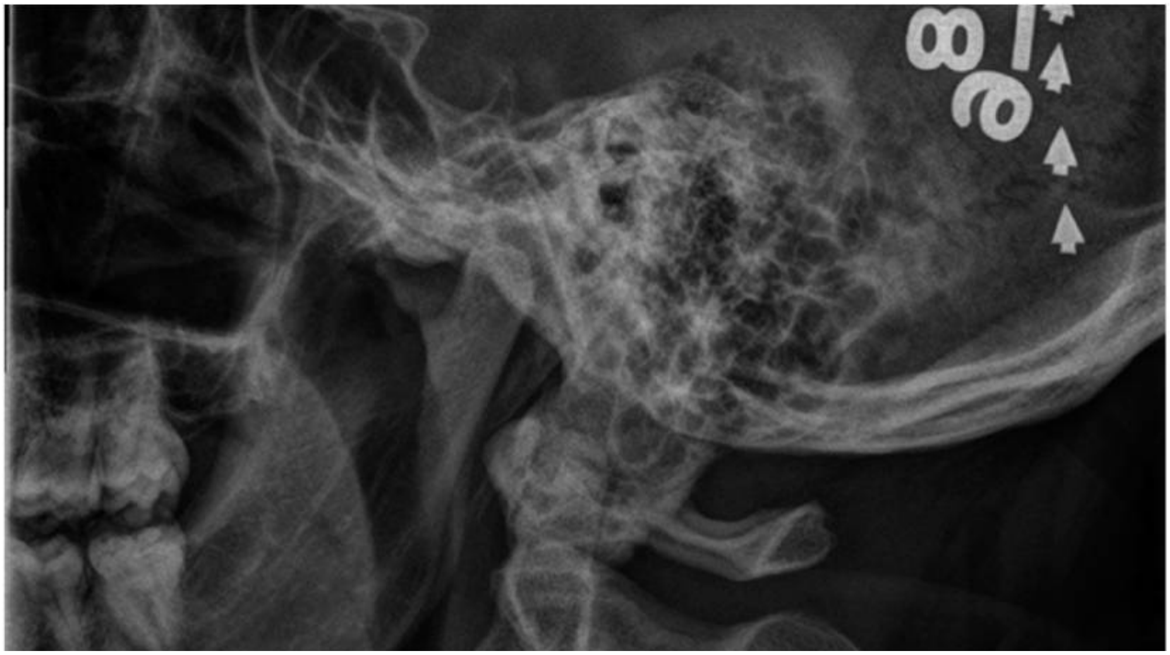
Diagnostic Imaging for Trauma

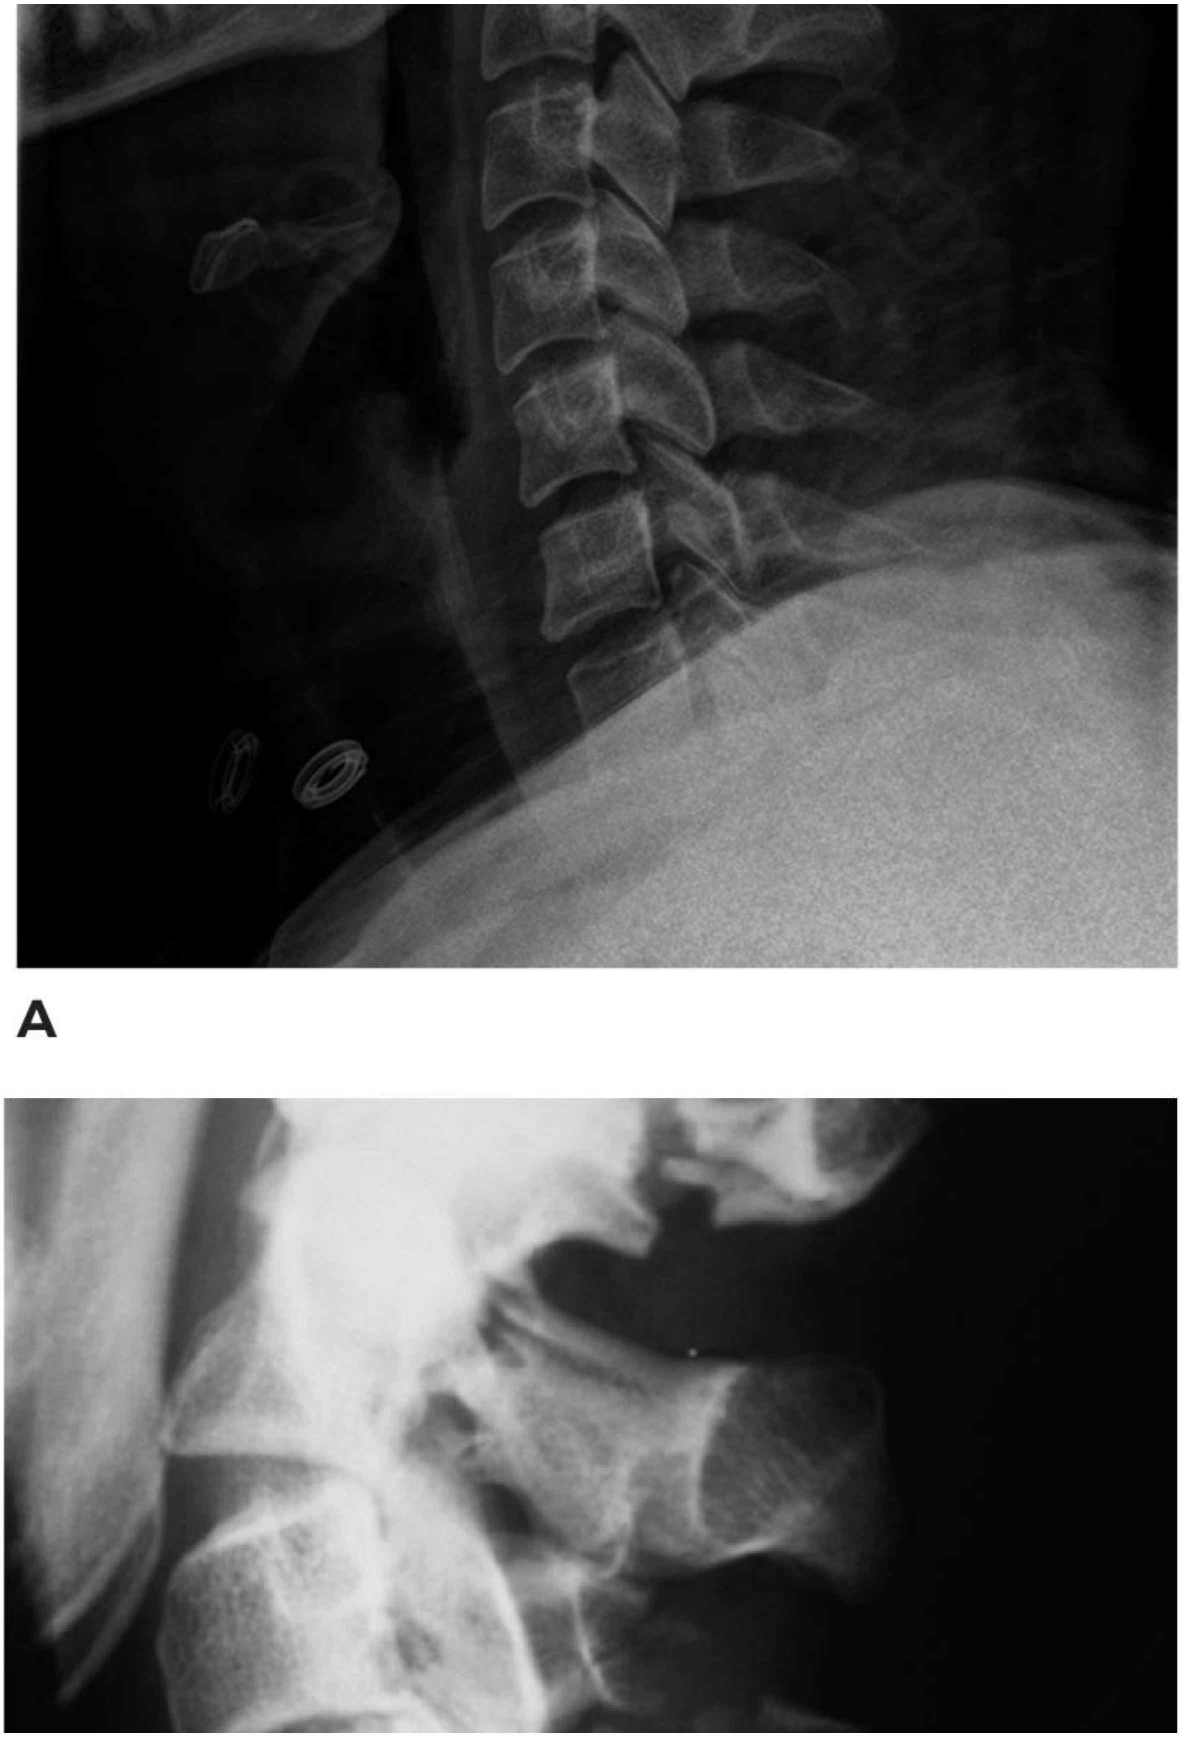
Obtaining and understanding imaging studies related to trauma is an integral component of the trauma care paradigm for the CCTP. The use of diagnostic imaging helps direct further care for the trauma patient. Diagnostic imaging also confirms the previous care that has been delivered, such as endotracheal tube placement and invasive catheters.

Many exciting advances and new procedures have been introduced in regard to diagnostic imaging. This section briefly covers the developments related to CCTPs' practice in trauma care.

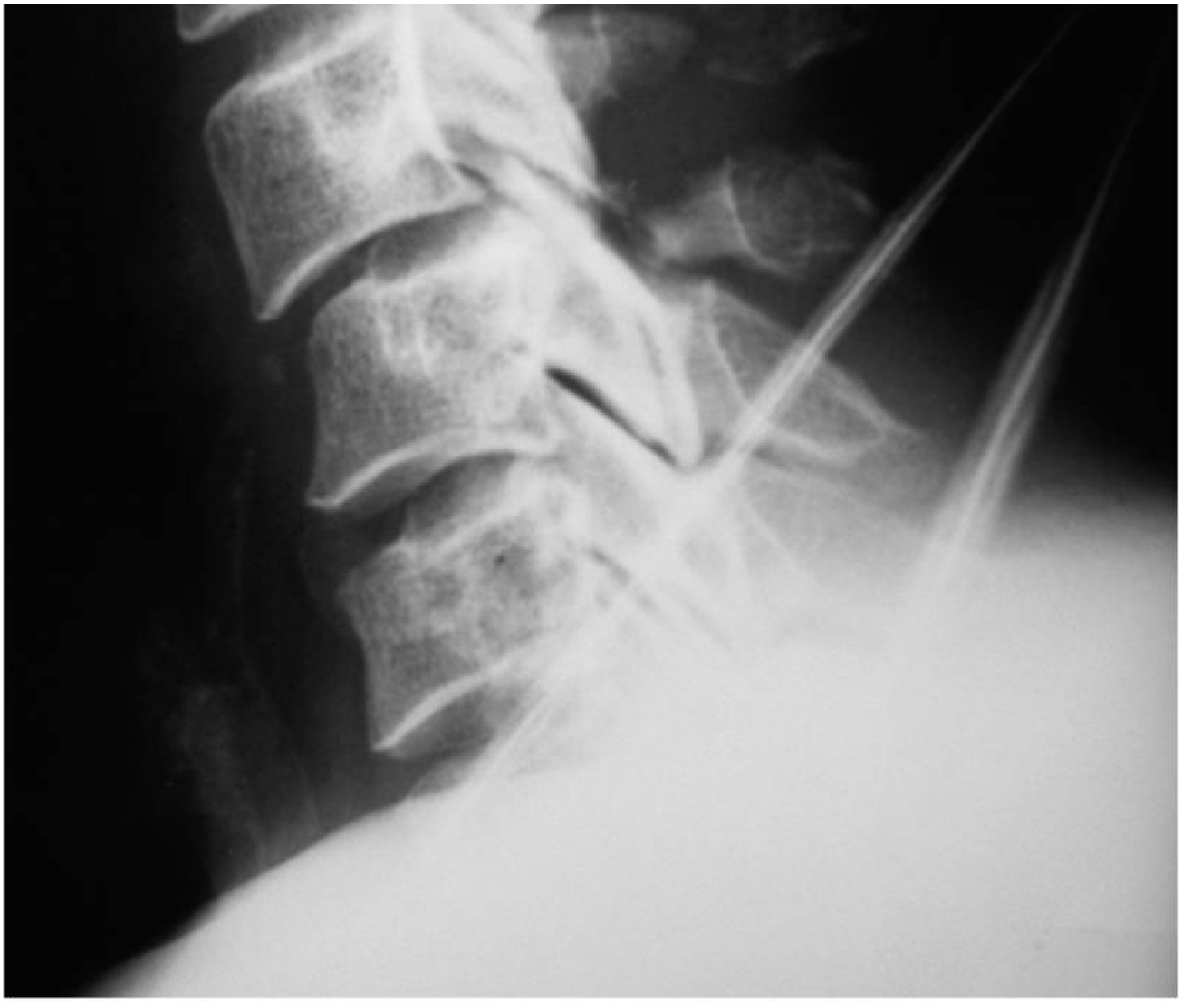
Standard Radiographs

Standard radiographs, such as a chest radiograph, are part of the initial assessment of the patient with multisystem trauma. They can provide information on endotracheal tube depth, fractures, and chest injuries. Examples of normal and abnormal cervical spine radiographs are shown in **FIGURE 11-4** and **FIGURE 11-5**.





A



B

FIGURE 11-4 A. Normal cervical radiograph. **B.** Abnormal cervical radiograph.

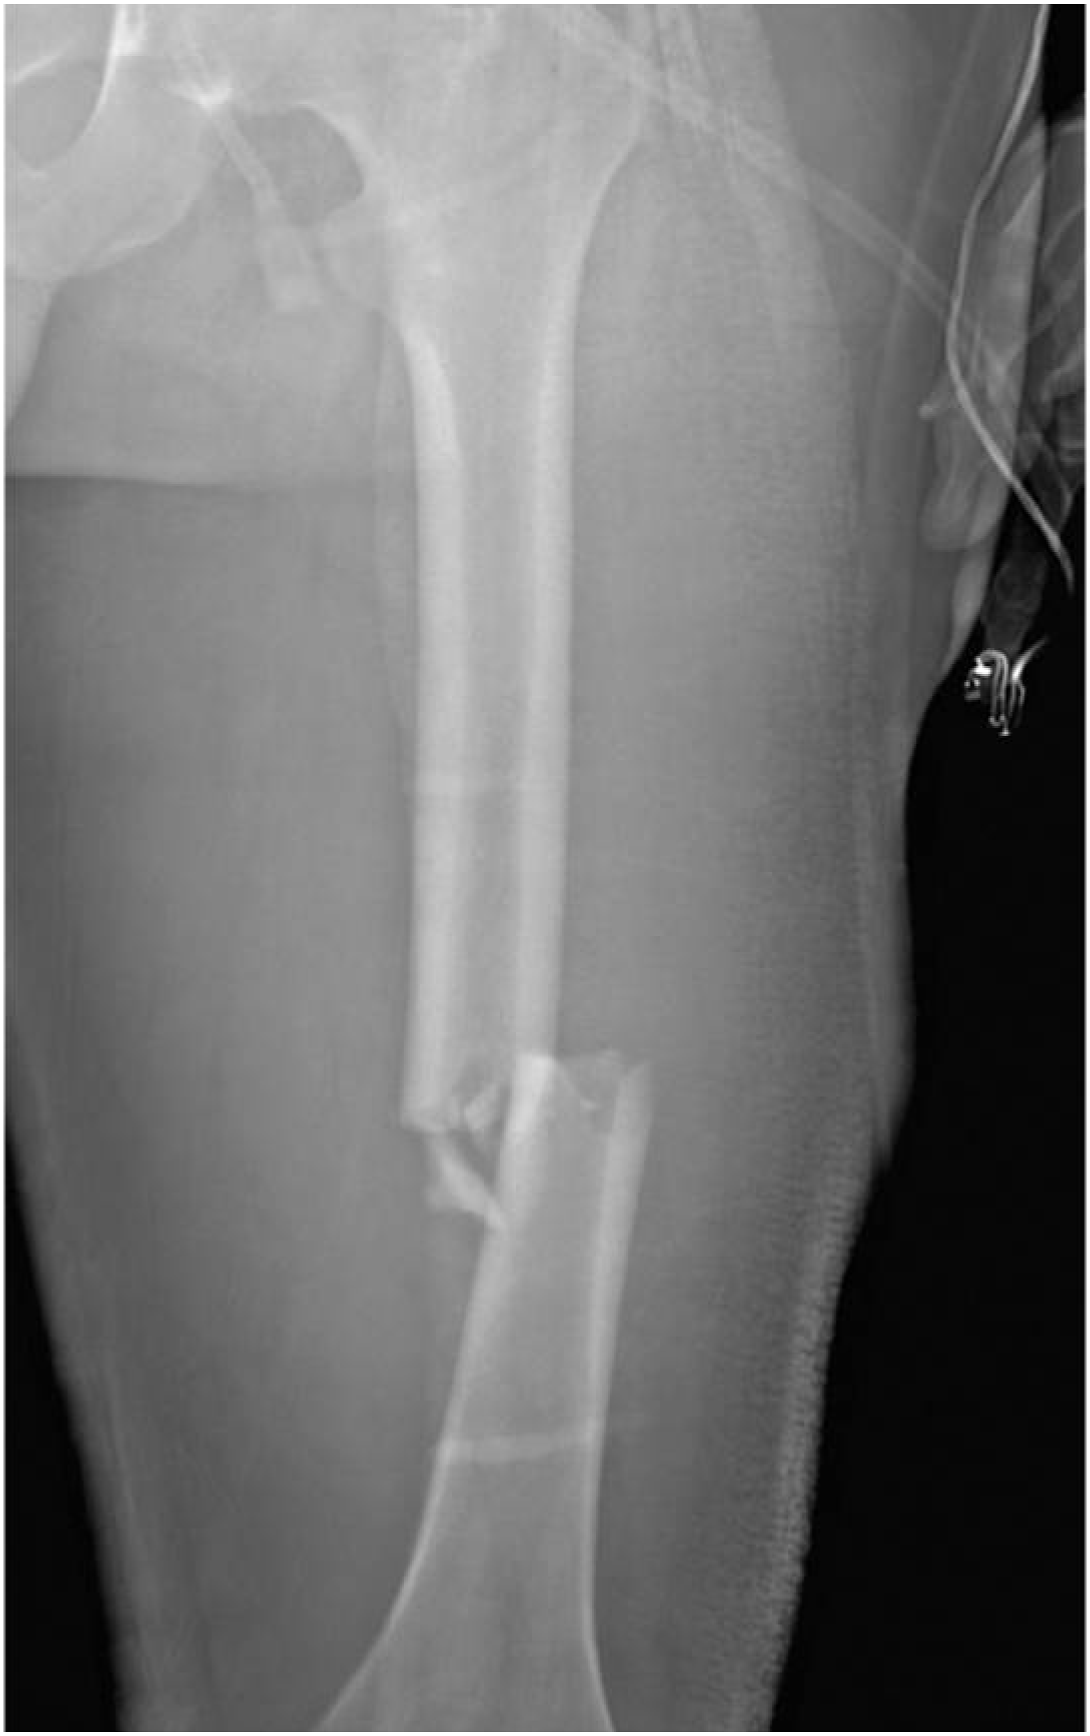
RIGHT
A



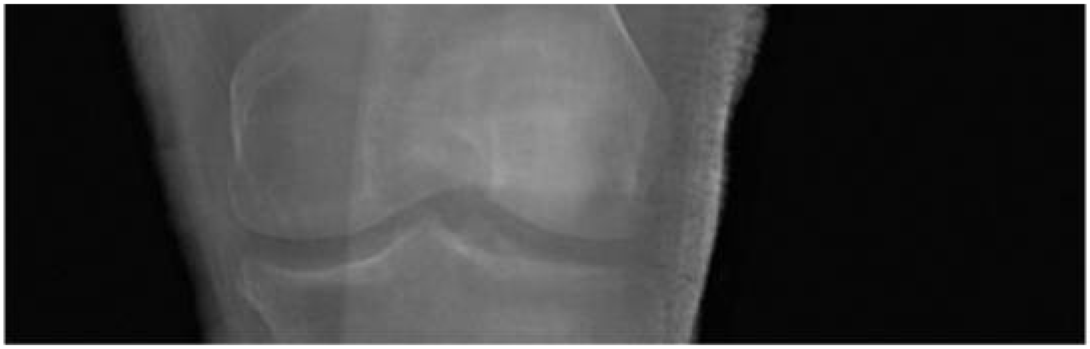


FIGURE 11-5 A. Normal long bone radiograph. **B.** Abnormal long bone radiograph (transverse femur fracture in an adult with shortening and marginal comminution).

Courtesy of Andrew N. Pollak, MD, FAAOS.

Typical interpretation of radiographs involves the following elements:

- Structure and landmark verification
- Proper size and placement of anatomic structure or devices
- Symmetry of structures
- Foreign object identification

Computed Tomography

Computed tomography (CT) is another imaging study that is essential in diagnosing traumatic injury. For trauma patients, it is typically used for head injury identification (**FIGURE 11-6**), identification of bleeding, and complex fractures. Typical studies will scan the head, cervical spine, thoracic and lumbar spines, chest, and abdominal-pelvic regions. Interpretation of CT images is similar to that for plain radiographs because the images depict the contrast between different structures.

Ultrasonography

Focused assessment with sonography for trauma (FAST) is an ultrasonographic examination directed at identifying the presence of pericardial or intraperitoneal free fluids. It was first described in the early 1970s and has since been adopted by a multitude of practitioners who perform point-of-care ultrasonography in the trauma setting. Recent studies have validated the use of the FAST examination as noninferior to more invasive methods of clinical investigation such as **diagnostic peritoneal lavage (DPL)** or CT scan. For the FAST examination to be effective, approximately 150 to 200 mL of free fluid must be present. Notably, negative imaging, especially in early assessments, does not necessarily rule out evolving injuries.

The role of ultrasonography in *blunt* abdominal trauma has been well studied. Excellent evidence supports the use of the FAST examination as the initial diagnostic modality for the evaluation of peritoneal free fluid in these patients. In the context of blunt abdominal trauma, practitioners accept the accuracy rate for ultrasonography as being nearly equivalent to that of DPL or CT. The adoption of the noninvasive FAST examination serves as an important diagnostic tool in determining which patients will require **exploratory laparotomy**—that is, open surgical exploration of the abdomen to look for a source of unexplained acute blood loss.

The evidence is less clear for the use of ultrasonography in the setting of *penetrating* thoracoabdominal trauma. The current literature demonstrates that ultrasonography is an excellent screening tool for penetrating pleural and cardiac injuries and has a high sensitivity for detecting injuries requiring acute intervention. For abdominal injuries, however, the sensitivity for detection of injury is low; thus, the utility of ultrasonography as a screening tool is limited in patients with such injuries. Most cases of penetrating thoracoabdominal trauma will require operative exploration, diminishing the value of imaging during the initial assessment.

The FAST examination is performed by imaging the pericardial space and three distinct areas of the abdomen. Several different cardiac views can be used while evaluating for an **anechoic** (an area free from echo; black on ultrasonogram) stripe between the heart and the pericardium. The abdominal area that is the most sensitive for the detection of free fluid—and is imaged first—is the hepatorenal space or Morison pouch. This region of the right upper quadrant is the interface between the liver and the right kidney. Free fluid will appear as an anechoic stripe between the organs in imaging of the hepatorenal space. The second area imaged is the left upper quadrant or splenorenal space; on imaging of this area, free fluid may be observed either under the diaphragm (superior to the spleen) or between the spleen and the left kidney. The third area of the abdomen imaged is the pelvis. Free fluid will accumulate here dependently in the rectouterine space (pouch of Douglas) in women or in the vesicorectal space in men. The FAST examination can be repeated if concern for evolving injury or ongoing bleeding exists.

Studies have also shown that the extended FAST (e-FAST) exam can reliably identify thoracic injuries such as pneumothorax and hemothorax. In the supine patient, the anterior chest wall is evaluated for contact between the pleural layers, shown by the lung sliding against the pleura. When this contact is confirmed, it excludes the possibility of air or fluid in the pleural space. The lung bases are evaluated for free fluid when evaluating for hemothorax. When present, anechoic free fluid will be visualized just above the diaphragm.

The FAST examination does have some limitations. First, it does not evaluate directly for solid-organ injury, but rather looks for the bleeding that occurs and accumulates as a result of injury to such an organ. Second, it does not evaluate the retroperitoneal space, so injuries to organs such as the pancreas or aorta may go undetected. Finally, the FAST examination evaluates for the presence of fluid, but does not identify the specific type of fluid. As a consequence, it may be impossible to differentiate blood from pericardial effusion, pleural effusion, or ascites. The presence of free fluid must always be assessed within the clinical context of the patient.

The FAST approach has been adopted by some transport services as well as for use in the prehospital setting, using smaller and more portable equipment **FIGURE 11-7**. It has shown much promise in the early identification of thoracoabdominal bleeding and may assist in transport decisions when varying levels of trauma care are available. Training standards for performing this procedure vary, but at a minimum usually require specific credentialing and substantial experience.

Transthoracic Echocardiography and Transesophageal Echocardiography

Critical care clinicians sometimes use other focused exam algorithms such as HEARTscan, FATE, FEEL, FEAR, and BLEEP, all of which are intended to rapidly determine pathology in critically ill or injured patients using transthoracic echocardiography (TTE). Additionally, transesophageal echocardiography (TEE), which involves inserting a probe into the esophagus, has revolutionized intraoperative cardiac monitoring. TEE is widely employed in cardiothoracic and vascular surgery cases to provide real-time evaluation of cardiac function and fluid volume status during surgery. As esophageal probe technology becomes more miniaturized, intensive care unit (ICU) clinicians, including critical care nurses, are beginning to use TEE for longer-term evaluation, assessment, and monitoring of patients' hemodynamics.

Magnetic Resonance Imaging

The contrast differences illuminated by magnetic resonance imaging (MRI) are sometimes used to identify abnormalities in trauma patients **FIGURE 11-8**. Nevertheless, MRI is typically of limited use in trauma patients because these devices are not always readily available and it takes considerable time to obtain the images—time that critically injured patients may not have.

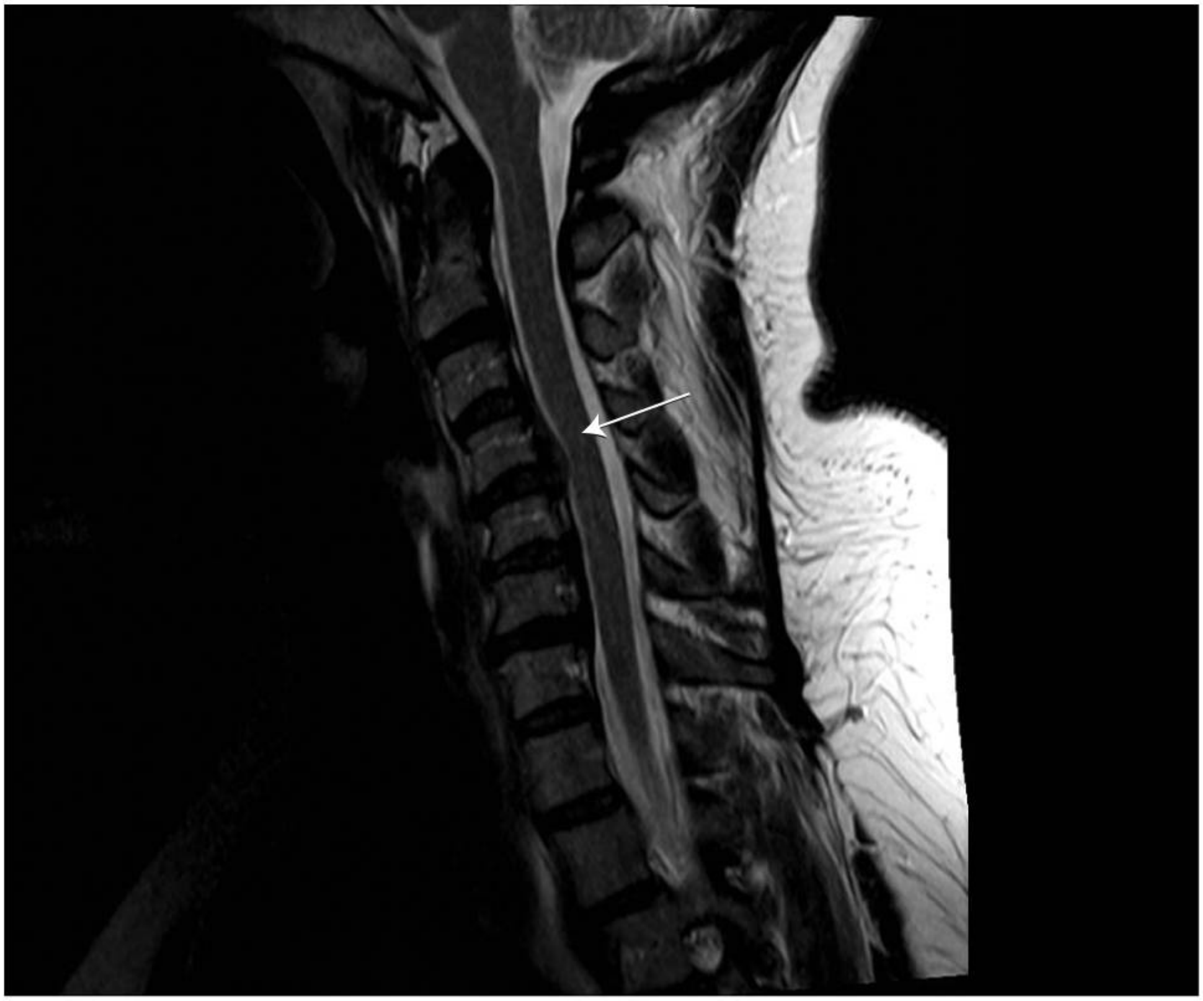

FIGURE 11-8 Magnetic resonance image showing C4-C5 bulge with pressure on the spinal cord (arrow).

Courtesy of Andrew N. Pollak, MD, FAAOS.

Intra-abdominal Pressure Monitoring

Intra-abdominal pressure (IAP) is the static pressure inside the abdominal compartment. Normally, IAP is approximately 0 to 5 mm Hg, with variations caused by respirations. Nonpathologic increases in IAP can occur with obesity. Recent studies of IAP in critically ill medical and surgical patients have found elevated pressures to be relatively common. The deleterious effects of intra-abdominal hypertension (IAH) can lead to abdominal compartment syndrome (ACS) and death if left untreated. ACS is thought to play a significant role in end-organ damage and multisystem organ failure during critical illness.

IAP can be measured with a variety of commercial devices or with user-assembled equipment. The current reference standard uses a transducer connected to an indwelling urinary drainage catheter located within the bladder. IAP is expressed in millimeters of mercury (mm Hg); it is measured at end expiration with the patient supine and the pressure transducer placed at the iliac crest at the midaxillary line. The recommended technique uses a pressure transducer connected by tubing at or near the aspiration port of the urinary catheter drainage tubing. To measure IAP, follow these steps:

1. Clamp the tubing distal to the connection.
2. Instill 50 mL or less of sterile room-temperature saline through the pressure measurement system into the bladder.
3. Record the measured pressure after a 30- to 60-second stabilization period **FIGURE 11-9**.

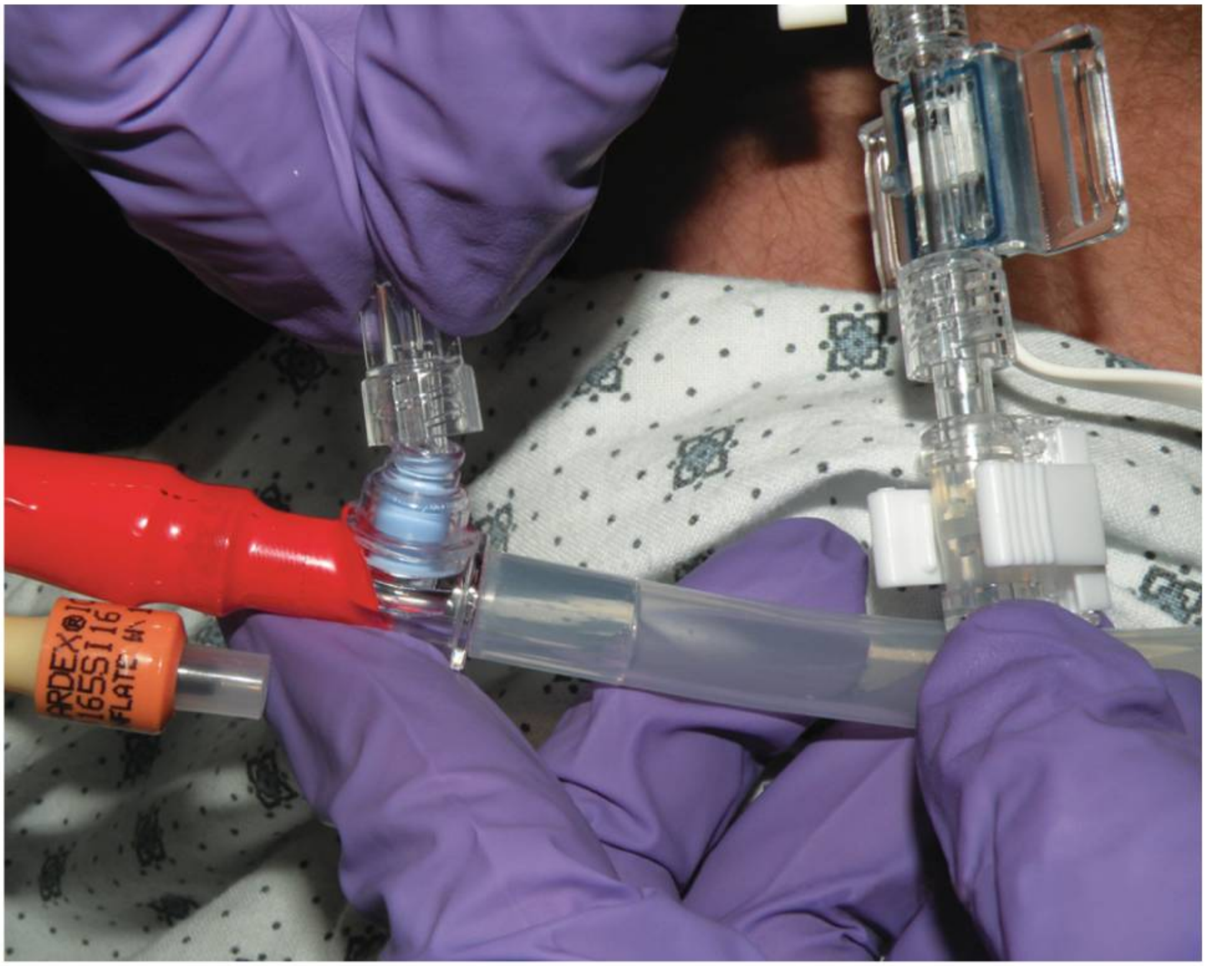

FIGURE 11-9 The CCTP may be asked to obtain intra-abdominal pressure measurements during transport.

© Jones & Bartlett Learning.

IAH is defined as a sustained IAP of greater than or equal to12 mm Hg. It has multiple causes, not all of which are associated with trauma or surgical procedures to the abdomen.

ACS is defined as a sustained IAP of greater than 20 mm Hg with new-onset single- or multiple-organ system failure. ACS is classified into three types:

- *Primary:* Results from surgical interventions or injuries to the abdominal-pelvic region—for example, in conjunction with damage-control exploratory laparotomy, massive retroperitoneal hematomas, liver transplantation, and failed nonoperative management of injury or disease.

- *Secondary:* Develops as a result of conditions outside the abdomen, such as sepsis, burns, and capillary leakage resulting from massive fluid resuscitation.
- *Recurrent:* Recurrence of ACS following initially successful surgical or medical treatment of primary or secondary ACS.

Although definitive treatment for acute ACS is surgical decompression (often with the abdomen left open until swelling is decreased), prevention through careful monitoring and targeted medical management is highly encouraged. Interventions to reduce the risk of IAH and to prevent IAH from progressing to ACS include neuromuscular blockade, drainage of free fluid in the abdominal cavity (**paracentesis**), decompression of the gastrointestinal tract using gastric tubes, prokinetic drugs (to stimulate intestinal motility), and close attention to prevention of fluid volume overload.

The CCTP may observe IAP monitoring equipment being used in the ICU or emergency department (ED) setting and may be asked to obtain IAP measurements during transport. Familiarity with the equipment used for this purpose is necessary to accurately obtain measurements.

Transport Considerations

Given the need to provide rapid care to the trauma patient, not all indicated studies may have been performed at the point in time when the CCTP encounters such a patient. Nevertheless, the CCTP should have and maintain some proficiency in interpreting imaging for obvious abnormalities. Reviewing imaging that has been performed can limit liability, confirm suspicions about the diagnosis, and document accurate placement of tubes and lines or performance of procedures. Various methods of training are available to the CCTP, and most services provide internal training sessions as well.

Even with advances in technology and the electronic transmission of imaging, the CCTP should always ask for and ensure that all copies of the imaging studies are present in the patient care record or have been uploaded to a portal accessible to the receiving facility. Some data storage devices may be as small as a disk or thumb drive, so be careful not to misplace or lose them.

Thoracic Trauma

Thoracic trauma accounts for approximately one-third of trauma-related deaths in the United States. Of all trauma deaths, one in four (25%) is directly associated with thoracic injuries. Falls and motor vehicle accidents are the leading causes of chest trauma, but these mechanisms can also cause underlying lung injury that does not become obvious until days after an accident. Given these statistics, it is imperative for the CCTP to have a thorough understanding of the complex anatomy and physiology of the thoracic cavity. Note that only 15% to 20% of these potentially catastrophic injuries require open chest surgery; the majority can be managed with relatively simple interventions within the scope of the CCTP.

The thorax is essentially a bony cage consisting of 12 pairs of ribs that join anteriorly with the sternum and posteriorly with the thoracic spine **FIGURE 11-10**. The chest consists of two thoracic cavities, each containing one lung. The mediastinum, which contains the heart, superior and inferior venae cavae, aorta, bronchi, trachea, and esophagus, is located between the two cavities. The diaphragm inserts into the thoracic cage below the fifth rib and separates the chest and abdominal cavities.

Description

The primary function of the thorax is to facilitate adequate oxygenation and circulation. Thus, injuries to the chest must be promptly found and managed to avoid compromise to this critical function. Injuries to the thoracic region can result from either blunt or penetrating injuries, and the CCTP must conduct a thorough assessment to avoid missing any such life-threatening injuries.

The chest is normally a closed compartment with a single inlet and outlet through the trachea. The changes in pressure necessary for ventilation depend on the ribs, diaphragm, and pleural membrane all being intact and working properly. One-half of all chest injuries involve the chest wall. Recent research has emphasized the importance of this anatomic relationship and the critical nature of normal intrathoracic pressures for adequate circulation and ventilation. Especially when the patient has hypotension, excessive intrathoracic pressure can interfere with adequate venous return or preload. Therefore, care must be taken in trauma patients to ensure adequate positive-pressure ventilations without allowing intrathoracic pressure to rise too high.

Maintaining this balance may become a challenge during flight. Atmospheric pressure declines as the aircraft goes higher, allowing gas volume to expand in a closed space. This gas expansion may make a small tension pneumothorax larger. In addition, less gas will be needed to ventilate a patient using a gas-powered ventilator.

Pneumothorax

A **pneumothorax**, which can be either open or closed **FIGURE 11-11**, is reported to be present in 15% to 50% of chest injuries. An **open pneumothorax** (also known as a communicating pneumothorax) is commonly called a sucking chest wound **FIGURE 11-12**, even though it does not always make a sucking noise. A **tension pneumothorax** occurs when a defect in the chest wall allows air to enter the thoracic space, disrupting the normal adherence between the pleura (think of the suction between a wet glass and the countertop), but not escape, which causes the lung to collapse **FIGURE 11-13**. This condition often results from a penetrating injury to the outer chest, such as a stab wound, but it can also occur internally from a sharp broken rib end.

Description

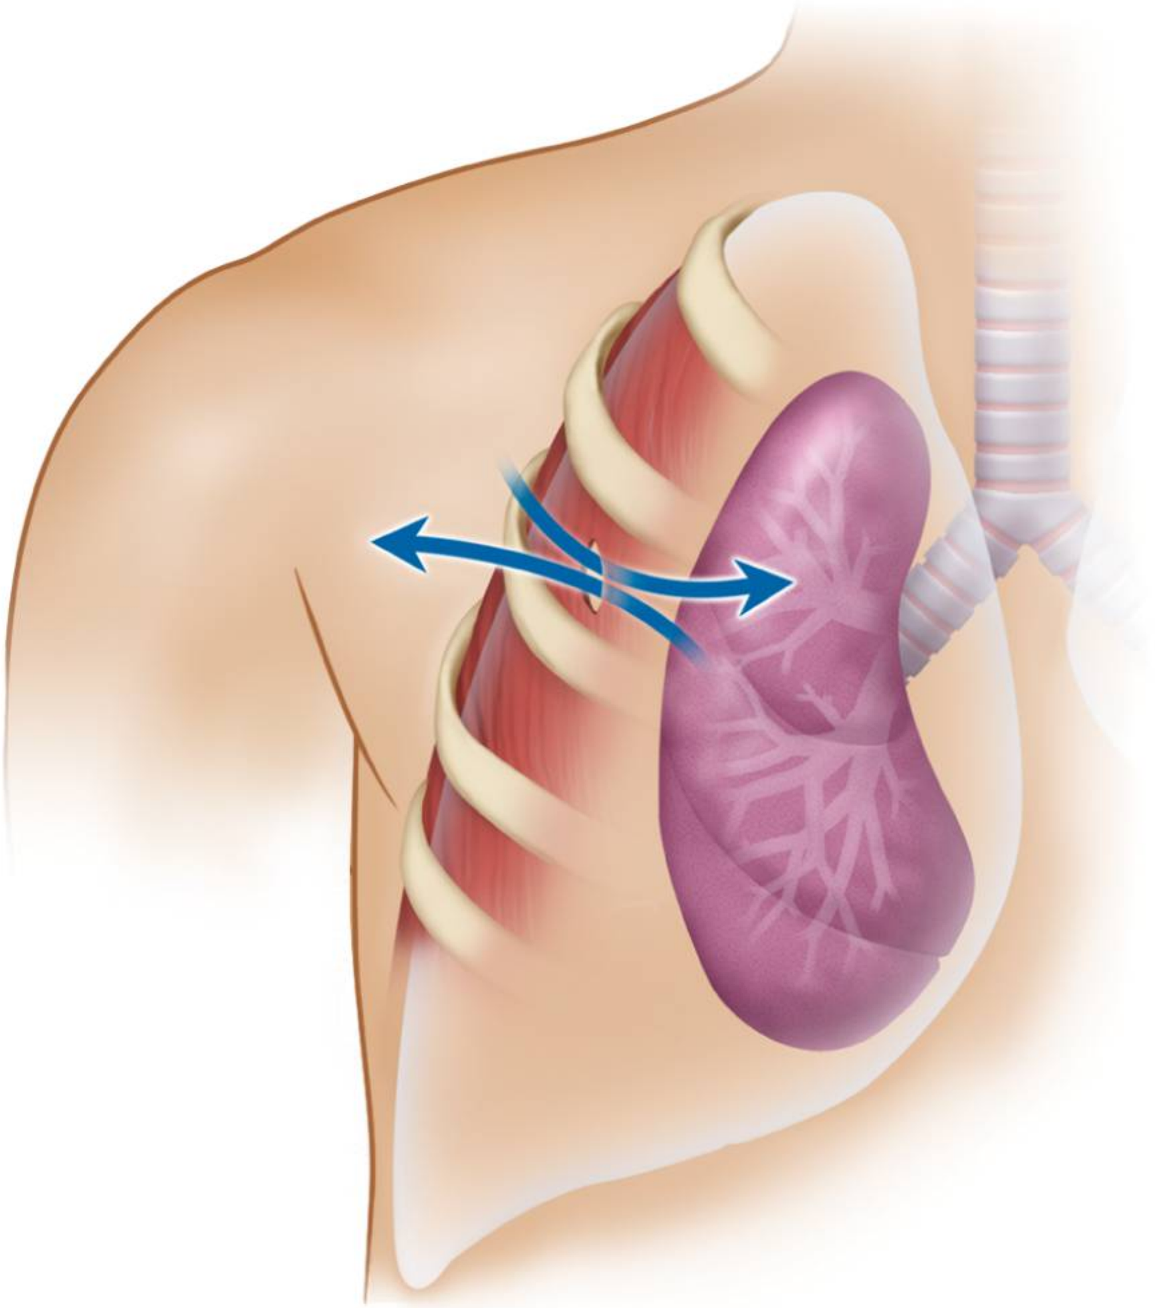

FIGURE 11-12 With a sucking chest wound, air passes from the outside into the pleural space and back out with each breath. The size of the defect does not need to be large to compromise ventilation.

© Jones & Bartlett Learning.

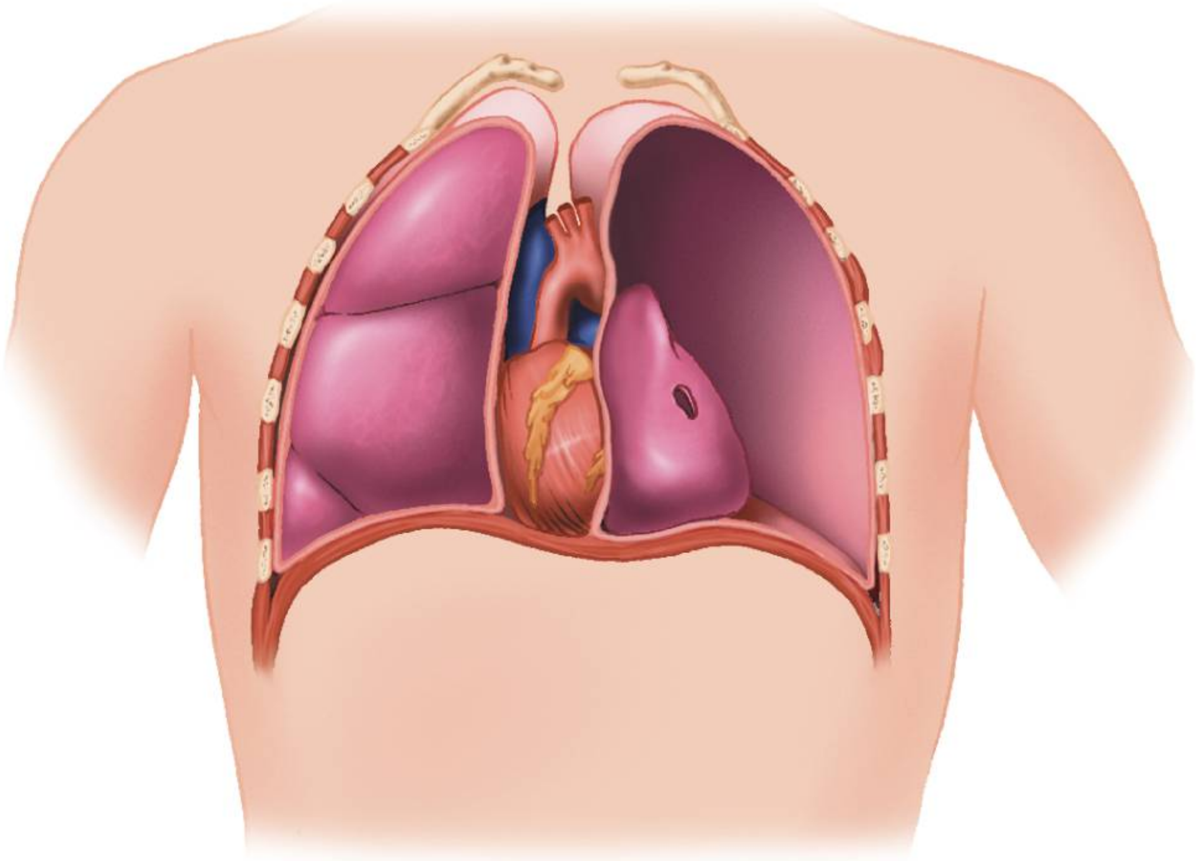

FIGURE 11-13 In a tension pneumothorax, air accumulates in the pleural space, eventually causing compression of the heart and great vessels.

© Jones & Bartlett Learning.

These types of injuries cause air to be drawn into the thoracic cavity with each breath. The air enters the space in the pleural cavity, increasing the pleural pressure and causing the lung to collapse due to its relative lower pressure. As the lung collapses, it does not oxygenate the blood, resulting in hypoxia and shortness of breath. A collapse as small as 10% can be life threatening if the patient has other comorbidities; additionally, a pneumothorax this small may be difficult to appreciate by auscultation.

The differential diagnosis for respiratory distress in chest trauma includes the following conditions:

- Simple pneumothorax
- Tension pneumothorax
- Flail chest
- Hemothorax
- Tracheobronchial injury
- Pulmonary contusion

Open Pneumothorax

To promote adequate oxygenation and ventilation, it is critical that the CCTP recognize and treat an open pneumothorax as soon as possible.

The following equipment is needed for managing an open pneumothorax:

- Appropriate personal protective equipment (PPE)
- Occlusive dressing
- Medical tape

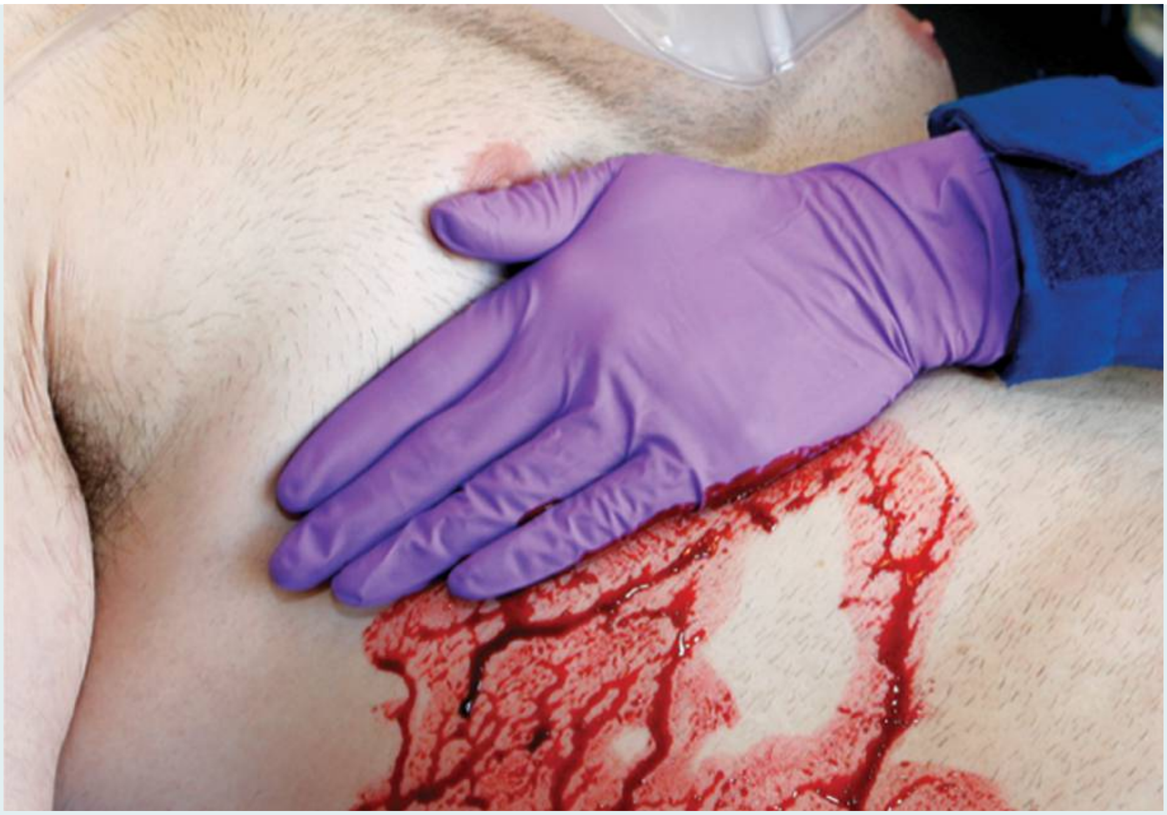
Indications for this treatment include emergency relief of dyspnea secondary to open pneumothorax. Contraindications include tension pneumothorax.

Sealing a sucking chest wound may induce a tension pneumothorax if air can enter the thoracic cavity but not escape. This condition can occur if air enters the pleural cavity from the lung side of the wound and builds up, or if the seal is incomplete. If this happens, the CCTP should “burp” the dressing by releasing an edge and allowing the pressure to equilibrate. Many techniques of sealing sucking chest wounds attempt to address these issues, but pressure buildup or an ineffective seal may still occur. Once a seal is applied, constant surveillance is necessary to guard against either possibility. Assisted ventilation and/or needle decompression may be necessary. Of note, debate exists regarding the most appropriate means of achieving an occlusive seal over an open chest wound. Regardless of the method employed, the objective is to achieve an occlusive seal and prevent or relieve subsequent pressure buildup.

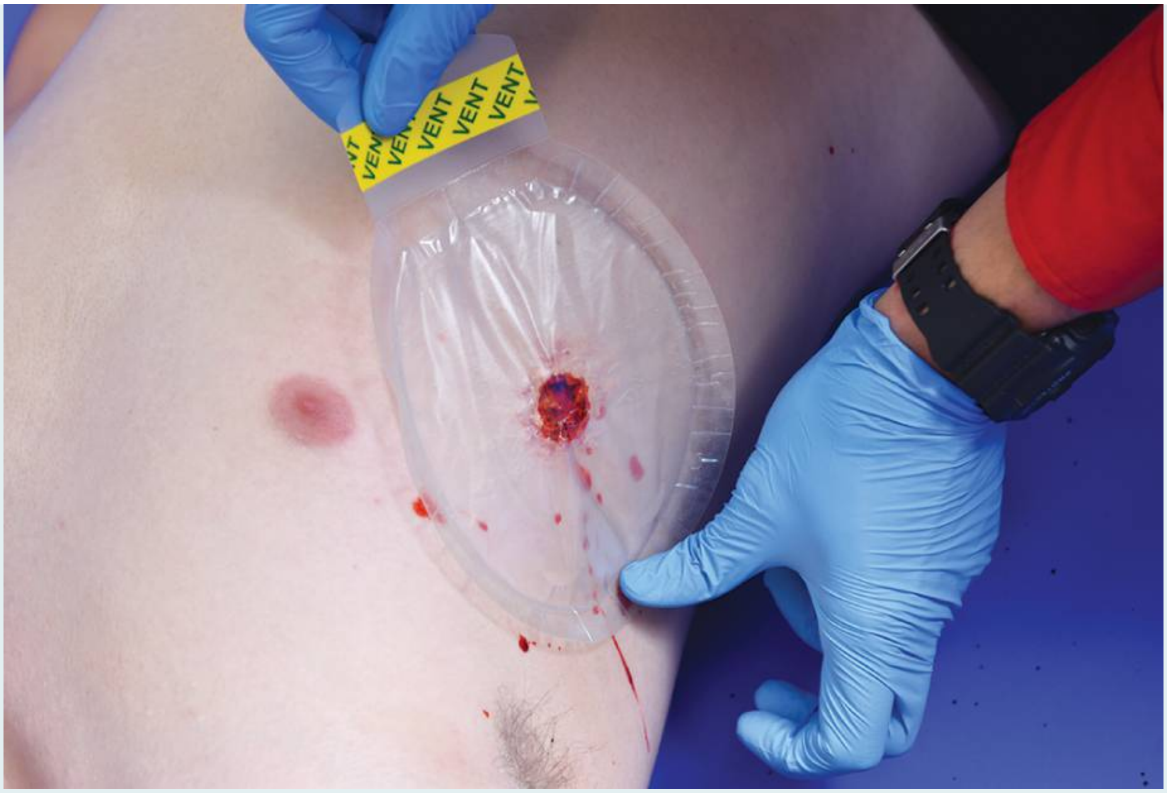
Skill Drill 11-1 illustrates the clinical procedure for managing an open pneumothorax, which is described here:

SKILL DRILL 11-1 Managing an Open Pneumothorax

Step 1
Maintain an open airway and administer appropriate oxygen therapy.



Step 2
Immediately close the chest wound, initially with a gloved hand.



VENT
VENT
VENT
VENT
VENT

Step 3
Apply an occlusive dressing, preferably during patient exhalation, that is taped down on three or four sides.

Step 4
Monitor oxygen saturation, vital signs, and the cardiac monitor. Watch for development of a tension pneumothorax or an inadequate seal, and stay alert to the need for needle decompression or assisted ventilation.

All images © Jones & Bartlett Learning.

1. Maintain an open airway and administer appropriate oxygen therapy **STEP 1**.
2. Immediately cover the chest wound **STEP 2**. This can be initially accomplished by the use of a gloved hand. However, to reduce the risk of a tension pneumothorax, apply an occlusive dressing, taped down on three or four sides **STEP 3**. Adequate overlap on the open edge is required to create a good seal. Many commercial devices are available for this purpose.
3. Monitor oxygen saturation, vital signs, and the cardiac monitor **STEP 4**.

4. Watch for development of a tension pneumothorax or an inadequate seal, and stay alert to the need for needle decompression or assisted ventilation.
5. Transport the patient to an appropriate facility.

Possible complications include converting an open pneumothorax to a tension pneumothorax. The CCTP should watch for increasing difficulty in breathing, elevated peak inspiratory pressures (PIPs), increased work of breathing, restlessness, and agitation. Late signs may include **tracheal tugging**, **tracheal deviation**, and jugular venous distention (JVD).

Signs and Symptoms

Open Pneumothorax

- Penetrating chest trauma with a sucking sound (“sucking chest wound”)
- Dyspnea
- Tachypnea

Transport Management

Open Pneumothorax

- Maintain an open airway and administer appropriate oxygen therapy.
- Immediately close the chest wound, initially with a gloved hand.
- Apply an occlusive dressing, taped down on three or four sides.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Watch for the development of a tension pneumothorax or an inadequate seal, and stay alert to the need for needle decompression or assisted ventilation.
- Consider inserting a chest tube or pigtail catheter if your protocol allows.
- Monitor the chest tube drainage system during transport.

Simple Pneumothorax

A simple pneumothorax is most often associated with a closed chest injury, such as from a fractured rib being driven inward into the lung or a collapsed lung that results from a medical cause—a condition often called a spontaneous pneumothorax. Loss of the negative pressure holding the two layers of the pleura together allows the lung to collapse like an empty balloon. The term “simple pneumothorax” actually refers to any pneumothorax that is not a tension pneumothorax; thus, it may be used to refer to an open or closed pneumothorax as long as there is no buildup of pressure in the pleural cavity outside the lung.

Tension Pneumothorax

A tension pneumothorax is a life-threatening injury that results from a continual influx of air into the pleural space. It may occur secondary to a closed simple pneumothorax or after sealing an open pneumothorax, which increases intrathoracic pressure, hampers the body’s ability to oxygenate blood or eliminate carbon dioxide from blood, and eventually collapses the affected lung. The collapse in the lung causes the mediastinum to shift away from the injured side, resulting in ventilatory and circulatory compromise from the collapsed lung. The great vessels and the heart become deformed under the pressure. Failure to treat a tension pneumothorax will cause the patient to progress to pulseless electrical activity and cardiopulmonary arrest.

Clinical signs and symptoms of a tension pneumothorax include dyspnea, anxiety, JVD (although this may be absent due to hypovolemia), tachypnea, and tracheal deviation (a late sign not often observed in the prehospital setting). Tracheal tugging during inspiration—a much more subtle sign—is observed much earlier in the process; the CCTP should actively look for this sign. The most important signs, however, are increasing dyspnea, decreasing ventilatory compliance with assisted ventilations, and increasing PIPs or peak airway pressures, depending on the settings if the patient is receiving ventilation. Auscultation of lung sounds will reveal diminished or absent breath sounds (which are difficult to appreciate in an aircraft and at noisy scenes) on the affected side if the pneumothorax is large enough. Pulsus paradoxus (a pulse that disappears on inspiration and that also can be associated with a drop in systolic blood pressure), electrical alternans (alternating between a large QRS complex and a small QRS complex), and elevated central venous pressure (CVP) may be present as well. In a patient with tension pneumothorax, PIP will increase despite the patient having an open airway.

Management of tension pneumothorax is performed by immediate needle decompression. The following equipment is needed to perform this procedure:

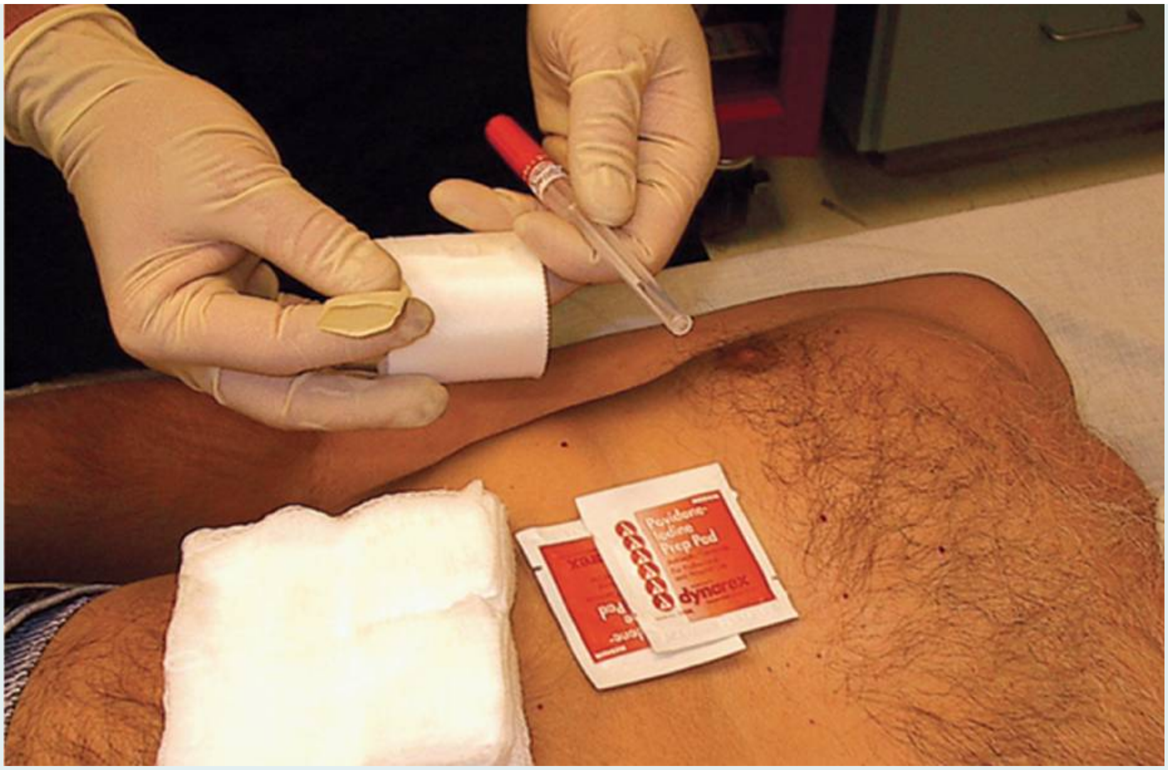
- Appropriate PPE, including sterile gloves
- 14-gauge or larger intravenous (IV) catheter (minimum 3.25 inches [8 cm] in length)
- 10-mL syringe with 1 to 2 mL of sterile saline in it, which enables the CCTP to see bubbling air escaping (it is too difficult to hear in many cases)
- 2% chlorhexidine
- Flutter valve (Heimlich or nonlubricated condom or glove finger) optional
- Sterile dressings

Indications for this treatment include emergency relief of tension pneumothorax. Contraindications include patients without signs of a tension pneumothorax.

Skill Drill 11-2 demonstrates the clinical procedure for managing a tension pneumothorax, which is described here:

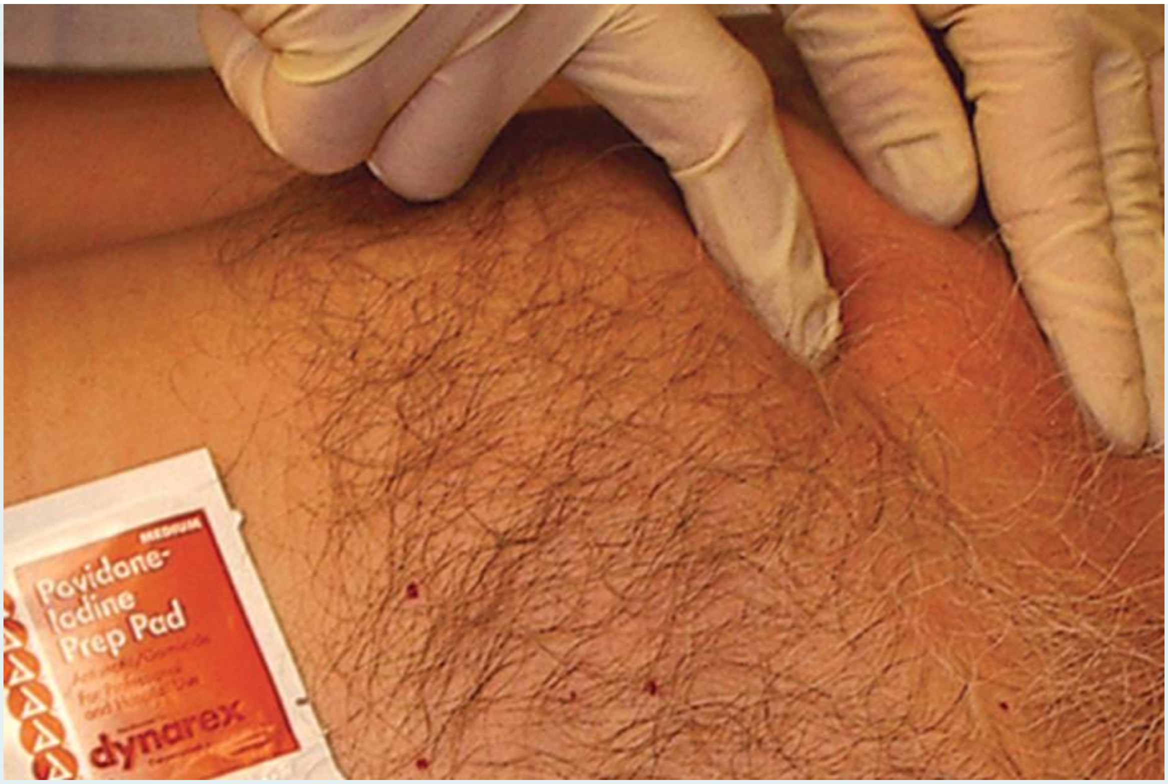
SKILL DRILL 11-2 Needle Decompression (Thoracentesis) of a Tension Pneumothorax

Step 1
Assess the patient.



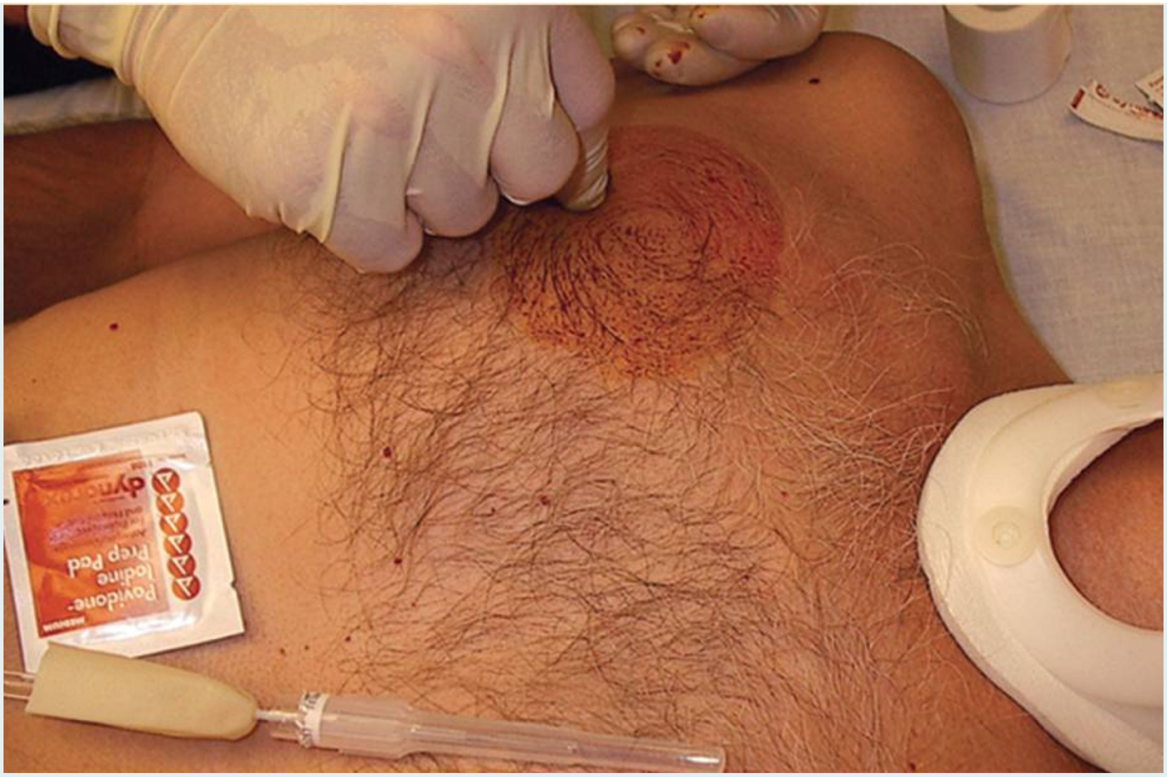
Povidone-Iodine Prep Pad
dynarex

Step 2
Prepare and assemble all necessary equipment.



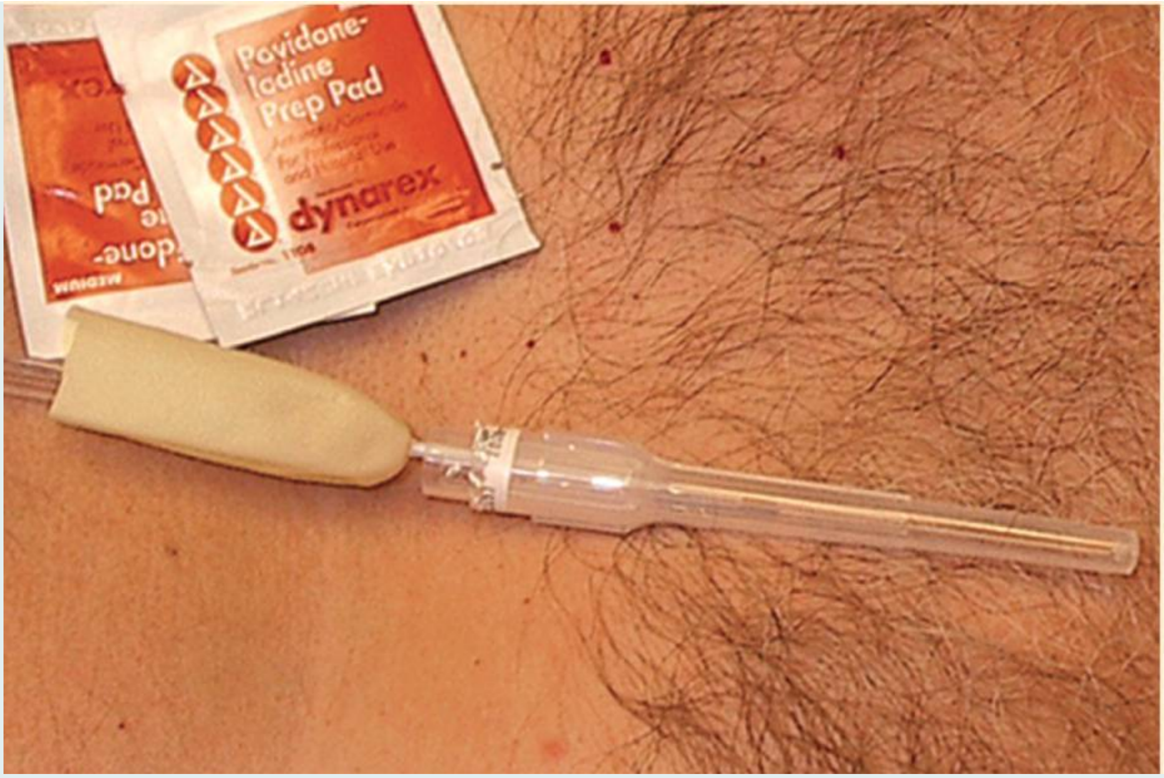
MEDIUM
Povidone-Iodine Prep Pad
dynarex

Step 3
Locate the appropriate site. The midclavicular line between the second and third ribs is shown here, but the space between the fifth and sixth ribs at the anterior axillary line may also be used.



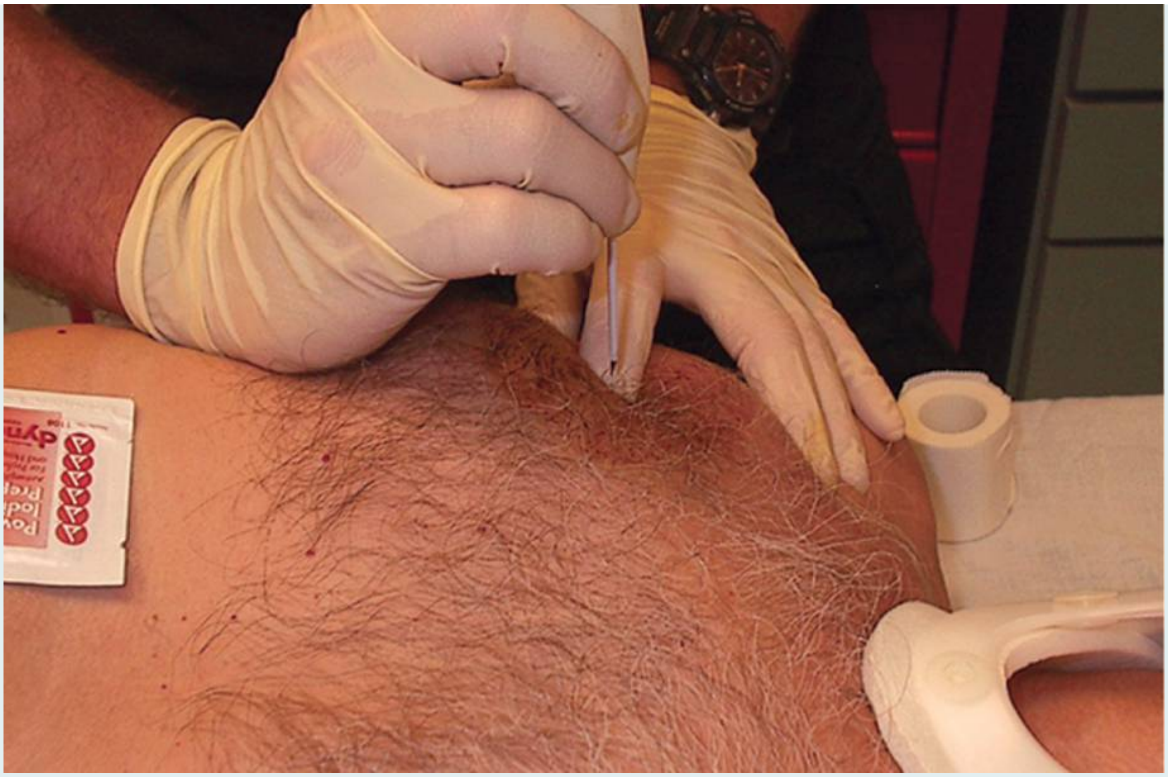
dynarex
Povidone-
Iodine
Prep Pad

Step 4
Cleanse the appropriate area using an aseptic technique.

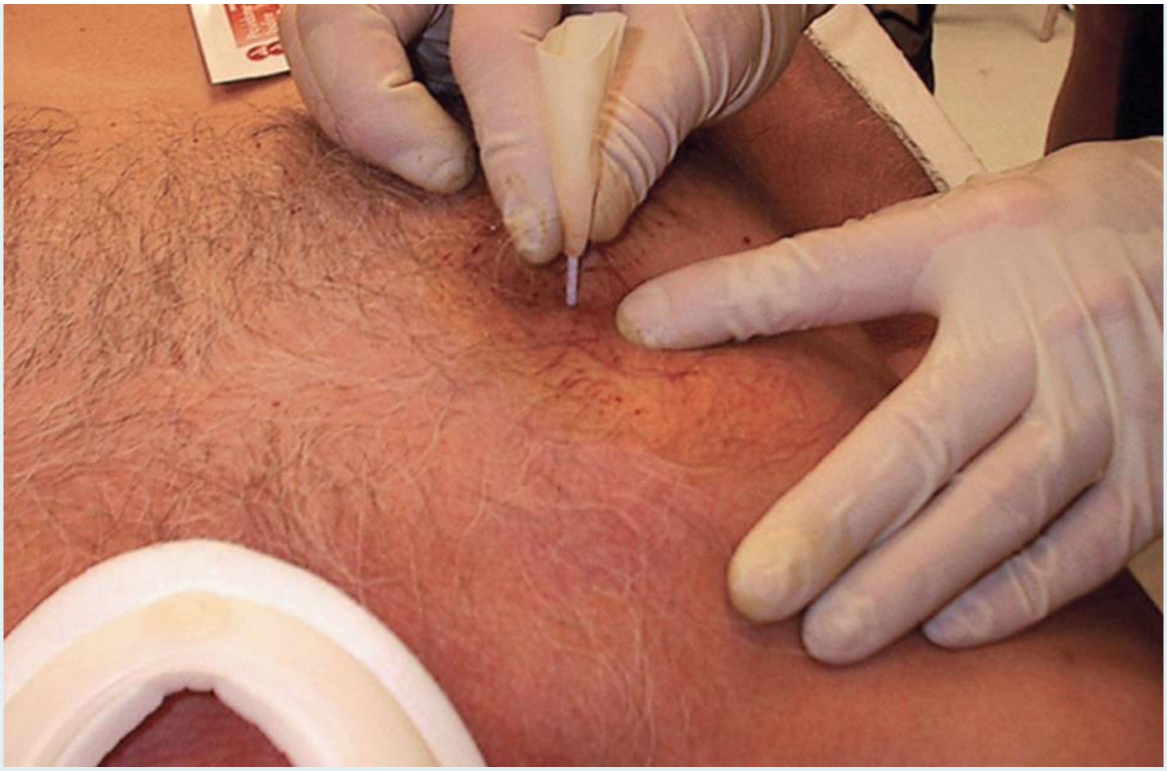


Povidone-
Iodine
Prep Pad
dynarex

Step 5
Insert the needle at a 90° angle to the skin and chest wall.



Step 6
Remove the needle and listen for the release of air or look for bubbling in the syringe. Properly dispose of the needle in a sharps container.



Step 7
Secure the catheter in place. Monitor the patient closely for recurrence of the tension pneumothorax.

All images © Jones & Bartlett Learning.

1. Assess the patient to ensure that the presentation matches that of a tension pneumothorax **STEP 1**.
    - Difficult ventilation despite an open airway (decreasing compliance or increasing PIP or peak airway pressure)
    - JVD (may not be present with associated hemorrhage)
    - Absent or decreased breath sounds on the affected side
    - Hyperresonance to percussion on the affected side
    - Tracheal deviation away from the affected side (a late sign that is not always present)
    - Electrical alternans and pulsus paradoxus
    - Elevated CVP

   - Signs of impending cardiovascular collapse
2. Prepare and assemble the necessary equipment **STEP 2**.
   - Large-bore IV catheter, preferably 10- to 14-gauge and at least 3.25 inches (8 cm) long on a syringe filled with 1 to 2 mL of sterile saline
   - Alcohol or 2% chlorhexidine
   - Adhesive tape
3. Select the appropriate site **STEP 3**: The placement shown is midclavicular, second intercostal space, above the third rib. Alternatively, you may use the anterior axillary line, above the fifth or sixth rib **FIGURE 11-14**. Go over the rib to avoid the neurovascular bundle under each rib.
4. Select the largest available needle. Optional: Attach the needle to a syringe with a few milliliters of saline so the bubbles are visible.
5. Cleanse the site with an appropriate aseptic technique **STEP 4**.
6. Insert the needle at a 90° angle over the rib **STEP 5**.
7. Remove the needle and listen for a rush of air or look for bubbles in the syringe **STEP 6**.
8. Advance the catheter over the needle and secure it in place **STEP 7**.
9. Dispose of the needle in a sharps container.
10. Closely monitor vital signs, oxygen saturation, and lung compliance.
11. Be prepared to repeat decompression if necessary.

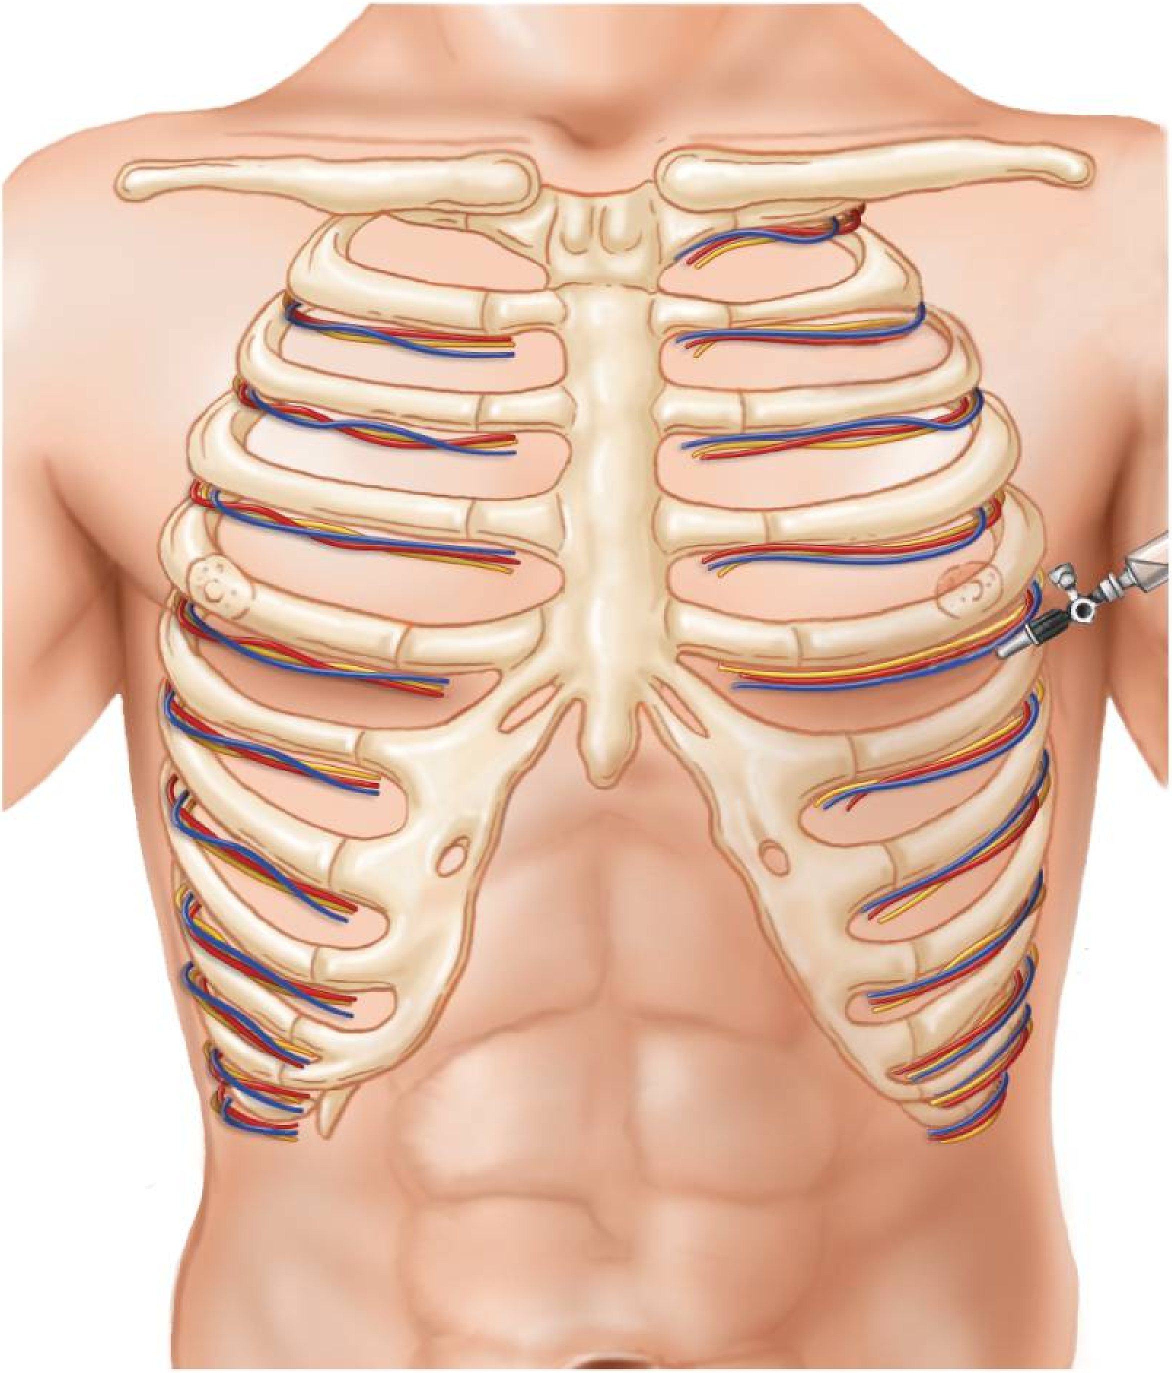


FIGURE 11-14 Correct placement for needle decompression if placing between the fifth and sixth ribs at the anterior axillary line. The positions of nerves, arteries, and veins are shown in relation to the ribs.

© Jones & Bartlett Learning.

Complications of needle decompression may include improper placement, which could lead to injury to the intercostal vessels and significant hemorrhage. Also, passing the needle into the chest may injure the lung parenchyma.

Signs and Symptoms

Tension Pneumothorax

- Dyspnea
- Anxiety
- JVD
- Tachypnea
- Tracheal deviation
- Tracheal tugging during inspiration
- Decreasing ventilatory compliance to bagging
- Increasing PIP or peak airway pressure, if the patient is on a ventilator
- Diminished or absent breath sounds on the affected side, if the pneumothorax is large enough
- Pulsus paradoxus
- Electrical alternans
- Elevated CVP

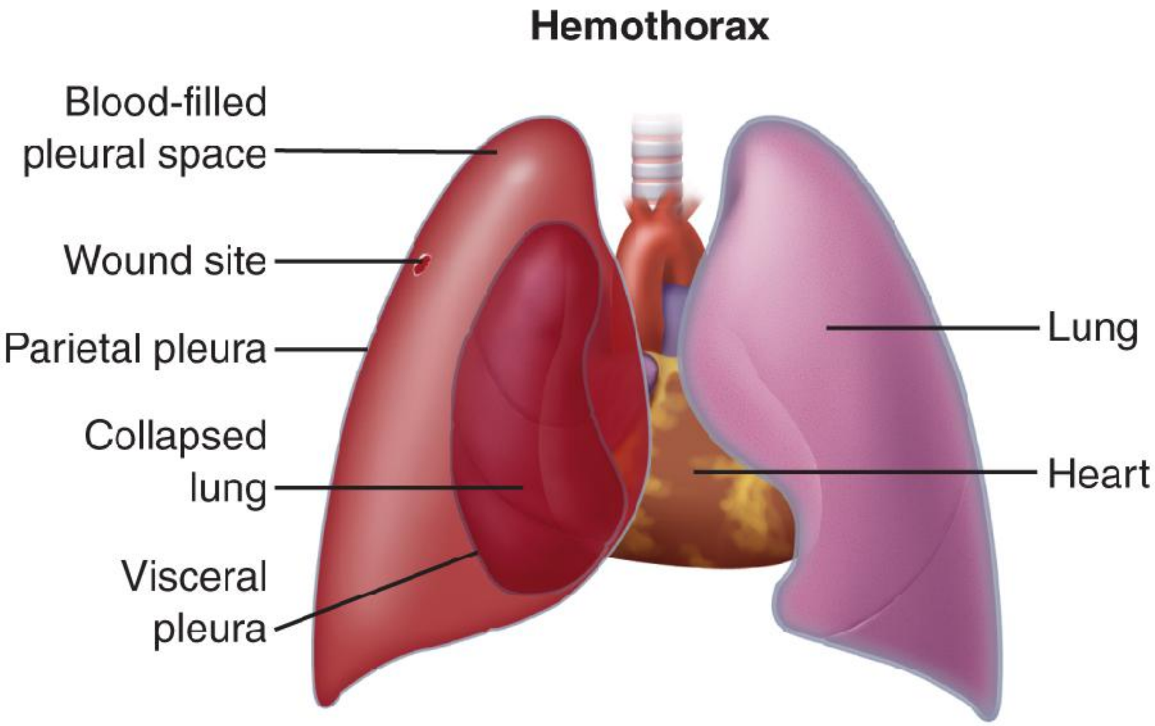
Transport Management

Tension Pneumothorax

- Perform immediate needle decompression.
- Consider inserting a chest tube if your protocol allows.
- Maintain the chest tube on suction during transport.

Hemothorax

Blood in the pleural space is called a **hemothorax** **FIGURE 11-15**. Each of the body's thoracic cavities can accommodate the accumulation of as much as 3,000 mL of blood. A massive hemothorax occurs when at least 1,500 mL of blood collects in a thoracic cavity. The obvious threat from a hemothorax is hypovolemic shock, although the presence of a large amount of blood in the pleural cavity can also interfere with lung function. Hemothorax can be caused by blunt trauma, but is more commonly the result of penetrating trauma. A torn intercostal artery can bleed at a rate of 50 mL/min. Medical causes include a tumor eroding through great vessels.



Hemothorax
Blood-filled pleural space
Wound site
Parietal pleura
Collapsed lung
Visceral pleura
Lung
Heart

FIGURE 11-15 A hemothorax is a collection of blood in the pleural space produced by bleeding within the chest.

© Jones & Bartlett Learning.

Clinical signs and symptoms of a hemothorax include hypoxia, agitation, hypotension, tachycardia, tachypnea, decreased breath sounds on the affected side, dullness to percussion on the affected side, hemoptysis, and worsening shock. A patient with a hemothorax rarely presents with JVD or tracheal deviation.

Management of a hemothorax is supportive and includes the following interventions:

1. Maintain an open airway and apply appropriate oxygen therapy.
2. Immediately transport if in the field.
3. Initiate IV fluids to maintain peripheral perfusion; however, raising blood pressure above 90 mm Hg systolic or 65 mm Hg mean arterial pressure (MAP) may increase blood loss, dislodge a clot, or restart bleeding.
4. Be alert for development of a tension pneumothorax.

Signs and Symptoms

Hemothorax

- Hypoxia
- Agitation
- Hypotension
- Tachycardia
- Tachypnea
- Decreased breath sounds on the affected side
- Dullness to percussion on the affected side
- Hemoptysis
- Worsening shock
- Falling CVP

Transport Management

Hemothorax

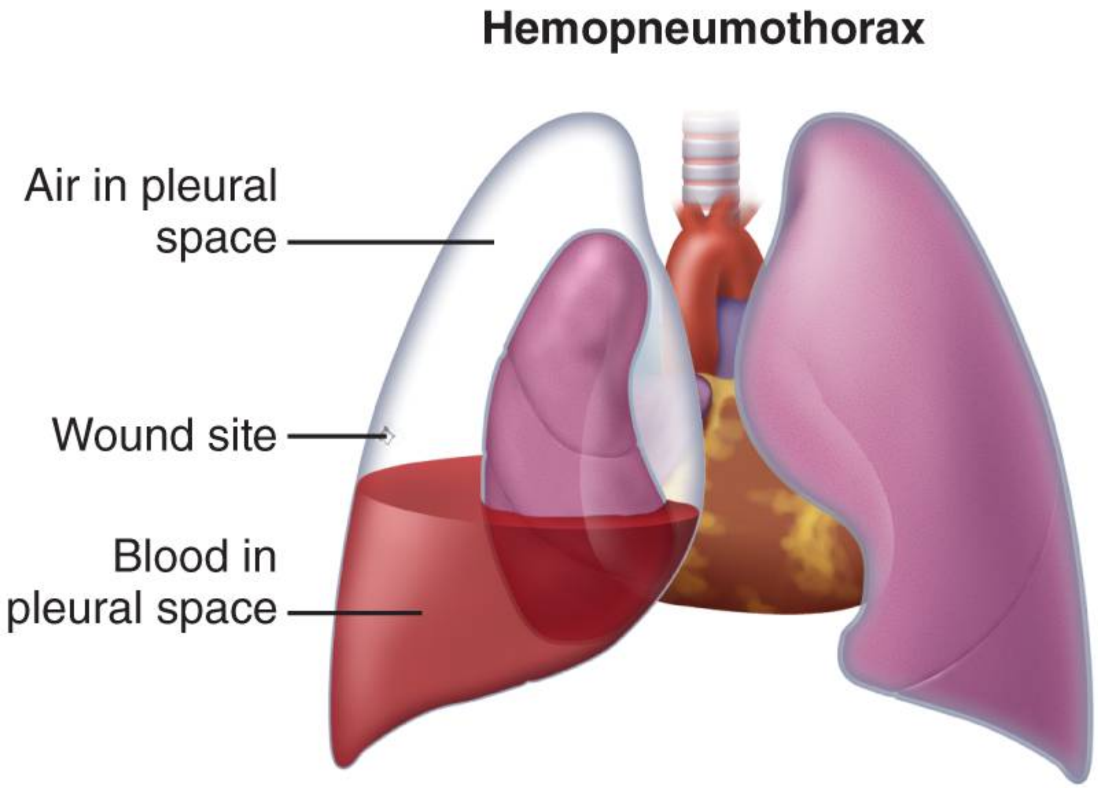
- Maintain an open airway; apply appropriate oxygen therapy.
- Immediately transport if in the field.
- Initiate IV fluids.
- Be alert for the development of a tension pneumothorax.
- Consider inserting a chest tube or pigtail catheter if your protocol allows.
- Maintain the chest drain on suction during transport.

CONTROVERSIES

Use of fluids in patients with uncontrolled internal bleeding is controversial. Although raising the blood pressure may increase blood loss or dislodge a clot, an adequate blood pressure of 90 mm Hg systolic or a MAP of 65 mm Hg must be maintained to perfuse the heart and brain. The ideal fluid for use is one that carries oxygen, such as blood.

Management: Chest Tube Insertion

Patients with a pneumothorax, tension pneumothorax, hemothorax, hemopneumothorax (combination of a pneumothorax and hemothorax) **FIGURE 11-16**, or **empyema** (an accumulation of pus in the pleural space) ultimately may need a chest tube inserted. A chest tube is a flexible plastic tube that is inserted sterilely through the side of the chest into the pleural space **FIGURE 11-17**. It was traditionally attached to an underwater seal to create a one-way system allowing for air or fluid to drain from the chest with each exhalation, reestablishing the interpleural negative pressure and reinflating the lung. Most modern systems no longer use a water chamber, but they have the same effect—namely, they are used to remove air, fluid, or pus from the pleural cavity. In some systems, the CCTP may place chest tubes, but in every critical care transport system the CCTP will care for and transport patients with chest tubes in place.



Hemopneumothorax
Air in pleural space

Pleural space
Chest tube
Fluid
Lung

FIGURE 11-17 A chest tube is inserted through the side of the chest into the pleural space.

© Jones & Bartlett Learning.

The procedure for insertion of a chest tube begins with collecting the needed equipment (often packaged as a "tray"):

- Appropriate PPE, including sterile gloves
- Scalpel
- Sterile chest tube: 28- to 36-French

- Kelly clamps (curved and straight)
- Sterile occlusive dressing
- Suturing material (typically a 0-silk or other large, nonabsorbable suture)
- 2% chlorhexidine
- A local anesthetic if the patient is awake
- A fluid collection device with a one-way valve that allows air, fluid, or pus to flow out of the chest; if not available, an indwelling catheter bag with a one-way valve may be used
- Tape
- Mechanical suction device (not always used)

Indications for insertion of a chest tube include the following:

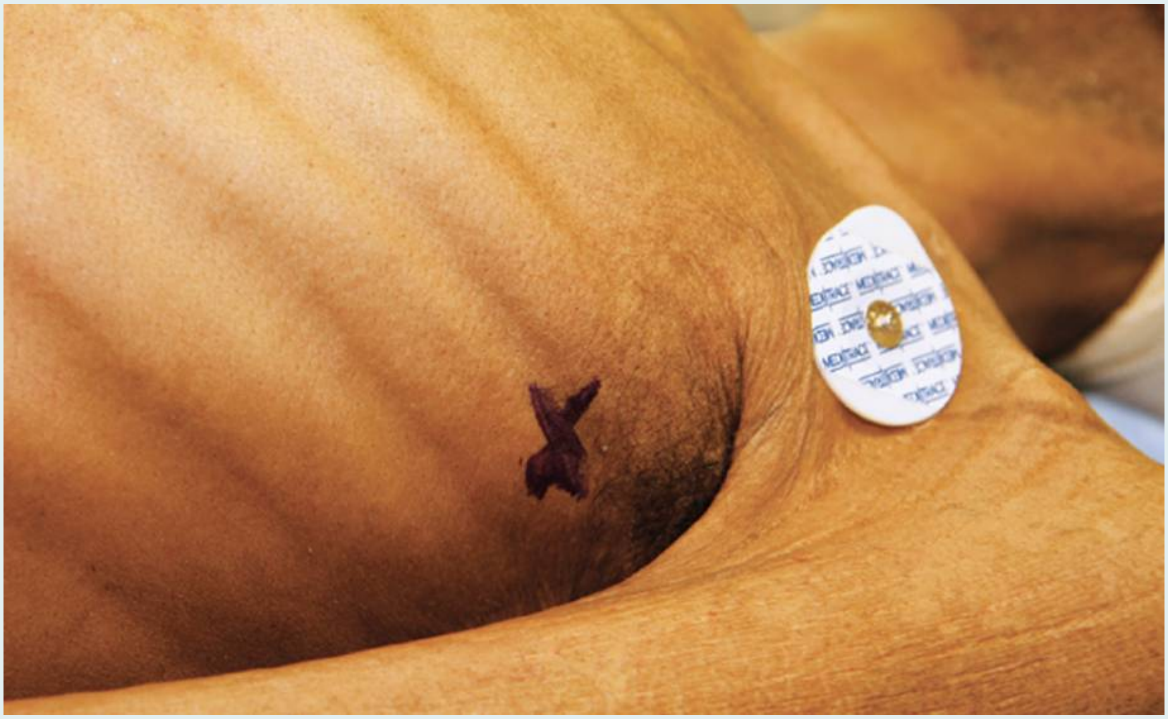
- Pneumothorax
- Hemopneumothorax
- Empyema

Numerous complications are possible:

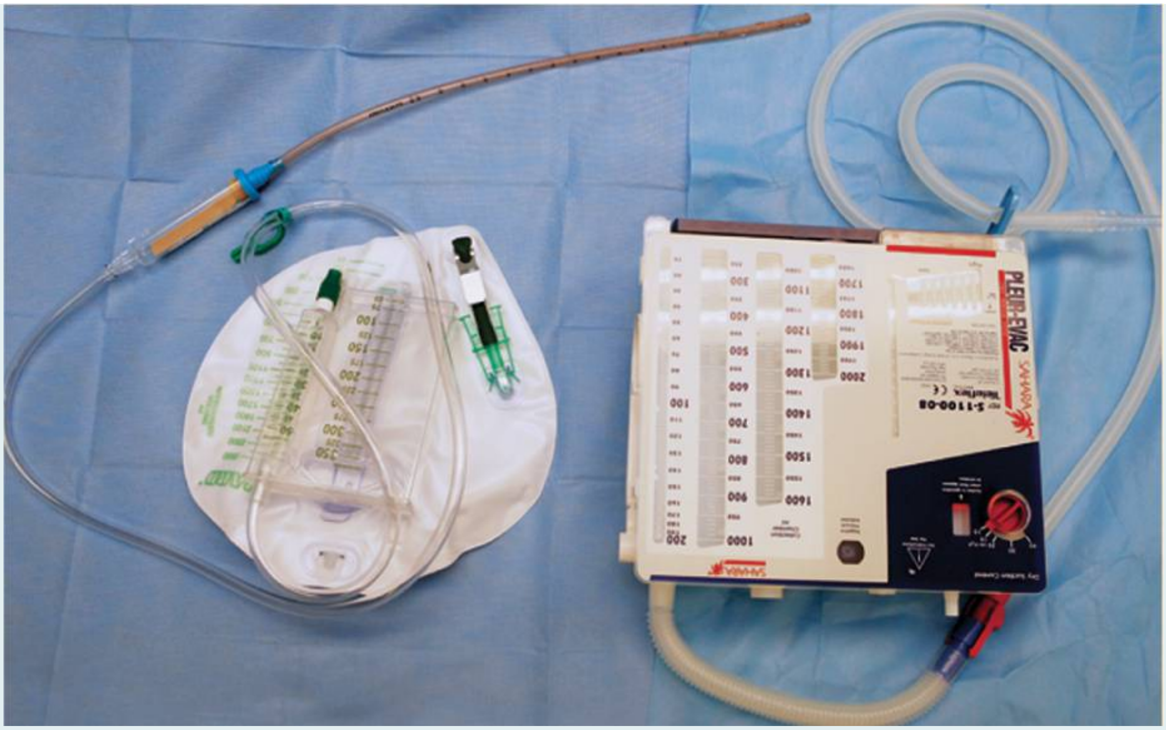
- Recurrent pneumothoraces
- Accidental removal
- Broken collection chamber
- Parenchymal injury
- Subcutaneous emphysema
- Laceration of intercostal vessels
- Creation of a hemothorax or bleeding
- Misplacement below the diaphragm
- Infection

Skill Drill 11-3 shows the clinical procedure for inserting a chest tube, which is described here:

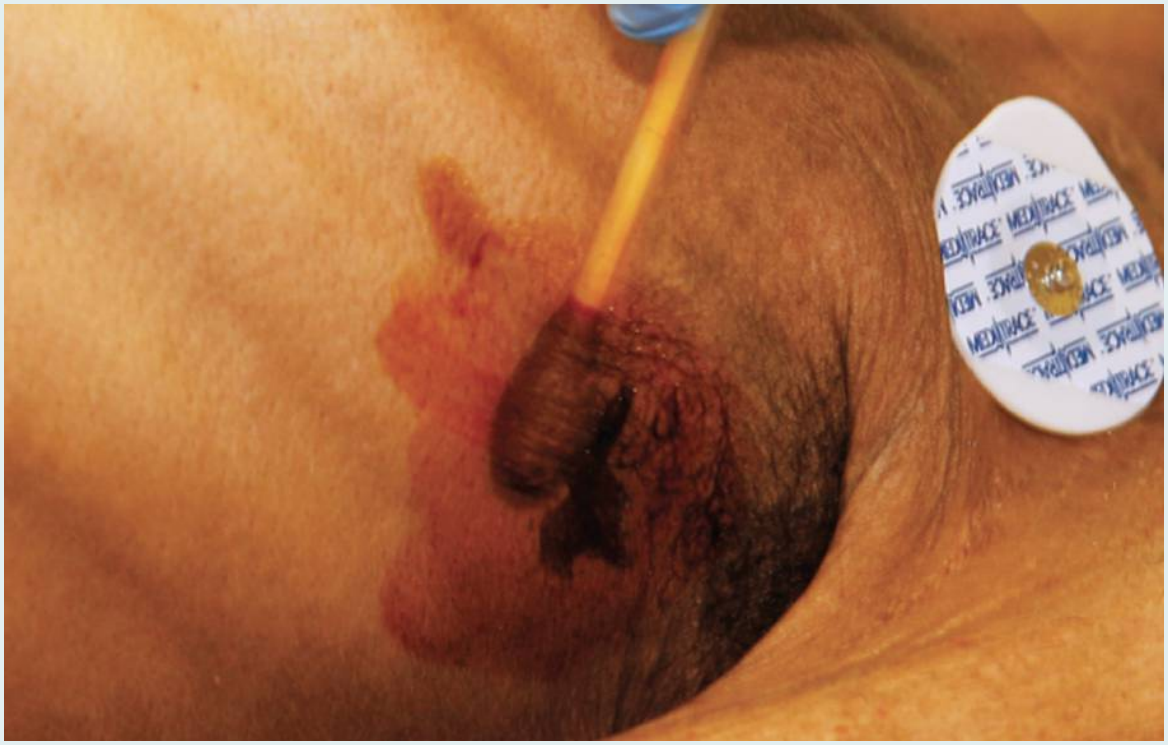
SKILL DRILL 11-3 Chest Tube Insertion



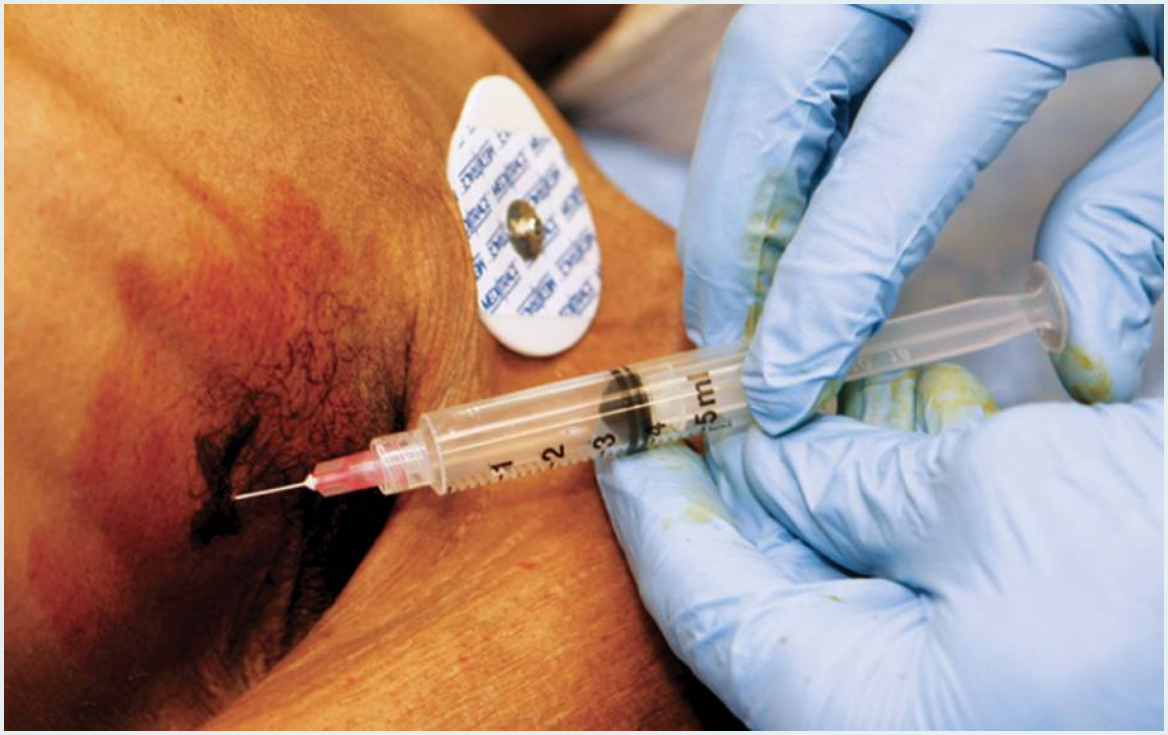
Step 1
Select the appropriate site.



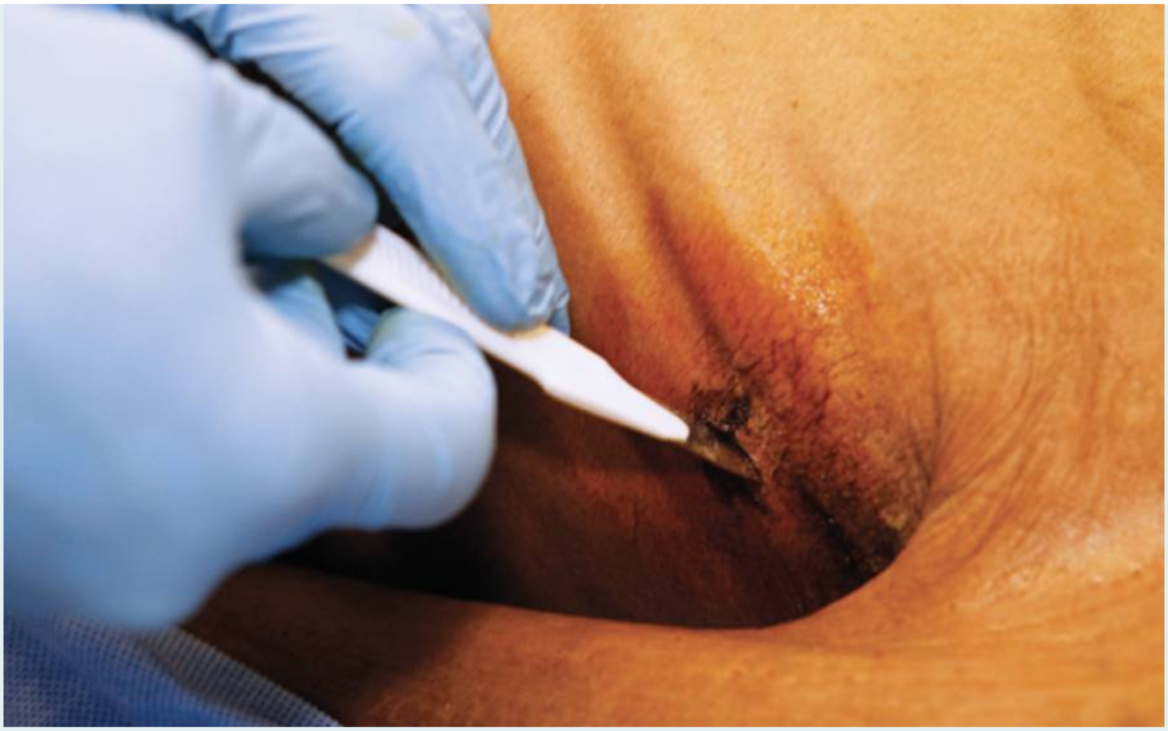
Step 2
Connect the collection device to the distal end of the one-way valve with a rubber band.



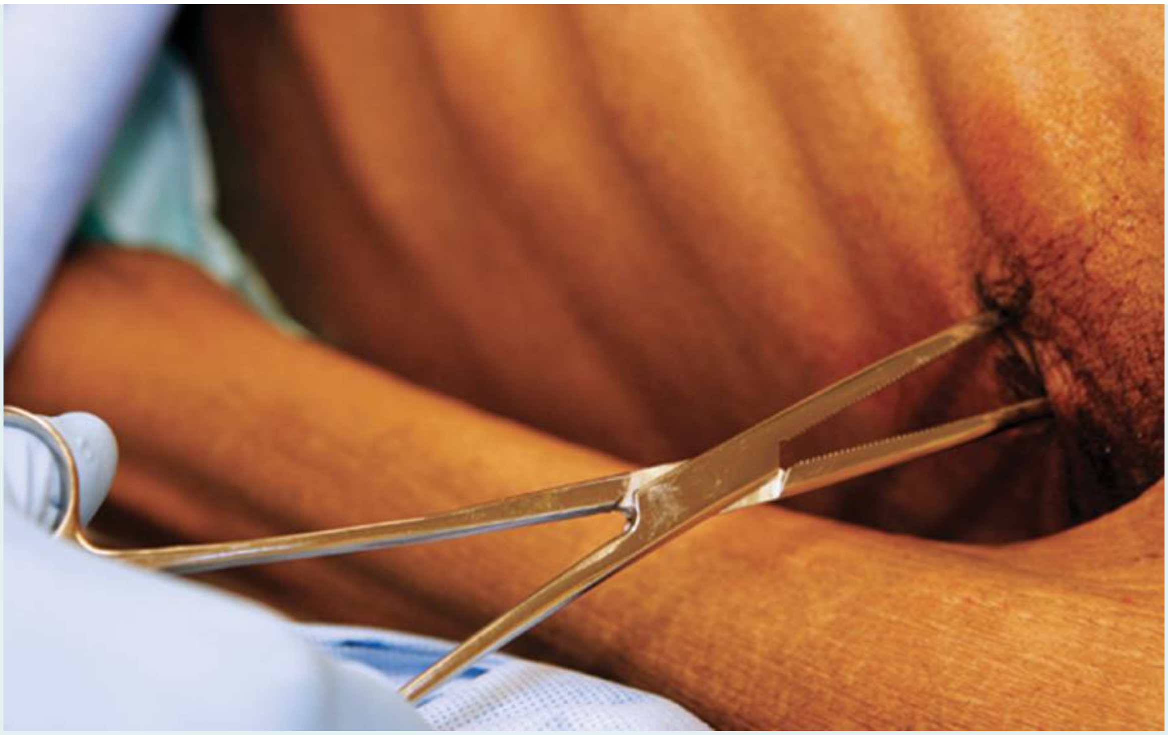
Step 3
Cleanse the site with an appropriate aseptic technique.



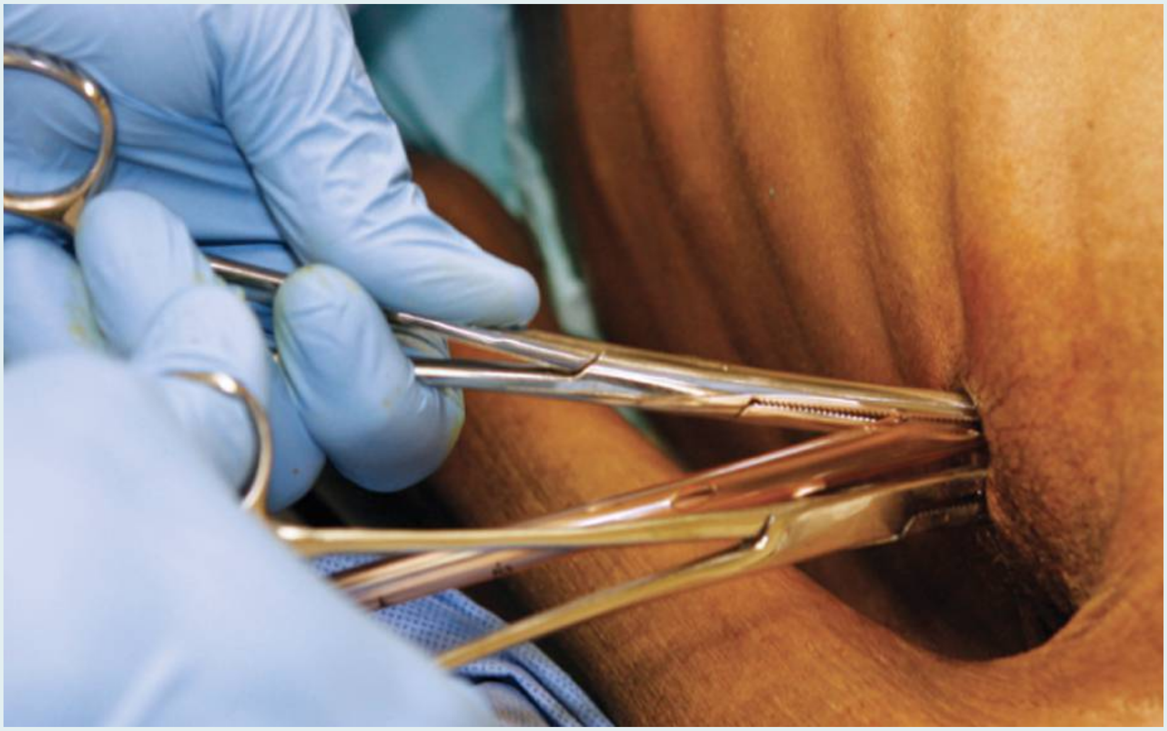
Step 4
Anesthetize the area, including the pleura and periosteum, over the fifth rib.



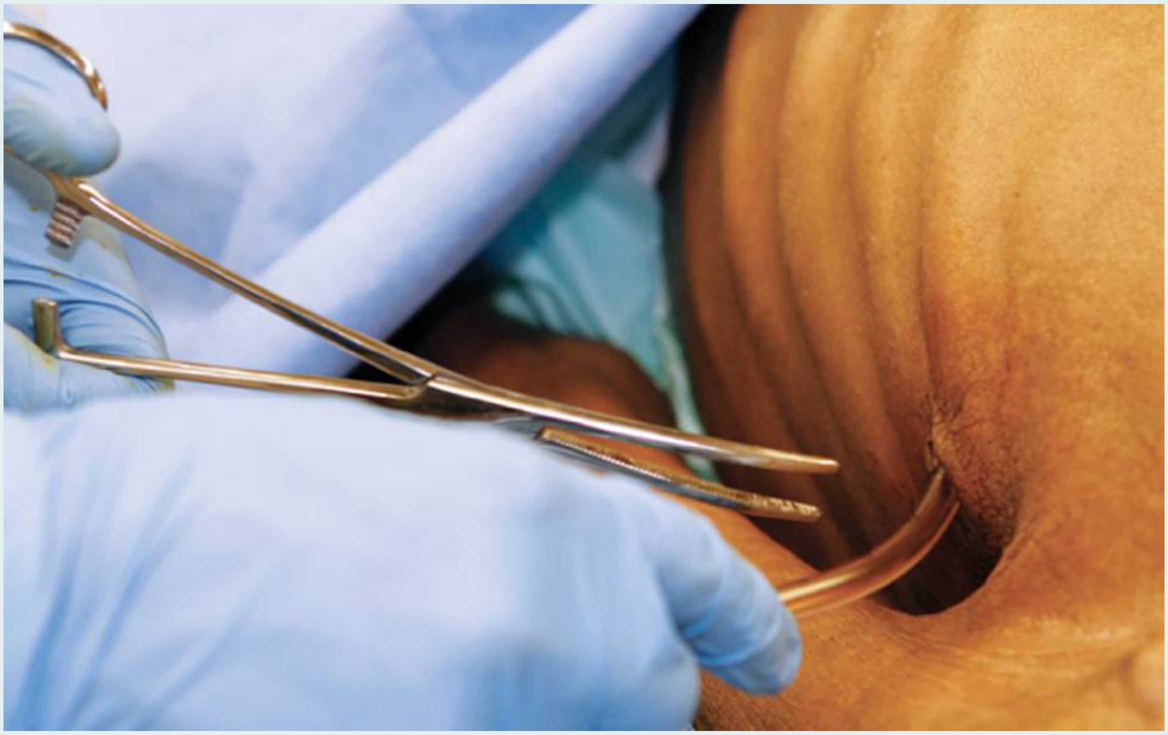
Step 5
Mark the tube for the desired length of insertion. Clamp the distal end of the tube with a large clamp and the proximal end of the tube with a curved clamp. Make a transverse incision over the fifth rib at the midaxillary line. If the patient has fractured ribs, use the anterior axillary line (between the midaxillary line and the nipple line).



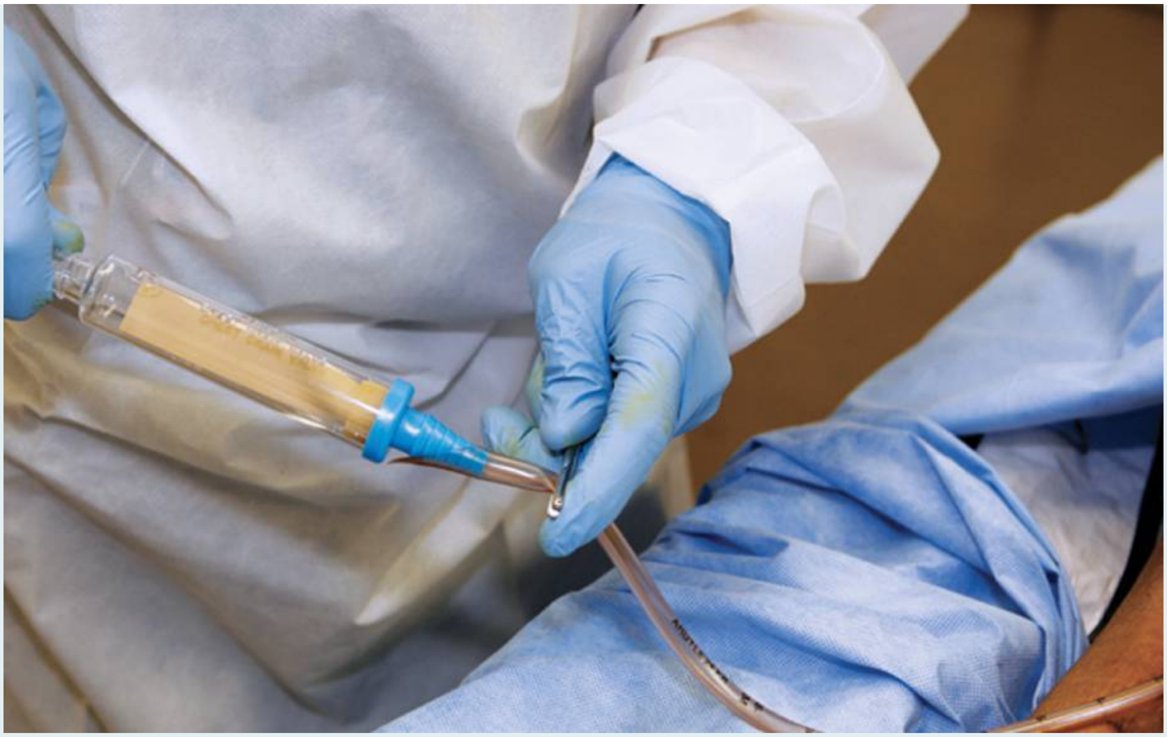
Step 6
Tunnel over the fifth rib with a large curved clamp, push through the pleura, spread the clamp, and replace the clamp with a finger.



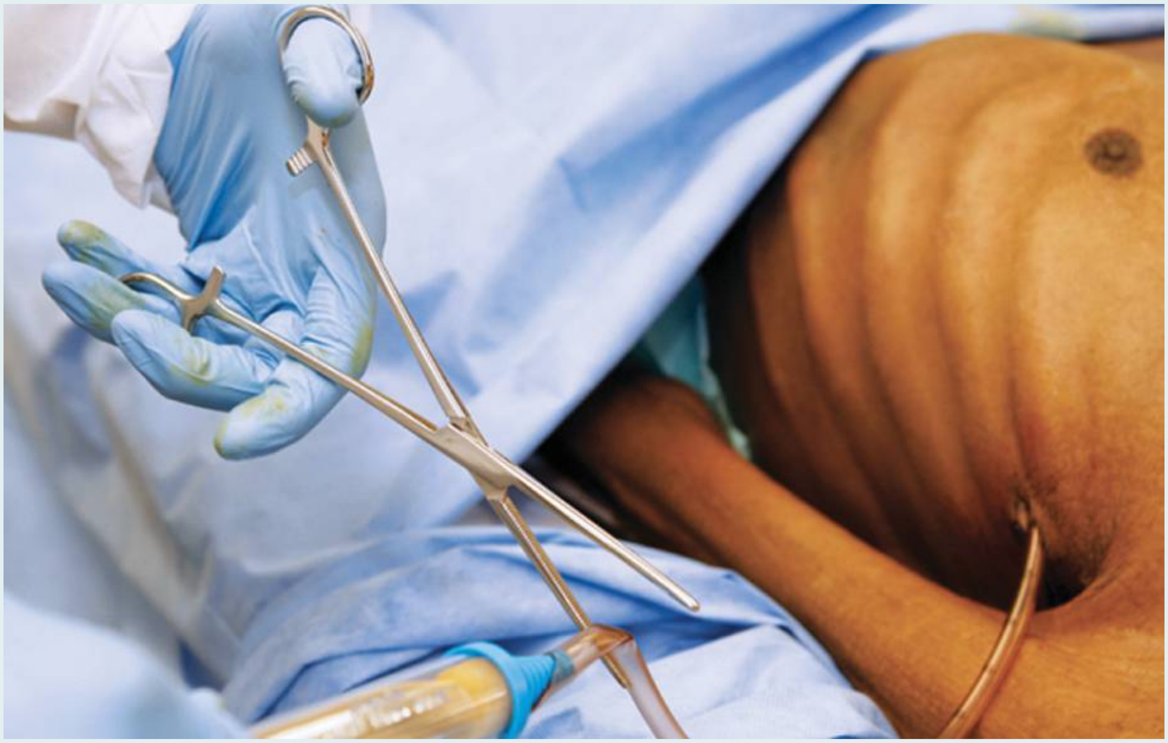
Step 7
Grasp the clamp attached to the end of the chest tube and advance it through the space created by the first clamp.



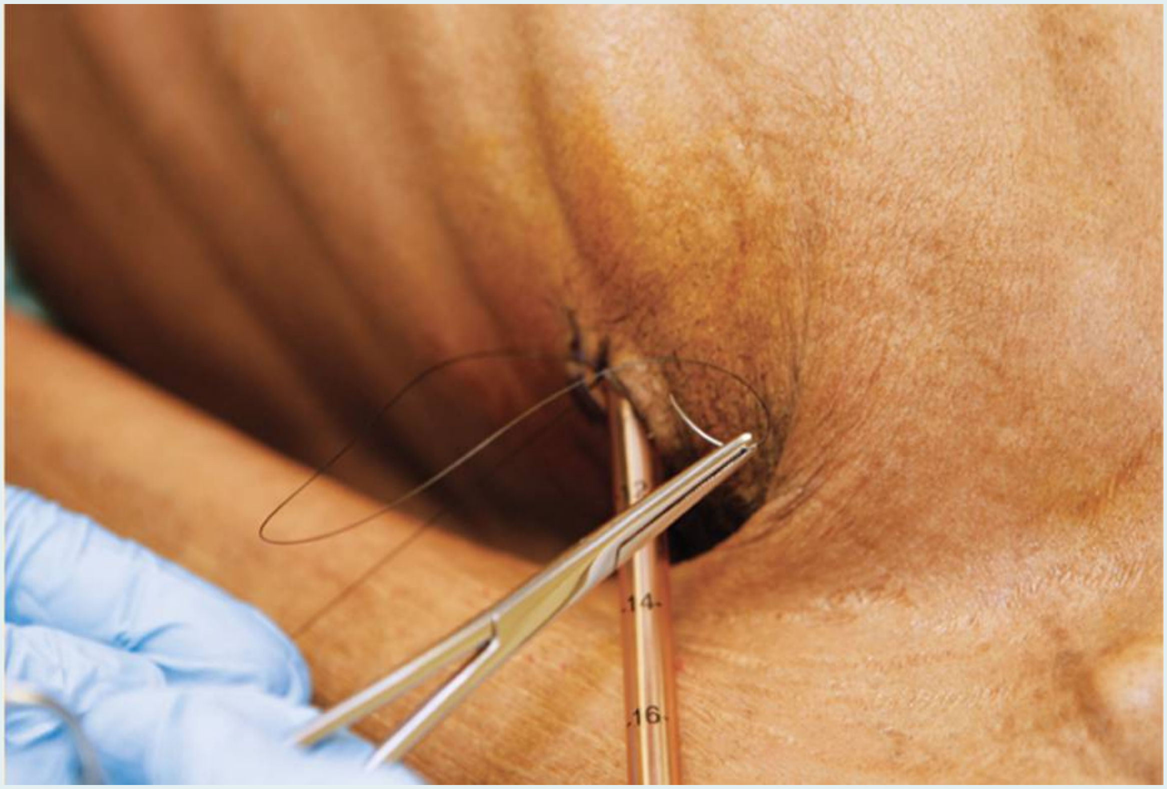
Step 8
Remove the clamps and advance the tube to the predetermined mark indicated on the tube, at least 5 cm past the most proximal hole, directed posteriorly and superiorly.



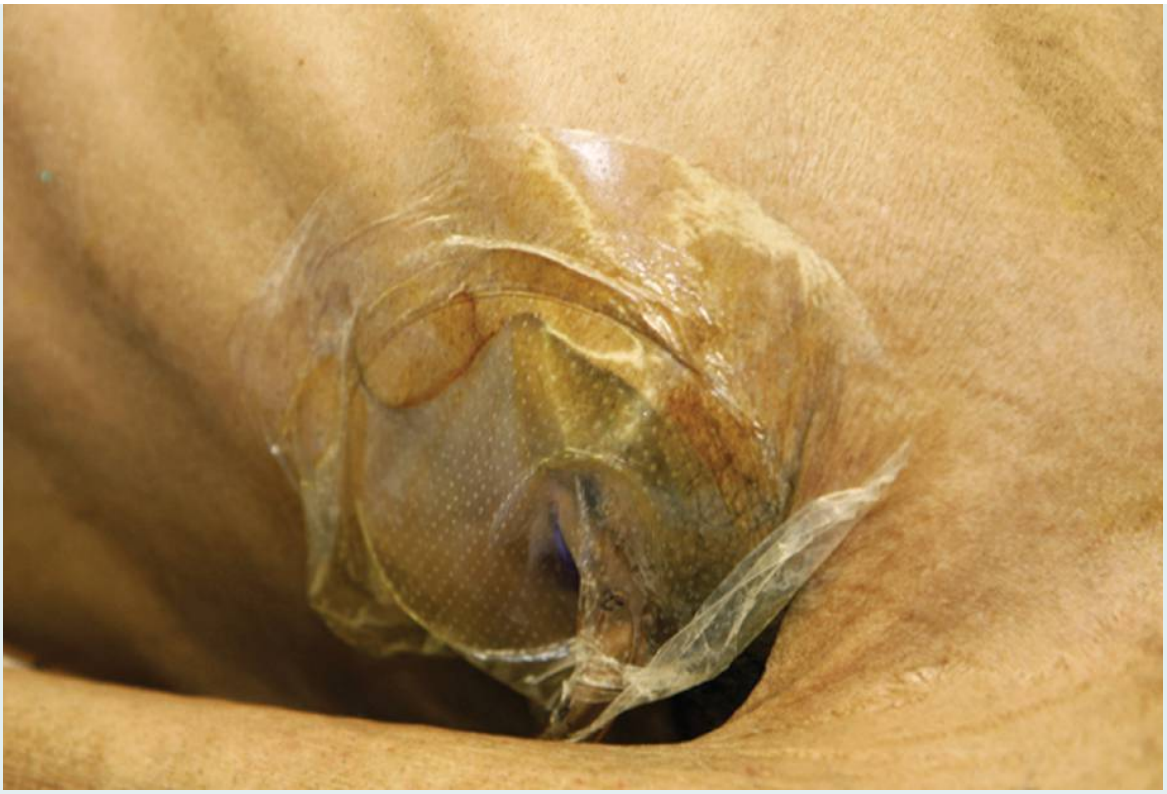
Step 9
Connect the collection device with the one-way valve.



Step 10
Remove the distal clamp.



Step 11
Suture the tube in place and close the wound according to local protocols.



Step 12
Cover the insertion site with an occlusive dressing. Upon arrival at the receiving facility, obtain a chest film to confirm proper placement of the chest tube. Document the procedure.

All images © Jones & Bartlett Learning.

1. Select the appropriate site: midaxillary over the fifth rib **STEP 1**.
2. Connect the collection device or the indwelling catheter bag to the distal end of the one-way valve with a rubber band **STEP 2**. Ensure the arrow on the valve is facing away from the patient.
3. Cleanse the site with an appropriate aseptic technique **STEP 3**.
4. Anesthetize the area, including the pleura and periosteum, over the fifth rib **STEP 4**, if the patient is conscious and time permits.
5. Mark the tube for the desired length of insertion.
6. Clamp the distal end of the tube with a large clamp (such as a Kelly clamp) and the proximal end of the tube with a curved clamp.

7. Make a transverse incision over the fifth rib in the midaxillary line **STEP 5**. If the patient has fractured ribs, use the anterior axillary line (between the midaxillary line and the nipple line).
8. Tunnel over the fifth rib with a large curved clamp, push through the pleura, spread the clamp, and replace the clamp with a finger. In a hemothorax, sudden evacuation of some blood is not uncommon. Ensure there are no palpable structures within the pleural cavity, such as pleural adhesions, that may prevent proper chest tube placement **STEP 6**.
9. Grasp the clamp attached to the end of the chest tube and advance it through the space created by the first clamp, directing it posteriorly and superiorly toward the patient’s head **STEP 7**.
10. Remove the clamps and advance the tube to at least 2 inches (5 cm) beyond the last hole, typically to around the 10- to 14-cm mark **STEP 8**.
11. Connect the collection device to the distal end of the chest tube **STEP 9**.
12. Remove the distal clamp **STEP 10**.
13. Suture the tube in place and close the wound according to local protocols **STEP 11**.
14. Note the depth of the tube at the skin (marked on the tube) and mark it with a felt-tip pen if possible.
15. Cover the insertion site with an occlusive dressing and reinforce all connections with tape **STEP 12**.
16. On arrival at the receiving facility, obtain a chest radiograph to confirm proper placement of the chest tube.
17. Document the procedure, including the size of the chest tube inserted, the amount of return of air/fluid after insertion of the tube, and any changes in the patient’s condition (including oxygen saturation).

When transporting a patient with a chest tube in place:

- Make sure all connections are taped or banded with wire to prevent accidental separation.
- Ensure that the dressing over the insertion site is securely taped and occlusive. Use a felt-tip marker to mark the depth of the tube; if there are markings, note the depth of the tube on the transfer chart. Make sure the tube is sutured, wired, or taped so it cannot be accidentally pulled out.
- Maintain the drainage unit below the level of the chest at all times during transport. Many units include bed hangers so that the unit can be hung on the stretcher. If there is water in the unit, keep it upright at all times.
- If the tube is attached to a suction device, determine whether the patient can tolerate discontinuing the vacuum for transport; if not, attach the chest tube to portable suction.
- Keep the tubing coiled to prevent kinks or dependent loops.
- Access and document bubbling in the water seal (does not have to be continuous), any output in the collection chamber, and its type (eg, frank blood).
- Do not clamp tubes for transport, as this is likely to cause a tension pneumothorax.
- Continuous bubbling may be a sign of tracheobronchial laceration. Large amounts of frankly bloody drainage need to be balanced by transfusion.

Pigtail Catheter

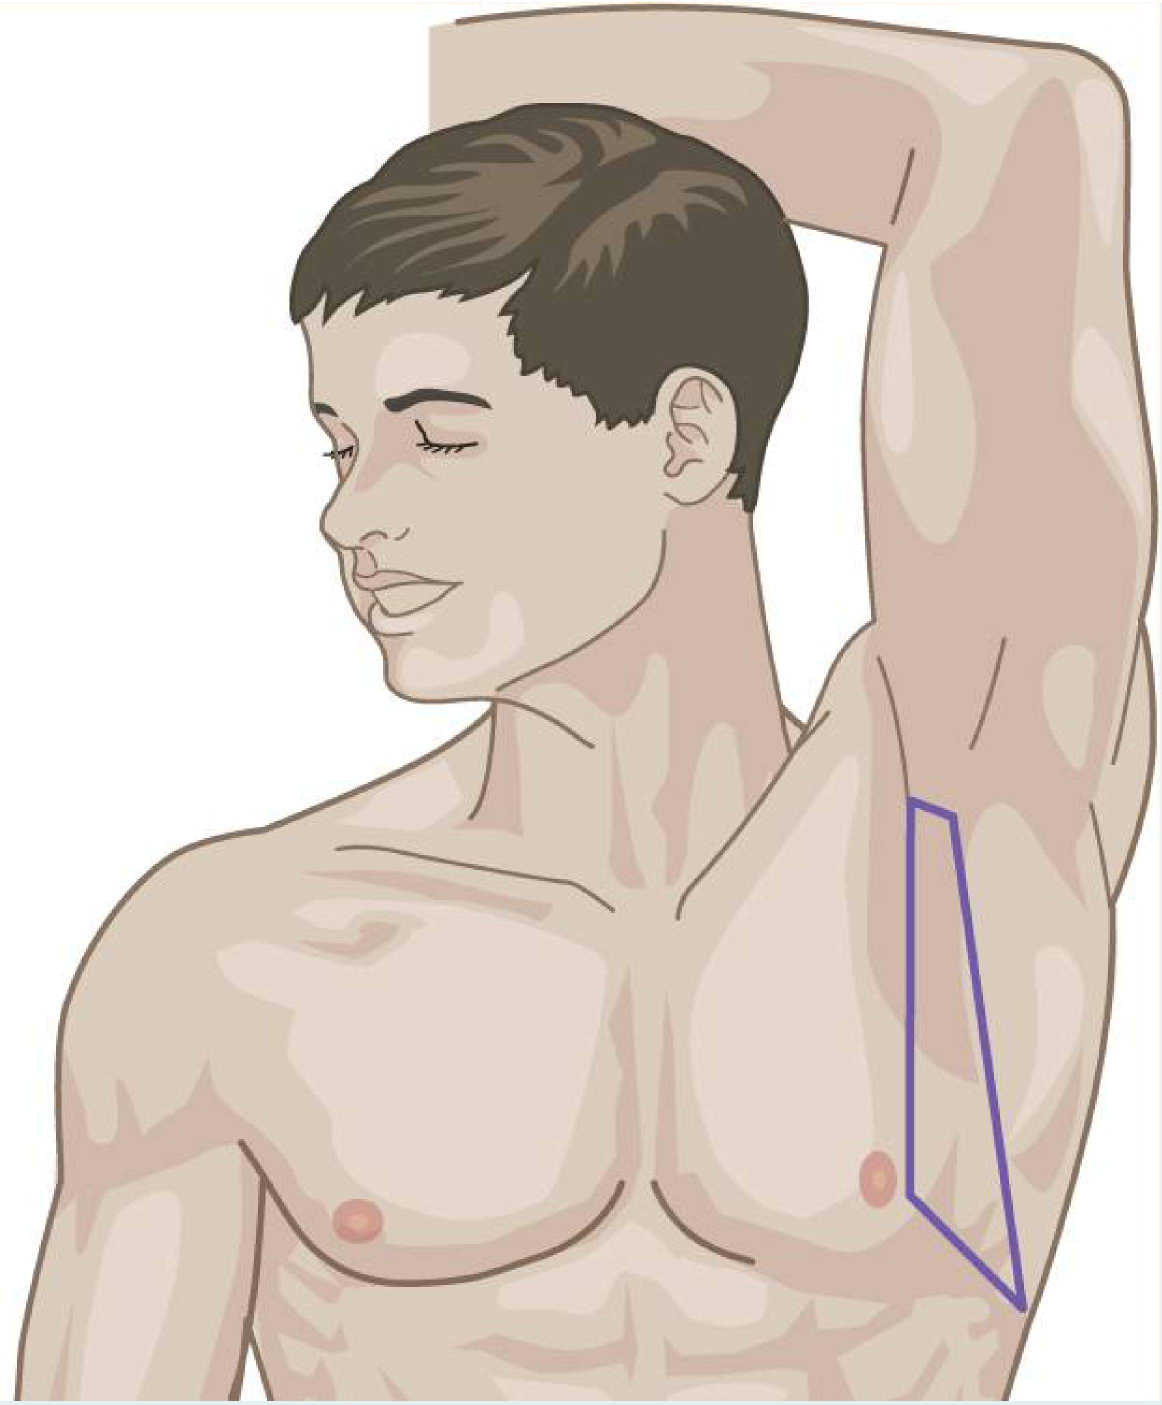
Pigtail catheters are small-bore (6- to 12-French) tubes inserted using a sterile Seldinger (catheter-over-wire) technique, often under ultrasonographic guidance. They are less painful for patients, produce less scarring, and do not require tissue dissection or skin closure on removal. Overall, there is less risk for complications with these devices than with the larger-bore versions. Recent studies comparing the effectiveness of pigtail versus larger conventional chest drainage tubes show no significant differences in resolution of pneumothoraces, hemothoraces, empyemas, or effusions. Pigtail catheters are managed in much the same way as chest tubes. In the future, it is possible that insertion of pigtail catheters will be included in some CCTPs' scope of practice.

The procedure for inserting a pigtail catheter begins with collecting the needed equipment (often packaged as a "tray"):

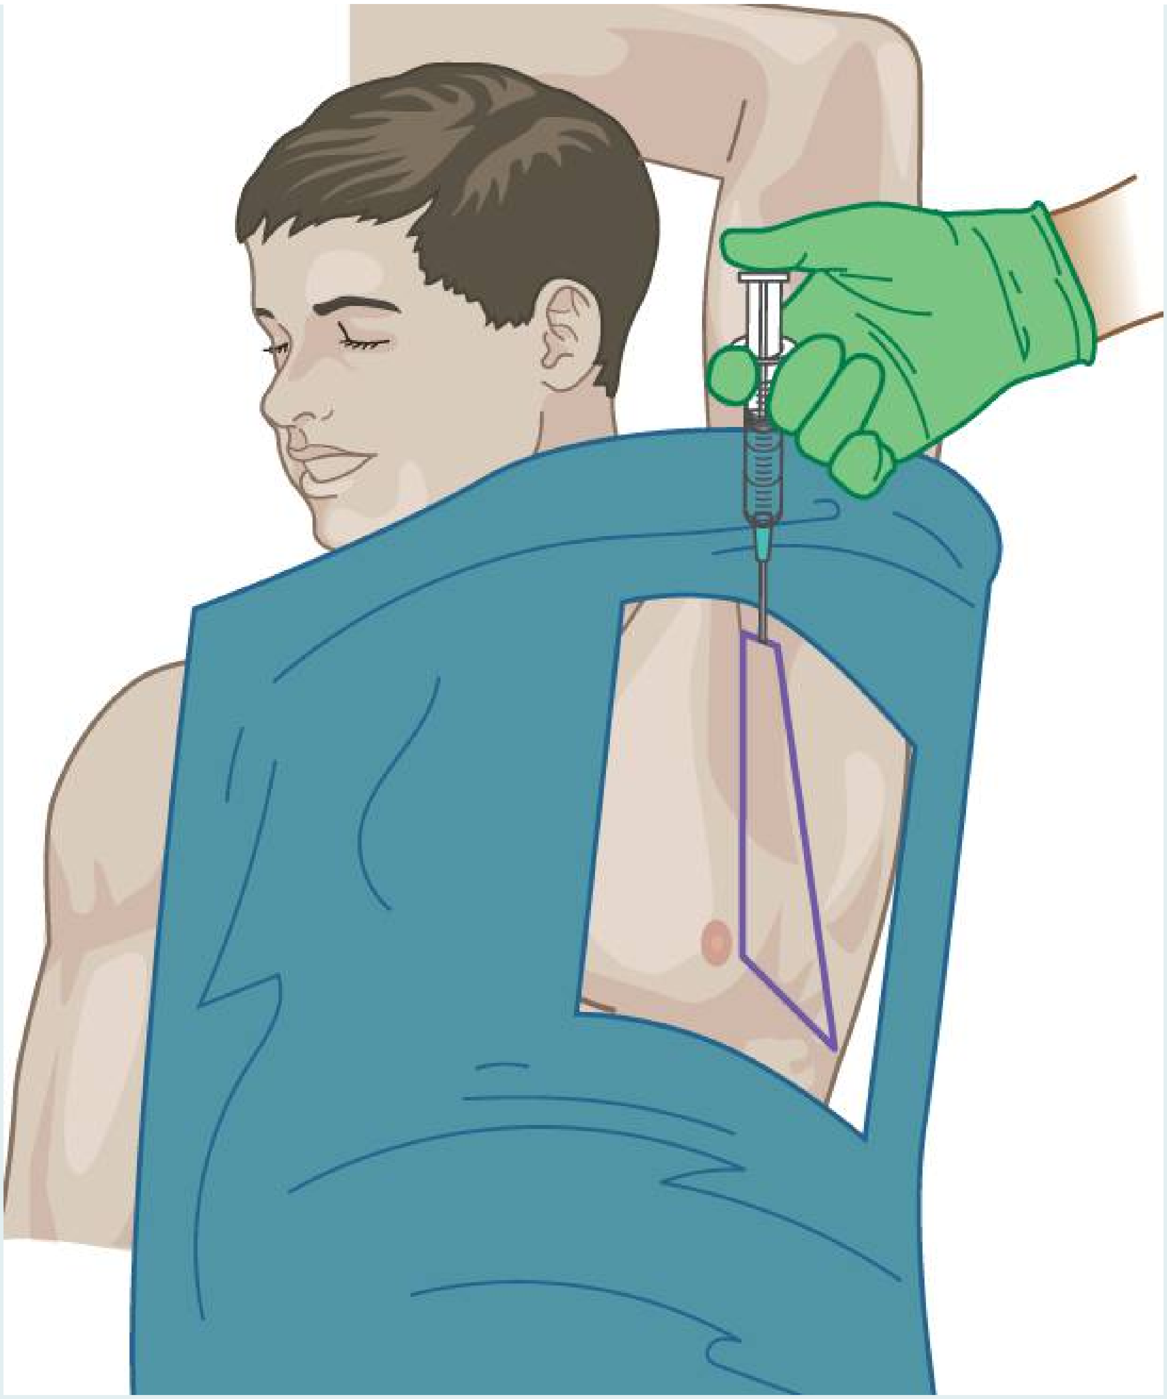
- Appropriate PPE, including sterile gloves
- Ultrasonography unit
- Scalpel
- Pigtail catheter: 6 to 12 French
- Sterile occlusive dressing
- Suturing material
- 2% chlorhexidine
- A local anesthetic if the patient is awake
- A fluid collection device with a one-way valve that allows air, fluid, or pus to flow out of the chest; if not available, an indwelling catheter bag with a one-way valve may be used
- Tape

Skill Drill 11-4 shows the clinical procedure for inserting a pigtail catheter, which is described here:

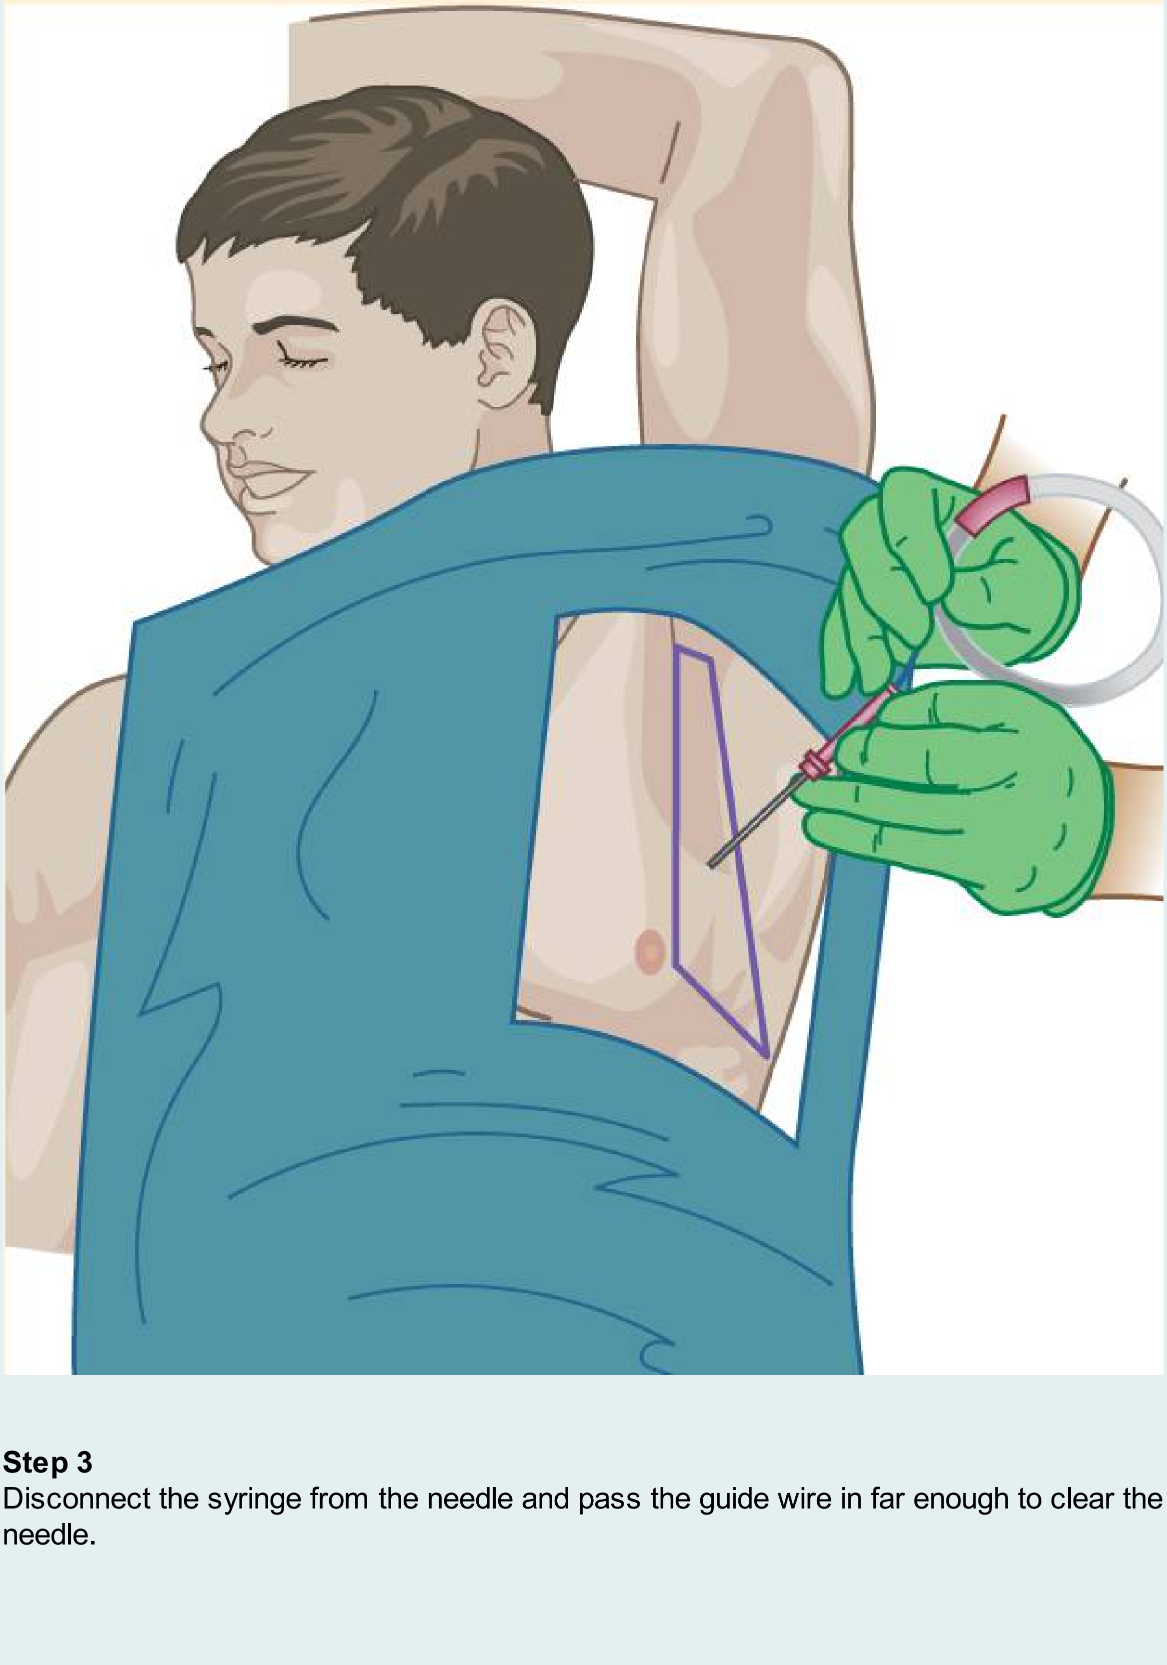
SKILL DRILL 11-4 Pigtail Catheter Insertion



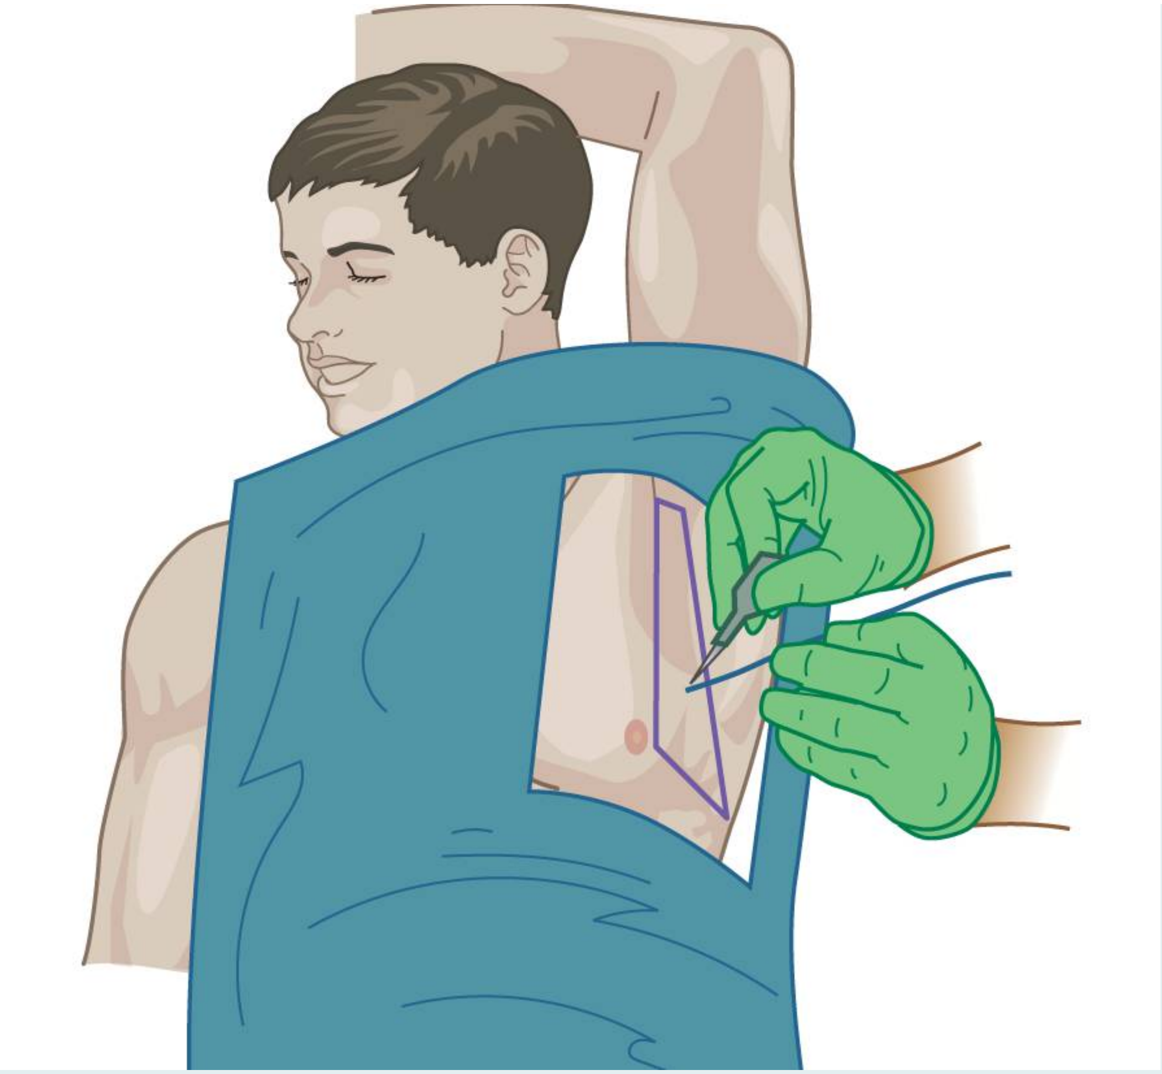
Step 1
Select the appropriate site. Connect the collection device to the distal end of the one-way valve with a rubber band or set up a chest tube drainage system.



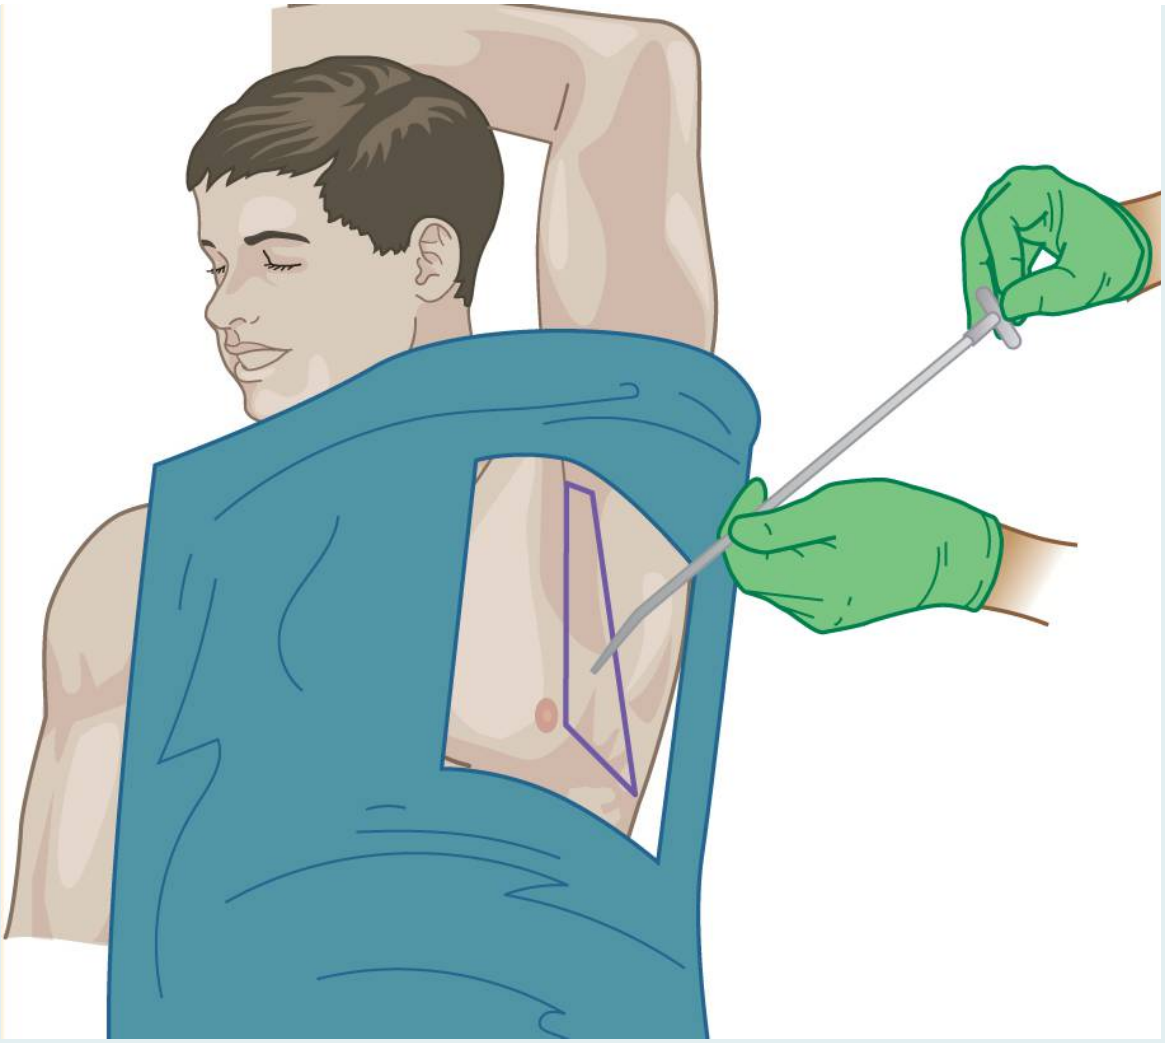
Step 2
Anesthetize the area, including the pleura and periosteum, over the fifth rib.



Step 3
Disconnect the syringe from the needle and pass the guide wire in far enough to clear the needle.



Step 4
Remove the needle over the wire and make a small incision adjacent to the guide wire.



Step 5
Pass the dilator over the wire into the pleural space. You should feel the dilator "pop" once you are in the correct location. Verify that the guide wire moves easily in and out of the dilator. Remove the trocar and guide wire. Suture the pigtail catheter in place and connect it to the drainage device.

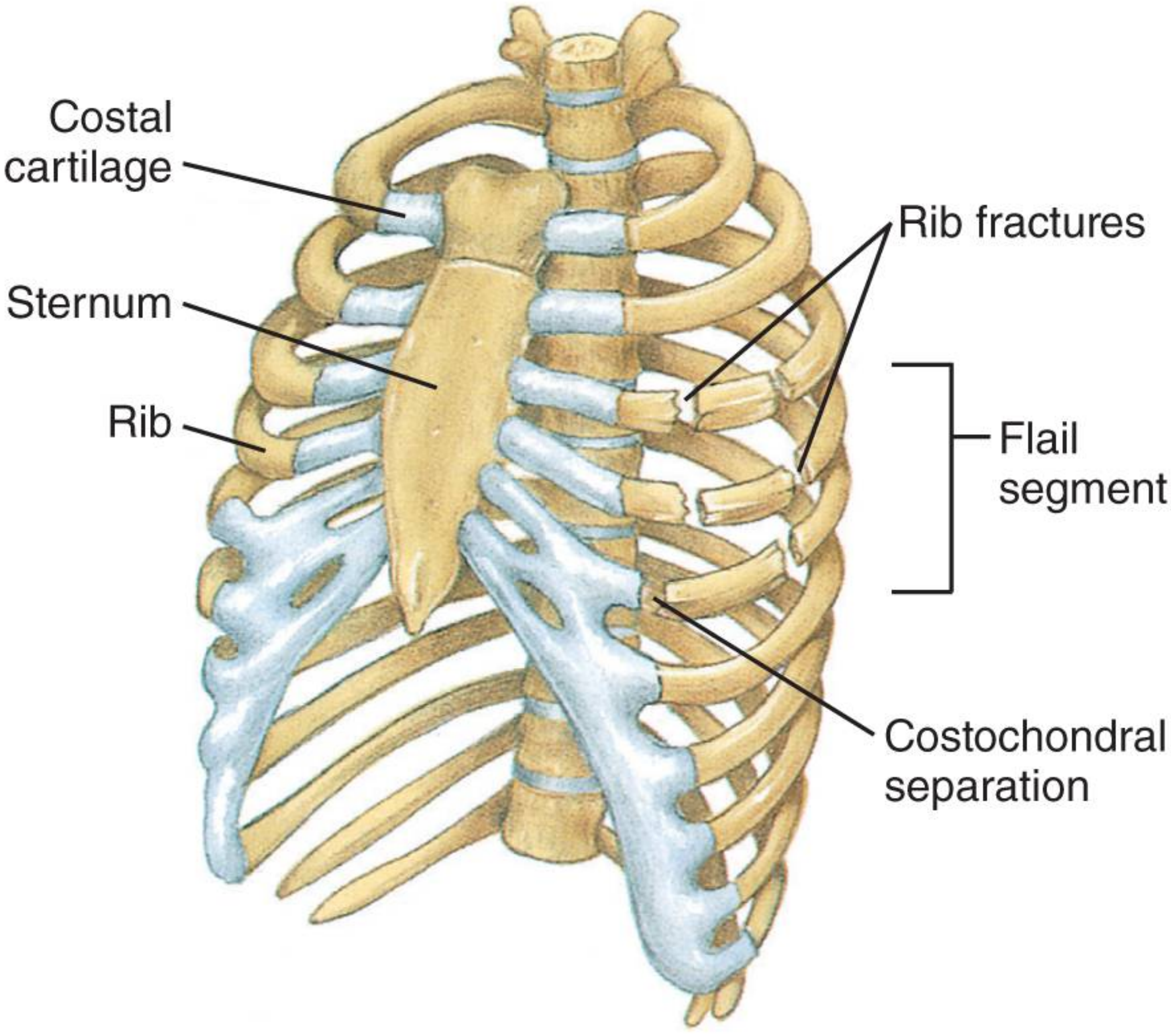
All images © Jones & Bartlett Learning.

1. Select the appropriate site. Ultrasonographic guidance has been shown to reduce complications and misplacement **STEP 1**.
2. Connect the collection device to the distal end of the one-way valve with a rubber band or set up a chest tube drainage system.
3. Cleanse the site with an appropriate aseptic technique.

4. Anesthetize the area, including the pleura and periosteum, over the fifth rib **STEP 2**.
5. Measure the pigtail catheter against the chest to determine the insertion distance. Keep in mind that pigtail catheters can be withdrawn but cannot be further inserted following completion of the procedure.
6. Draw a few milliliters of sterile water into the finder needle so you can visualize aspiration of air during insertion. Insert the needle over the superior aspect of the rib while aspirating the syringe. Once in the pleural space, the syringe plunger will provide a way to aspirate bubbles in a pneumothorax and pleural fluid or blood in an effusion or hemothorax.
7. Disconnect the syringe from the needle and pass the guide wire in far enough to clear the needle **STEP 3**. Inserting the wire too far will make it difficult to direct the pigtail catheter superiorly.
8. Remove the needle over the wire and make a small incision adjacent to the guide wire (as when inserting a central line) to accommodate the dilator and catheter. Pass the dilator over the wire into the pleural space **STEP 4**. You should feel the dilator "pop" once you are in the correct location. Ensure there are no kinks by verifying that the guide wire moves easily in and out of the dilator.
9. Pass the pigtail and trocar over the wire, ensuring you advance them sufficiently to locate all holes in the pleural space.
10. Remove the trocar and guide wire. Suture the pigtail catheter in place and connect it to the drainage device **STEP 5**.
11. Cover the insertion site with an occlusive dressing. On arrival at the receiving facility, obtain a chest film to confirm proper placement of the pigtail catheter. Document the procedure.

Flail Chest

A fracture in two or more places of two or more adjacent ribs is known as a **flail chest** or a flail segment **FIGURE 11-18**. This condition is relatively common in trauma patients. In one study, flail chest was found to be present in as many as one-third of serious chest injuries. Many of these injuries escape detection for as long as 6 hours following hospital admission.



Costal cartilage
Sternum
Rib
Rib fractures
Flail segment
Costochondral separation

FIGURE 11-18 In flail chest injuries, two or more adjacent ribs are fractured in two or more places. A flail segment may move paradoxically when the patient breathes, although this sign is usually present only in very young children, older adults, or other patients with underdeveloped pectoral and latissimus muscles.

© Jones & Bartlett Learning.

A flail segment may appear to move paradoxically relative to the chest wall, but actually is stationary while the rest of the chest moves around it. This movement may be more obvious in unconscious patients who are no longer “splinting.” Often, bruises to the underlying tissue may cause a pulmonary or myocardial contusion and represent the most dangerous sequelae of a flail chest. Flail segments are generally caused by blunt trauma, such as striking a steering wheel in an MVC. A central flail involves the sternum.

Clinical signs and symptoms of a flail chest are dyspnea, severe pain, decreased breath sounds on the affected side, tenderness, and crepitus to palpation, with possible bruising over the area. Signs and symptoms are often difficult to assess as a result of the patient’s efforts to splint the area and ease the pain that occurs with respiration. The pain associated with flail segments may mask abdominal tenderness. When this condition is present, the CCTP must maintain a high clinical suspicion for underlying injury.

Flail segments pose a threat to the patient’s ability to breathe, increase the risk for developing a hemothorax or pneumothorax, and require immediate treatment. Definitive treatment for flail chest with significant symptoms involves pain control and positive-pressure ventilation.

Management of a flail chest is as follows:

1. Maintain an open airway and apply appropriate oxygen therapy. Analgesia is a major determinant of a patient’s ability to ventilate unassisted, and proper pain control should be initiated and maintained.
2. Assist ventilation with a trial of noninvasive ventilation (continuous positive airway pressure or bilevel positive airway pressure), and be prepared to intubate.
3. Immediately transport the patient if the call involves a field transport.
4. Monitor the patient’s oxygen saturation, vital signs, and cardiac monitor. Be alert for development of tension pneumothorax,

hemothorax (shock), or respiratory failure secondary to a pulmonary contusion.

5. The gold-standard treatment for flail chest is positive-pressure ventilation (also known as internal fixation) with a sedated patient who has been adequately treated for pain. It may be possible to manage some patients conservatively with pain medications and noninvasive ventilation alone.

Attempts to splint (also called external fixation) or wrap the chest have been shown to be ineffective, and this practice has been abandoned.

Signs and Symptoms

Flail Chest

- Dyspnea
- Severe pain
- Decreased breath sounds on the affected side
- Tenderness
- Crepitus to palpation
- Bruising over the area

Transport Management

Flail Chest

- Maintain an open airway; apply appropriate oxygen therapy.
- Assist ventilation with a trial of continuous positive airway pressure; be prepared to intubate.
- Immediately transport the patient if the call involves a field transport.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Be alert for development of tension pneumothorax, hemothorax (shock), or respiratory failure secondary to a pulmonary contusion.

Pericardial Tamponade

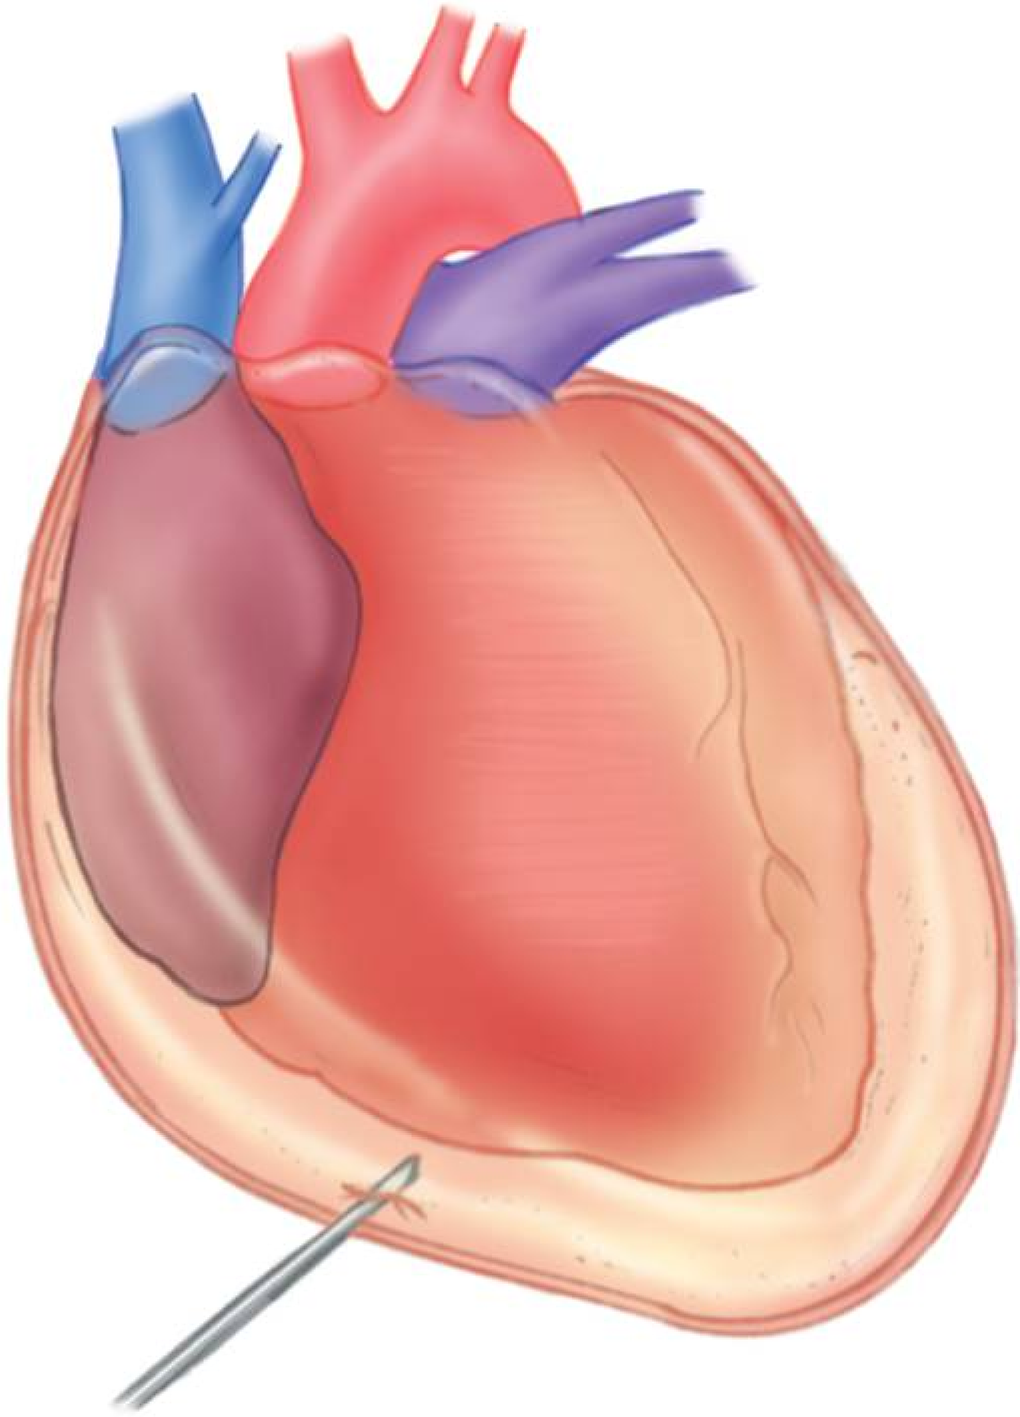
Pericardial tamponade is a life-threatening condition that may require immediate treatment. This condition is reported in 2% of penetrating injuries to the chest and upper abdomen. It is more common in stab wounds to the heart (occurring in as many as 80% of such cases) than in gunshot wounds.

The pericardium normally contains a small amount of fluid that cushions and lubricates the heart as it expands and contracts. When an abundance of blood or fluid accumulates in the pericardial sac, it compresses the ventricles of the heart, which in turn compromises cardiac filling and output. Abnormal amounts of fluid may result from any of the following conditions:

- Pericarditis caused by infection and inflammation
- Trauma
- Surgery or other invasive procedures performed on the heart (ie, pacemaker insertion, ablation)
- Cancer
- Myocardial infarction and congestive heart failure
- Renal failure

The classic clinical signs and symptoms of a pericardial tamponade are summarized as the **Beck triad**: narrowing pulse pressure, JVD, and muffled heart tones. However, Beck triad is present in only 10% to 40% of patients with pericardial tamponade and can be difficult to assess in the transport environment. In patients with hypovolemia or hemorrhage, there may be no JVD. Additionally, patients may present with a paradoxical pulse (loss of radial pulse on inspiration, often with a drop of 10 to 15 mm Hg in the systolic pressure as well), electrical alternans, progressive decreases of ECG voltage, hypotension, cyanosis, dyspnea, tachycardia, and pulseless electrical activity. A rising CVP greater than 15 cm H_2O may also be present (until precipitous decompensation occurs), especially if the patient is otherwise normovolemic. Chest radiographs may show a widened mediastinum. Diagnosis is usually established with an ultrasonographic (FAST) exam, using a portable ultrasonography unit.

Most often, prehospital management of pericardial tamponade is only supportive, and administering a fluid bolus may prevent decompensation. On some occasions, with proper training and certification, the CCTP may be called upon to perform or assist in an emergency **pericardiocentesis** **FIGURE 11-19**. The equipment needed for this procedure includes:



Pericardiocentesis

FIGURE 11-19 Pericardiocentesis in pericardial tamponade.

© Jones & Bartlett Learning.

- Appropriate PPE, including sterile gloves, gown, and mask
- Cardiac monitor and defibrillator
- Pericardiocentesis kit (Mansfield catheter)
- 50-mL Luer-lock syringes
- Sterile tubes for specimen collection
- 2% chlorhexidine
- Appropriate medications (cardiac, sedating, and numbing)
- Pigtail catheter
- Drapes
- 16- to 18-gauge by 5.5-inch (14-cm) spinal needle
- Three-way stopcock
- Sterile alligator clip
- Scalpel
- Assorted needles and syringes
- Preferably, the availability of ultrasonographic imaging

Indications for pericardiocentesis include the following conditions:

- Chest trauma with patient in extremis, such as those with pulseless electrical activity
- FAST exam showing pericardial blood with clinical signs

Contraindications include:

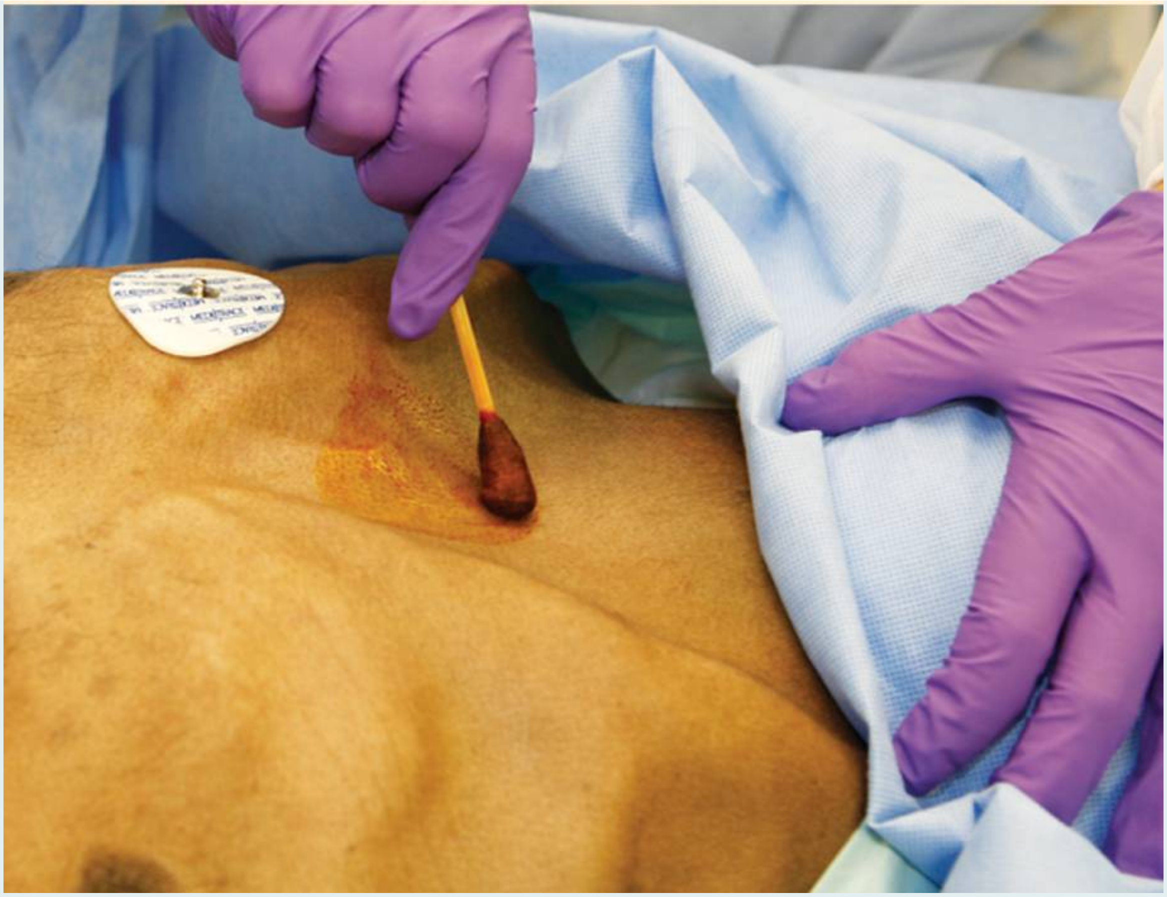
- No demonstrable pericardial effusion
- Severe thrombocytopenia or noncorrectable coagulopathy
- Skin or soft-tissue infection at the proposed needle site (except in a critical patient)

Pericardiocentesis is associated with several potential complications:

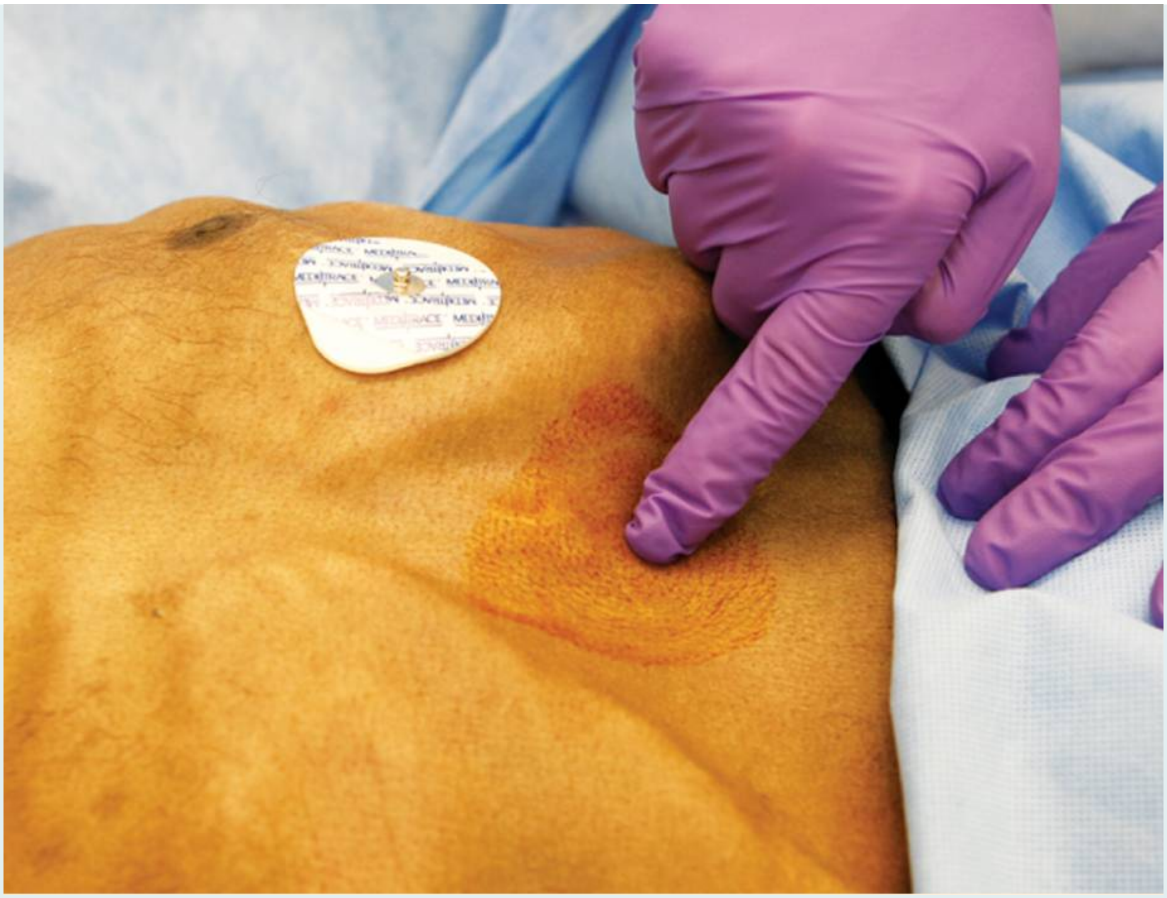
- Malignant ventricular arrhythmias, including cardiac arrest
- Puncture of the ventricles or atria (most commonly the right ventricle)
- Laceration of the coronary arteries and lung
- Pericardial tamponade from a myocardial laceration
- Air embolism
- Acute pulmonary edema
- Puncture of the liver or stomach
- Infection

Skill Drill 11-5 illustrates the clinical procedure for pericardiocentesis, which is described here:

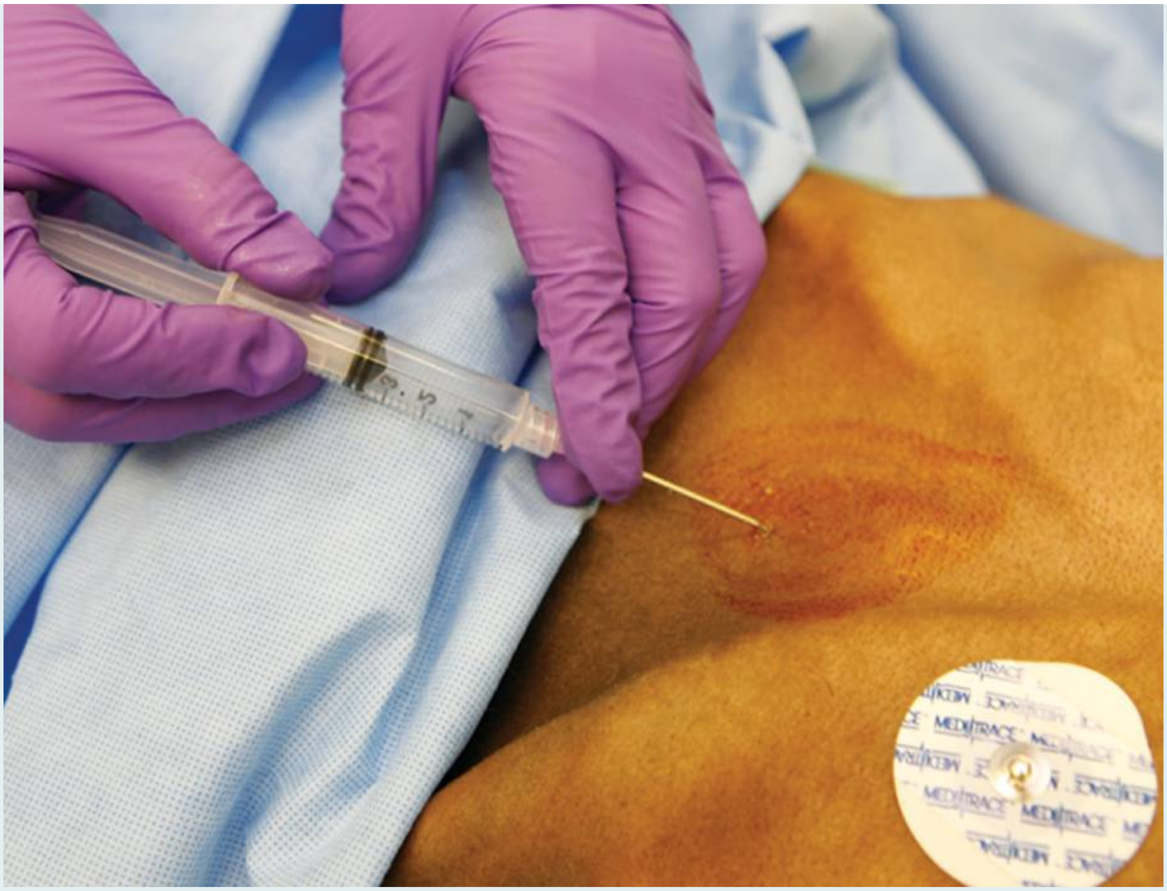
SKILL DRILL 11-5 Pericardiocentesis



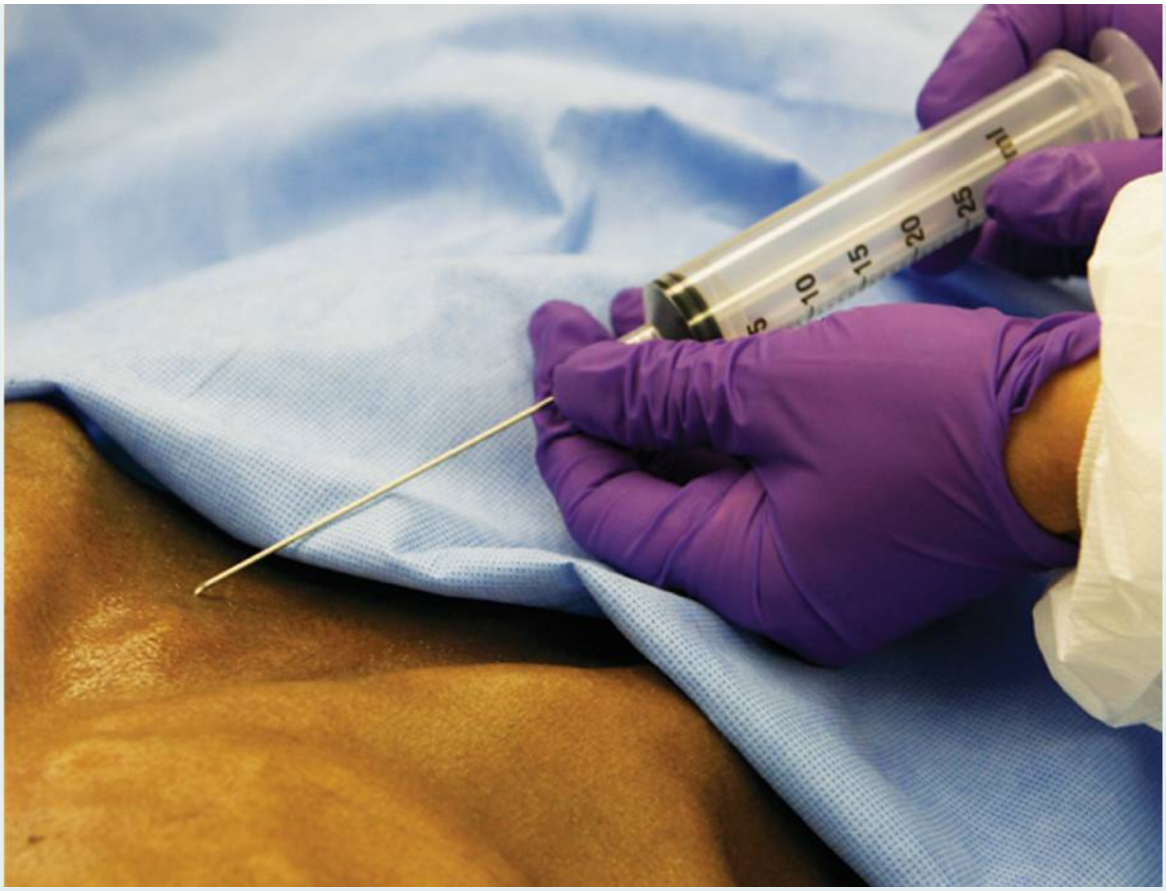
Step 1
Prepare the equipment and obtain baseline vital signs, including pulse oximetry findings. Place the patient into a supine position with the head of the stretcher elevated to a 20° to 30° angle as tolerated. Premedicate per your protocol or online medical control. Don a mask, gown, hair cover, and sterile gloves. Cleanse the site with an appropriate aseptic technique and drape the area.



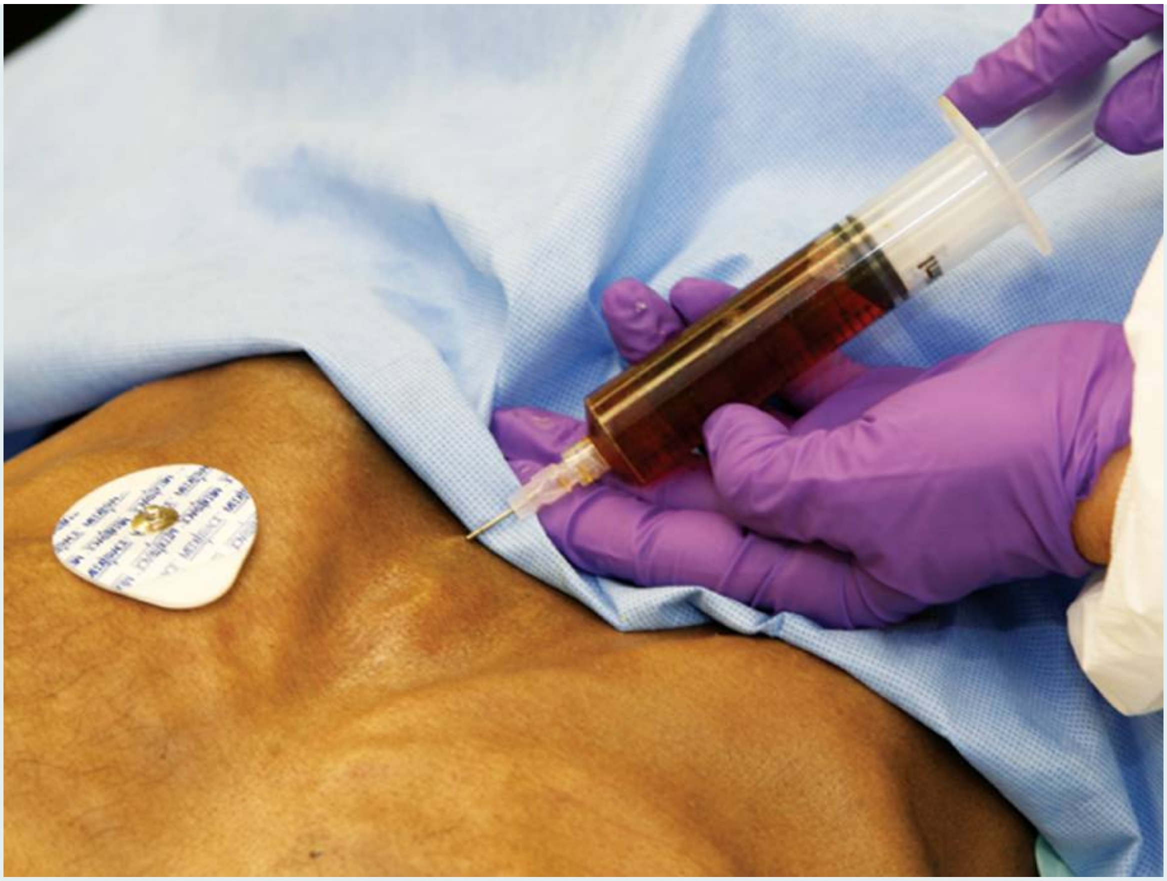
Step 2
Identify the needle entry site directly below the xiphoid.



Step 3
Infiltrate the area with 1% lidocaine into the skin and deeper tissues.



Step 4
Insert the needle-on-syringe at the identified entry site, at a 30° angle directed toward the left shoulder or directly cephalad.



Step 5
Gently aspirate while inserting the needle. *If the needle is advanced too far, the myocardium will become irritated. Pull the needle back slightly until you can aspirate fluid.* Place the blood sample into the collection container and transport it with the patient. Administer medications per your protocol or online medical control. Monitor for postprocedure complications. Monitor vital signs and for JVD at 15-minute intervals for 1 hour, and then every hour for 4 hours.

All images © Jones & Bartlett Learning.

1. Prepare the equipment and obtain baseline vital signs, including pulse oximetry findings.
2. Place the patient into a supine position with the head of the stretcher elevated to a 20° to 30° angle as tolerated.
3. Premedicate per your protocol or online medical control.
4. Don a mask, gown, hair cover, and sterile gloves.

5. Cleanse the site with an appropriate aseptic technique and drape the area **STEP 1**.
6. Identify the needle entry site directly below the xiphoid—approximately 0.4 inch (1 cm) left of midline **STEP 2**.
7. Infiltrate the area with 1% lidocaine into the skin and deeper tissues, if the patient is conscious **STEP 3**.
8. Insert the needle-on-syringe, with 2 to 3 mL of sterile saline in it, at the identified entry site, at a 30° angle directed toward the left shoulder or directly cephalad **STEP 4**.
9. Gently aspirate while inserting the needle **STEP 5**. Some resistance may be felt as the needle enters the pericardial sac. *If the needle is advanced too far, the myocardium will become irritated. The needle may vibrate with the pulse. Pull back the needle slightly until you can aspirate fluid.*
10. If blood is withdrawn and placed in an open container, it should not clot if it comes from the pericardial sac. Place the sample into the collection container and transport it with the patient.
11. Administer medications per your protocol or online medical control.
12. Monitor for postprocedural complications.
13. Monitor vital signs and for JVD at 15-minute intervals for 1 hour, and then every hour for 4 hours.
14. The entire procedure should occur under ultrasonographic guidance, when possible, to visualize entry into the pericardium and prevent cardiac injury.
15. In some cases, a catheter or drain may be placed, with the stopcock being opened for periodic drainage as needed.

Signs and Symptoms

Pericardial Tamponade

- Beck triad: narrowing pulse pressure, JVD, and muffled heart tones
- Paradoxical pulse
- Electrical alternans

- Progressive decreases of ECG voltage
- Hypotension
- Cyanosis
- Dyspnea
- Tachycardia
- Pulseless electrical activity
- Increasing CVP (greater than 15 cm H_2O)
- Widened mediastinum on chest radiograph

Transport Management

Pericardial Tamponade

- Provide supportive care.
- Administer a fluid bolus.
- If necessary, perform an emergency pericardiocentesis or pericardial window.

Pericardial Window

CCTPs should be familiar with the anatomic landmarks of a pericardial window (an in-hospital surgical procedure) and postprocedural monitoring. A pericardial window is performed by incising the skin just inferior to the xiphoid process, in the midline, and dissecting down to the anterior and inferior surface of the pericardium **FIGURE 11-20**. Once identified, the pericardium is incised and fluid is allowed to drain. Typically, a small section, approximately 1 × 1 inch (2.5 × 2.5 cm), is removed to prevent reaccumulation of fluid and tamponade recurrence. Sudden decompensation can occur if cardiac preload is not adequate during the initial phases of this procedure. The pericardial window procedure concludes with placement of a drain through the dissection tract into the pericardium. For the CCTP, it is important to note the quality and color of drainage and the drain output on initial contact with the patient and to monitor for postprocedural complications, such as arrhythmia or recurrence of tamponade.

FIGURE 11-20 A large pericardial window. Sutures ensure that all the layers stay in place.

Aortic Dissection/Transection

Traumatic aortic rupture is the most common cause of immediate death in MVCs. The body's entire blood volume passes through the aorta; therefore, it is easy to understand how death could occur immediately when the aorta is torn. Most people with aortic rupture die within minutes, often prior to the arrival of the CCTP. Those who do survive require emergent surgical intervention as soon as possible.

The most widely accepted etiology of traumatic aortic tears is that the aorta is injured at the ligamentum arteriosum, the remnant of the fetal ductus arteriosus, as a result of decelerating injuries and shear force. Tears in the ascending aorta are almost uniformly immediately fatal, but patients with tears on the descending side have approximately a 15% chance of surviving until they reach the operating room. The mortality rate among those patients who make it to the hospital is 30%. Some trauma centers are now using endovascular stenting with some success to treat patients with aortic rupture.

Diagnosis of traumatic aortic tears is very difficult in the prehospital setting and may even be missed in the hospital. The CCTP should closely evaluate the mechanism of injury to assess the likelihood of an aortic injury. A pulse deficit or blood pressure difference from one arm to the other, usually greater than 15 to 20 mm Hg, may be noted if the dissection is at the top of the arch of the aorta (ie, beyond the left subclavian artery). Level of consciousness may be decreased due to decreased carotid pressure. Other signs include hypertension of the upper extremities; decrease of pulse amplitude in the lower extremities; chest pain; chest wall bruising; widened mediastinum on chest radiograph with blurring of the aortic knob; and fractures of the first and second ribs.

Definitive diagnosis is made with CT and TEE. Potential aortic tears are managed as follows:

1. Maintain an open airway and apply appropriate oxygen therapy.
2. Assist ventilation and be prepared to intubate.
3. Initiate IV fluids to maintain blood pressure *only* at 90 mm Hg systolic or 65 mm Hg MAP.
4. Medications such as beta blockers (eg, esmolol or metoprolol) may be administered and fluids withheld to keep the MAP around 65 to 70 mm Hg.
5. Initiate transport immediately.
6. Monitor oxygen saturation, vital signs, and the cardiac monitor.
7. Transport the patient to an appropriate facility with early advance notification.

Signs and Symptoms

Traumatic Aortic Rupture

- Pulse deficit or blood pressure difference from one arm to the other
- Hypotension
- Decreased level of consciousness
- Hypertension of the upper extremities
- Decreased pulse amplitude in the lower extremities
- Decreased blood pressure
- Chest pain
- Chest wall bruising
- Widened mediastinum on chest radiograph with blurring of the aortic knob
- Fractures of the first and second ribs

Transport Management

Traumatic Aortic Rupture

- Maintain an open airway; apply appropriate oxygen therapy.
- Assist ventilation; be prepared to intubate.
- Initiate IV fluids.
- Administer beta blockers (eg, esmolol or metoprolol) and withhold fluids to keep the MAP at 65 to 70 mm Hg (90 mm Hg systolic blood pressure).
- Begin immediate transport.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Transport to an appropriate facility with early advance notification.

Myocardial Contusion

A contusion, or bruise, results from damage to small blood vessels, causing localized bleeding and direct trauma to cells. A contusion to the myocardium primarily results from blunt trauma to the anterior chest wall. MVCs are an obvious mechanism of injury, but other blunt trauma to the anterior part of the chest (eg, gunshot to a bulletproof vest, baseballs) may also cause this condition. Myocardial contusions have been reported even in low-speed (20 to 35 mph) MVCs, without external chest wall bruising. Estimates of this injury’s frequency vary widely, ranging from 16% to 76% of all blunt chest trauma cases.

The amount of damage to myocardial cells also varies widely in these injuries. Areas downstream of injured blood vessels may no longer be perfused, resulting in damage similar to that caused by a myocardial infarction resulting from atherosclerotic coronary artery disease. In turn, the most common signs and symptoms are similar to those associated with acute myocardial infarction: chest pain, palpitations, and arrhythmias. Arrhythmias may develop as late as 12 to 72 hours after injury. Irregular rhythms to watch for include premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation. The appearance of premature ventricular contractions should prompt high suspicion for an evolving cardiac injury. ST-segment elevations may be evident on the 12-lead ECG, particularly in the right-side (V_4R) leads. Bundle branch blocks, especially on the right (anterior) side of the heart, and atrioventricular blocks may develop if the intraventricular septum is involved. The wider the QRS in a bundle branch block, the more the ventricles are out of phase, reducing the ejection fraction and compromising cardiac output. Other signs include cardiac murmur, pericardial friction rub, and persistent tachycardia. If the injury is large enough, cardiogenic shock may result from the myocardium's reduced contractibility.

Lab tests for myocardial contusion may be performed in the field with a point-of-care device but are more likely to be performed in the hospital. They include measurements of troponin I and troponin T. These proteins are very specific to cardiac injury and are elevated in the presence of myocardial injury. The creatine kinase MB–fraction test is not used to assess for this condition.

Current recommendations for the management of myocardial contusion are mostly supportive. Treatment modalities include assessment of cardiac function (typically with echocardiography), oxygen administration if indicated, resuscitation without fluid overload, and continuous ECG monitoring for the development of arrhythmias.

Signs and Symptoms

Myocardial Contusion

- Chest pain
- Palpitations
- Arrhythmias: premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation
- ST-segment elevation on the 12-lead ECG, particularly the V_4R leads
- Bundle branch blocks, especially on the right side
- Atrioventricular blocks
- Cardiac murmur
- Pericardial friction rub
- Persistent tachycardia without other cause
- Cardiogenic shock

Transport Management

Myocardial Contusion

- Administer appropriate oxygen therapy.
- Provide pharmacologic treatment of arrhythmias.
- Watch closely for development of hemopericardium, leading to pericardial tamponade, myocardial rupture, or ventricular aneurysm.

Diaphragmatic Rupture

Either blunt or penetrating trauma may lead to rupture of the diaphragm. Penetration inferior to the nipple line or scapula may lacerate the diaphragm. These lacerations are usually small and not an immediate problem, but will require eventual surgical repair. A larger problem is blunt compression of the abdomen that causes a large rupture and herniation of abdominal organs into the thoracic cavity. This displacement impinges on lung function and decreases venous return, such that both ventilatory function and cardiac output are reduced.

Signs and symptoms of diaphragmatic rupture include chest and/or abdominal pain, acute respiratory distress, decreased breath sounds, and abdominal sounds in the chest cavity. Patients may also have subcutaneous emphysema or obvious penetration in the thoracic region.

Management of diaphragmatic rupture includes supporting ventilation and oxygenation. Nasogastric or orogastric decompression of the stomach may temporarily assist in reducing the volume of abdominal organs in the thoracic cavity. Surgical repair is the definitive treatment for these patients, and transport should not be delayed to perform additional prehospital procedures.

Signs and Symptoms

Diaphragmatic Rupture

- Chest or abdominal pain
- Acute respiratory distress
- Decreased breath sounds
- Abdominal sounds in the chest cavity
- Subcutaneous emphysema
- Obvious penetration in the chest or abdomen

Transport Management

Diaphragmatic Rupture

- Assist ventilation.
- Administer appropriate oxygen therapy.
- Insert a nasogastric or orogastric tube to decompress the stomach if advised by medical control.

Tracheobronchial Disruption

Tracheobronchial injuries are rare, but often life threatening. They occur in less than 3% of blunt and penetrating (the more common cause) chest injuries, but may have a fatality rate as high as 30%. Most tracheobronchial injuries occur within 1.5 inches (4 cm) of the carina, although they can occur anywhere along the tracheobronchial tree. The leakage of air may cause a tension pneumothorax or tension pneumomediastinum, which will act like a cardiac tamponade. Signs and symptoms include severe respiratory distress, hypoxia, tachycardia, subcutaneous emphysema (especially in the neck), hemoptysis, JVD, and tracheal deviation.

An apparent tension pneumothorax that does not improve after needle thoracostomy or one associated with continuous flow of air from the needle or chest tube is probably a tracheobronchial tear. Management includes judicious use of ventilatory support. If positive-pressure ventilation makes the patient worse and no relief is obtained from needle decompression, then oxygen supplementation alone may be necessary.

Signs and Symptoms

Tracheobronchial Disruption

- Severe respiratory distress
- Hypoxia
- Tachycardia
- Subcutaneous emphysema, especially in the neck
- Hemoptysis
- JVD
- Tracheal deviation
- Continuous air leak after chest tube placement

Transport Management

Tracheobronchial Disruption

- Administer appropriate oxygen therapy.
- Provide positive-pressure ventilation, unless it worsens the patient’s condition.
- Perform needle decompression, if necessary.
- Insert a chest tube or pigtail catheter, if necessary and if protocols allow. Patients may need more than one in rare cases of very proximal bronchial injury.

Pulmonary Contusion

Tearing and lacerations to the lung tissue can cause bleeding and leakage of plasma into the alveoli and the interstitial spaces around them **FIGURE 11-21**. This damage occurs when the lung hits the inside of the chest wall (such as in blunt chest injury) or as a result of shearing force causing stretching and tearing of capillaries and alveoli. Pressure waves from explosions may also stretch and tear lung tissue. With this injury, blood in and around the alveoli interferes with gas exchange and leads to severe hypoxemia. The bleeding may begin soon after the impact, but more often develops over hours; the patient's deterioration may occur over a period of 24 hours or longer. Uninjured parts of the lung undergo gradual thickening of the alveolar capillary membranes as the inflammatory process evolves. Close monitoring is necessary for at least 48 hours after injury, as the inflammatory response of the lung to trauma can cause fluid shifts that compromise the ability to exchange gases across capillary membranes.

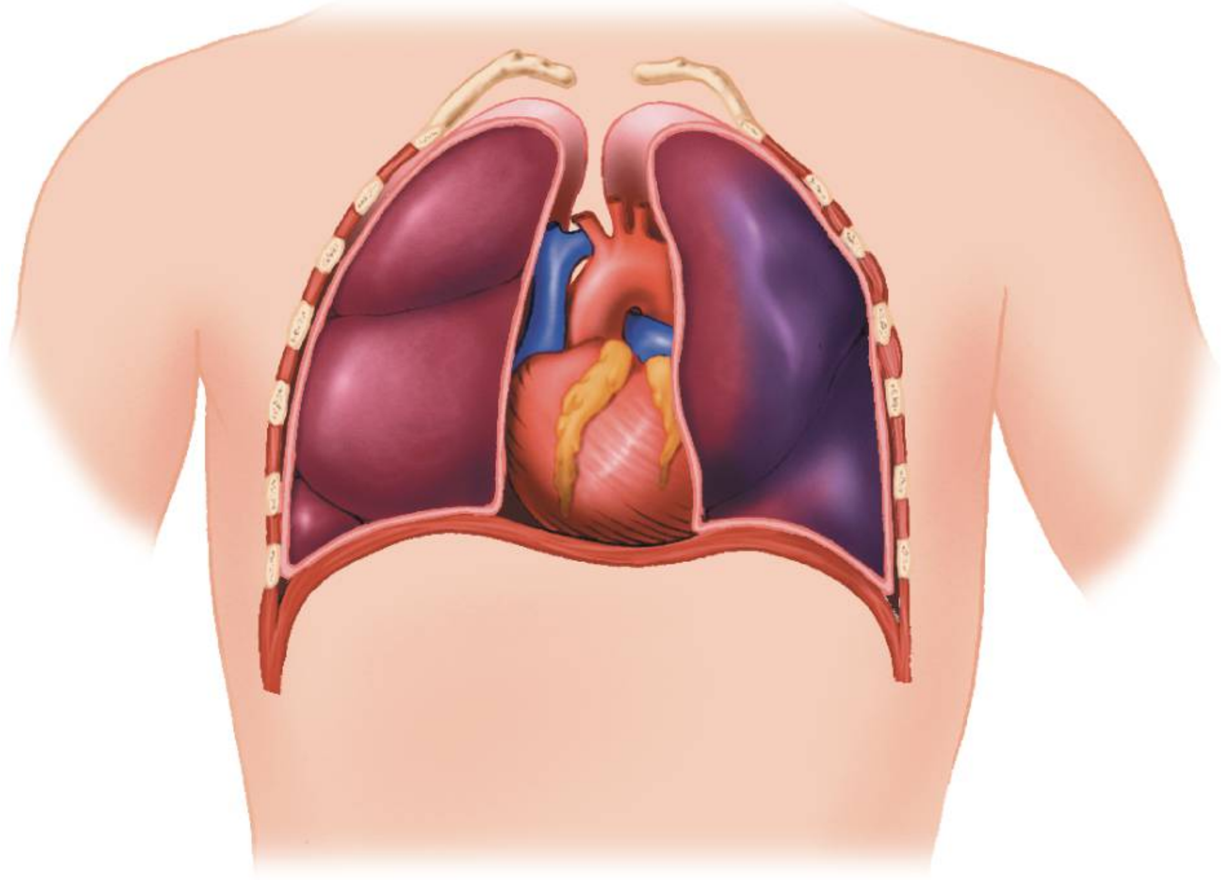

FIGURE 11-21 Pulmonary contusion.

© Jones & Bartlett Learning.

Patients with flail chest or similar significant mechanisms of injury may be assumed to have a developing pulmonary contusion. Signs and symptoms may initially be absent, but over time the trauma patient's condition will deteriorate; at that point, the CCTP may be called to transfer the patient to a medical center that has more sophisticated technology. The primary sign of this deterioration is increasing hypoxia. Although definitive chest radiographs will show an opacity in the area of chest wall damage, a clear chest radiograph does not rule out a pulmonary contusion. Worsening oxygenation and increased difficulty ventilating over time with a pertinent mechanism of injury are sufficient to make this diagnosis.

Treatment is to support ventilation with mechanical ventilation—traditionally done with pressure-control ventilation and a positive end-expiratory pressure of 10 to 15 cm H_2O. Today, however, more patients are being successfully supported with noninvasive ventilation. In either case, and especially in patients with rib fractures or flail chest, adequate analgesia is imperative. Fluid restriction may be helpful as well, but volume resuscitation in difficult-to-ventilate patients has become controversial unless physiologic parameters suggest volume resuscitation would be beneficial. In the field, resuscitation fluids should be given as needed for systolic pressure support.

Signs and Symptoms

Pulmonary Contusion

- Initially absent (no signs and symptoms)
- Increasing hypoxia over hours to days
- Opacity in the area of chest wall damage on chest radiograph
- Worsening oxygenation and increased difficulty ventilating over time as fluid accumulates in the lungs secondary to inflammation

Transport Management

Pulmonary Contusion

- Provide ventilatory support: either (1) pressure-control or another pressure-limited mode of ventilation with positive end-expiratory pressure of 10 to 15 cm H_2O or (2) noninvasive ventilation.
- Provide adequate analgesia.

Esophageal Perforation

Esophageal perforations are most often caused by penetrating injuries, such as projectiles, or caustic ingestion. They can also result from a medical cause, such as cancer or gastroesophageal reflux disease erosions. Excessive vomiting may cause a Mallory-Weiss tear.

Signs and symptoms of esophageal perforation include pain, fever, dysphagia, subcutaneous air in the neck and neck stiffness, and pleuritic-type pain. Free mediastinal air or widening may be found on imaging studies. The air introduced into the mediastinum may produce a crunching sound on auscultation.

Treatment is supportive of the ABCs. Nasogastric tube insertion is usually contraindicated.

Signs and Symptoms

Esophageal Perforation

- Pain
- Fever
- Dysphagia
- Subcutaneous air in the neck and neck stiffness
- Pleuritic-type pain
- Free mediastinal air or widening on imaging studies
- A “crunching” sound on auscultation

Transport Management

Esophageal Perforation

- Monitor the ABCs. Support physiologic parameters as indicated.
- Do not insert a nasogastric tube. If one is in place, do not remove it.

Traumatic Asphyxia

Traumatic asphyxia describes a severe, sudden crushing injury to the chest and abdomen, such as occurs when a patient is caught between a truck and a loading dock or when a vehicle falls off a jack. This injury forces blood backward out of the right side of the heart, engorging the veins of the chest, neck, and head. The deoxygenated blood makes the chest, neck, and head look blue or purple, as in extreme cyanosis, giving rise to the name “asphyxia” **FIGURE 11-22**.

Traumatic asphyxia is not a form of asphyxia, nor is it by itself fatal, despite its undeserved reputation for high mortality. Associated injuries, if present, are far more serious—for example, brain hemorrhage, possible cardiac rupture, eye injuries, flail chest, ruptured diaphragm, and pulmonary or myocardial contusions. If the patient survives the initial injury, the dramatic purple color will fade after several weeks.

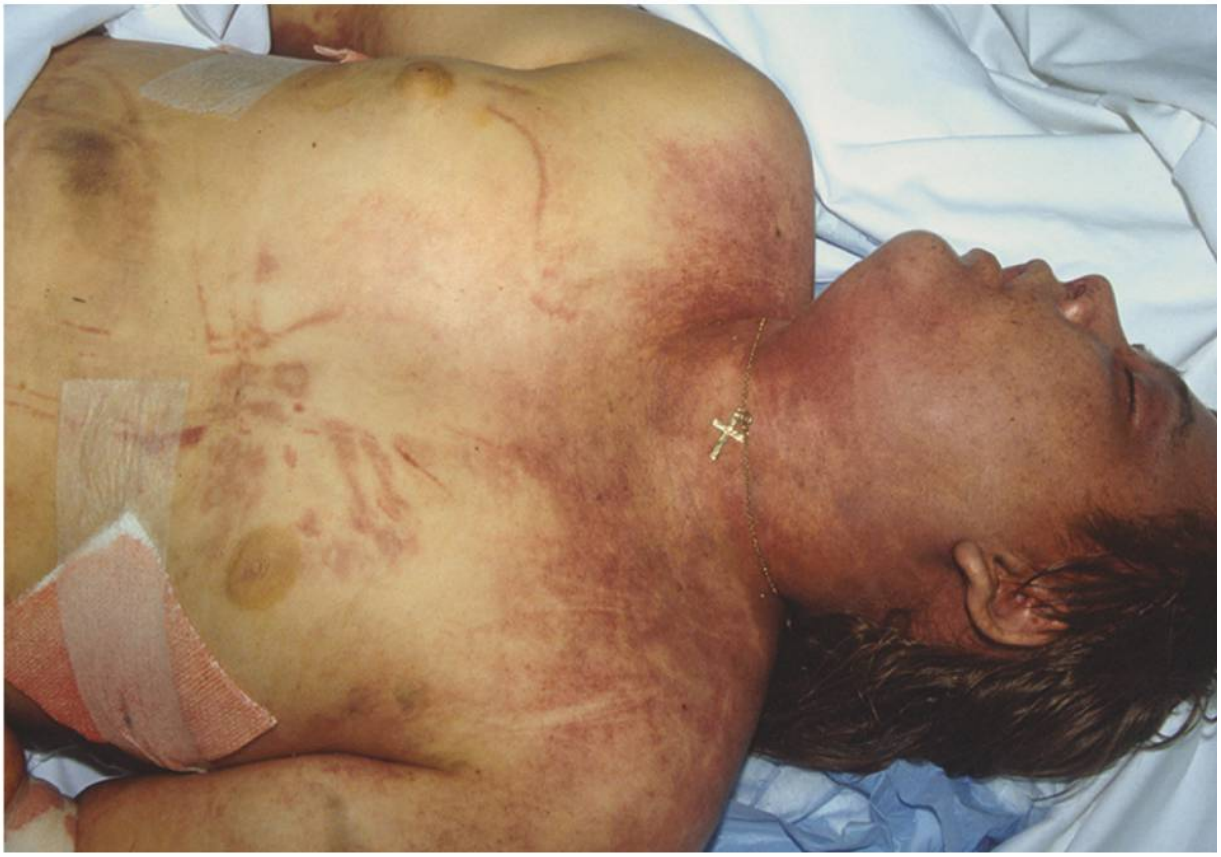

FIGURE 11-22 Traumatic asphyxia.

© Charles Stewart, MD, EMDM, MPH.

Specific assessment findings, besides the mechanism of injury and the purple discoloration, include JVD, conjunctival or scleral petechiae, and a sharp line of demarcation with normal skin color below it. Treatment is primarily supportive, including treatment for the associated injuries. If the patient is found entrapped, IV lines and a treatment plan to deal with sudden hypotension and possible release of myoglobin and potassium are necessary when the patient is freed. (The patient may have crush syndrome, depending on how long the individual was entrapped.)

Signs and Symptoms

Traumatic Asphyxia

- Blue or purple color of the chest, neck, and head
- Associated injuries at the site of crush
- JVD
- Conjunctival or scleral petechiae
- Sharp line of demarcation with normal skin color below it

Transport Management

Traumatic Asphyxia

- Provide supportive care.
- Treat the associated injuries.
- If the patient is found entrapped, insert IV lines and develop a treatment plan in consultation with the receiving facility to deal with sudden hypotension and possible release of myoglobin and potassium when the patient is freed.

Facial Trauma

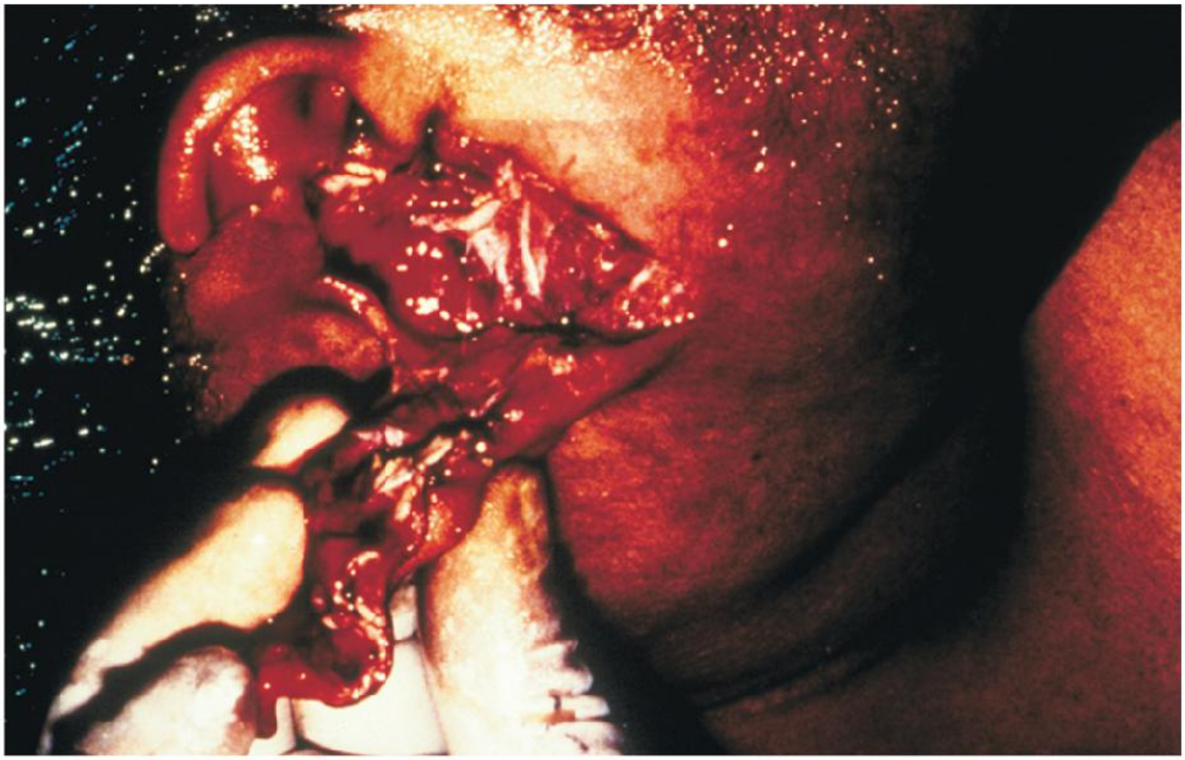
Facial trauma can be life threatening and has many implications for patients both socially and in terms of self-image. Such trauma can be distracting for providers as well. Facial injuries are of special significance because the patient experiences an immediate life threat as a result of airway compromise and the loss of sensory inputs through sight and hearing. CCTPs must also be aware of their own emotional response and reactions to these injuries.

Ear Injuries

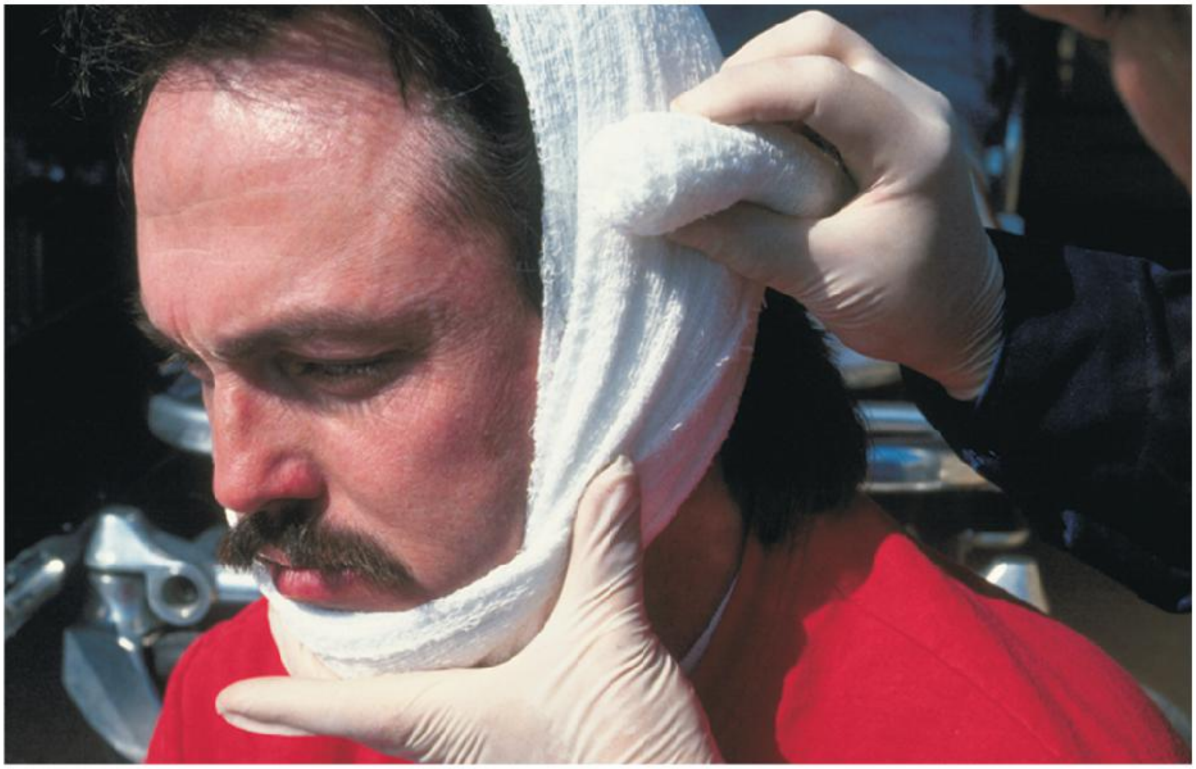
Ear injuries are generally not considered an area of concern for CCTPs because they are not life threatening and do not involve technology for transport. Ear injuries may be present in patients who have other more serious injuries, but they usually do not need much attention on either a scene call or an interfacility transport. A punctured eardrum, however, may cause vertigo and nausea, which the CCTP may need to control with medication. The patient should be protected from aircraft noise.

External Ear Injury

External ear injuries are considered a local injury with no acute systemic implications. The long-term possibility of infection or deformity (cauliflower ear) is not usually life threatening. Standard soft-tissue injury care applies **FIGURE 11-23**.



A



B

FIGURE 11-23 A. A major laceration of the ear. **B.** Place a soft, sterile pad behind the ear, between it and the scalp. Then wrap a roller gauze bandage (eg, Kling or Kerlex) around the head to include the entire ear.

A. © American Academy of Orthopaedic Surgeons; **B.** © Jones & Bartlett Learning.

Blood or fluid coming from the auditory canal indicates a more serious injury. A halo test for cerebrospinal fluid mixed with blood, indicating basilar skull fracture, is easily done with a piece of filter paper or a gauze pad. Do not pack the ear canal; rather, use a loose dressing. Chapter 12, *Neurologic Emergencies*, covers neurologic emergencies in depth.

Ruptured Tympanic Membrane

A ruptured tympanic membrane may be the result of overpressure injury, such as occurs with an explosion or a direct blow to the ear. Rupture may also result from failure to equalize middle ear pressure during scuba diving. In the absence of infection, most of these injuries will heal spontaneously and are not life threatening, but their presence should raise the suspicion for other, much more serious overpressure injuries. Principal signs and symptoms are pain and vertigo, possibly accompanied by vomiting. Sometimes blood may be visible in the ear canal. Treatment includes an external dressing to reduce the chance of infection (do not pack the ear canal), and possibly use of an antiemetic. This injury is a relative contraindication to aircraft transport of the patient.

Signs and Symptoms

Ruptured Tympanic Membrane

- Pain
- Vertigo
- Vomiting
- Blood visible in the ear canal

Transport Management

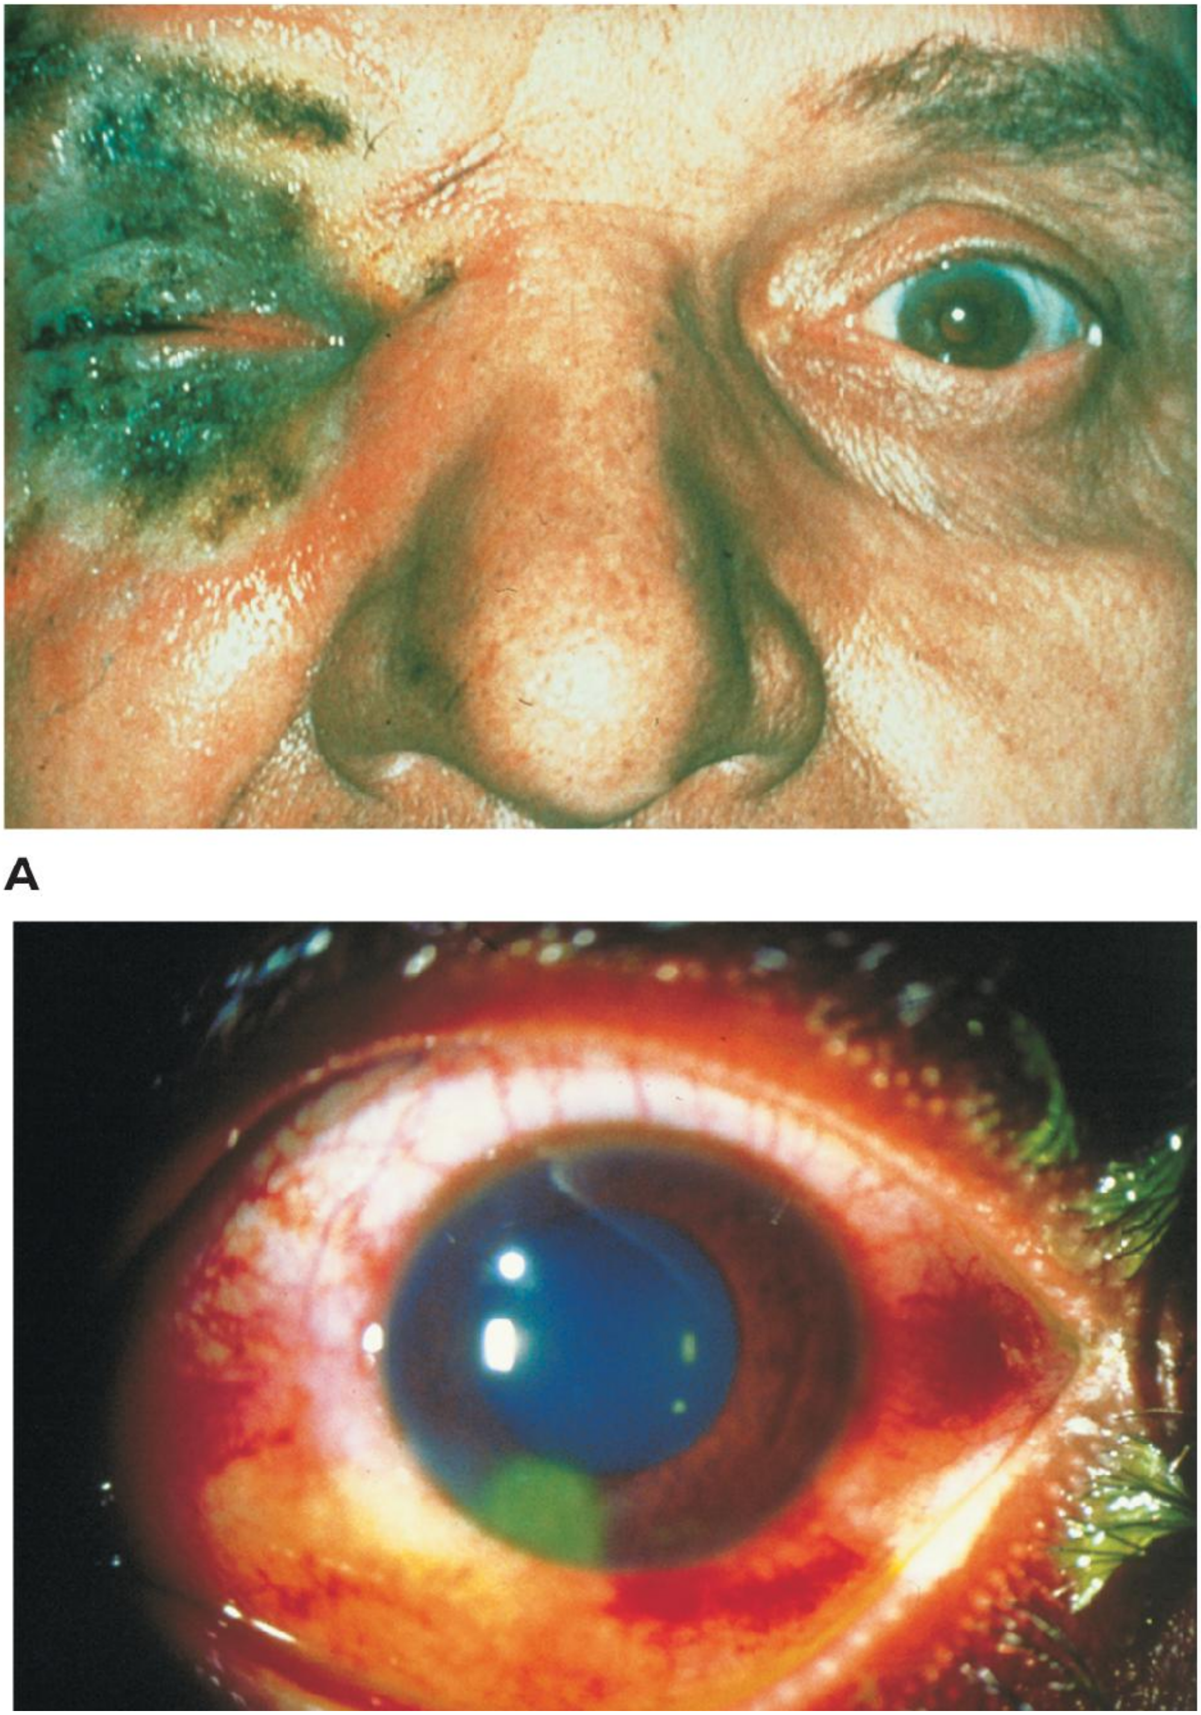
Ruptured Tympanic Membrane

- Apply an external dressing (do not pack the ear canal).
- Administer an antiemetic, if necessary.

Eye Injuries

The CCTP may transport patients with eye injuries from the field or from a local hospital to a specialty center with ophthalmologic services. Eye injuries, although often dramatic, are not life threatening. Although vision loss is serious, there is usually little for the CCTP to do other than protect the eye from further injury and transport the patient to the ophthalmology service.

The major exception to this rule is chemical burns to the eye **FIGURE 11-24**—a case in which transport can actually interfere with appropriate care. Adequate washing is essential and should be performed with (preferably) sterile saline or dextrose solution for at least 10 minutes prior to transport for acid burns and at least twice as long for alkali burns. Lavage should then continue en route if possible, though such care may be difficult to administer in an aircraft. Use of topical anesthesia such as tetracaine (TetraVisc) or proparacaine (Alcaine) is necessary for flushing to be effective. The CCTP must be alert to the possibility of other more serious injuries that may have been overlooked and should always be treated first. Many techniques may be used when irrigating the eyes; the Morgan Lens is one.



A

B

FIGURE 11-24 A. Chemical burns typically occur when an acid or alkali is splashed into the eye. **B.** A chemical burn from lye, an alkaline solution.

© American Academy of Orthopaedic Surgeons.

Eyelid Lacerations

Soft-tissue injuries to the eye and surrounding structures include lacerations and swelling. Direct pressure, applied in a manner so as not to push on the globe (pressure directly on the globe may cause vagal stimulation), will usually stop any bleeding. Application of cold may reduce swelling. The CCTP should have concern for concomitant eye injuries when an eyelid laceration is observed.

Conjunctival and Corneal Injuries

The most common conjunctival and corneal injuries are abrasions and foreign bodies. More serious injuries involve shrapnel from high-speed equipment such as drills and saws. These types of injuries often involve objects impaled in the eye. If possible, the eye and the object should be prevented from movement for transport. A cup or shield is generally used for this purpose **FIGURE 11-25**. The unaffected eye may need to be patched to prevent sympathetic movement, although this practice has fallen out of favor, as little evidence supports any benefit to the patient. Removal of most objects will need to be visualized with a slit lamp or ocular loupe under local anesthetic.

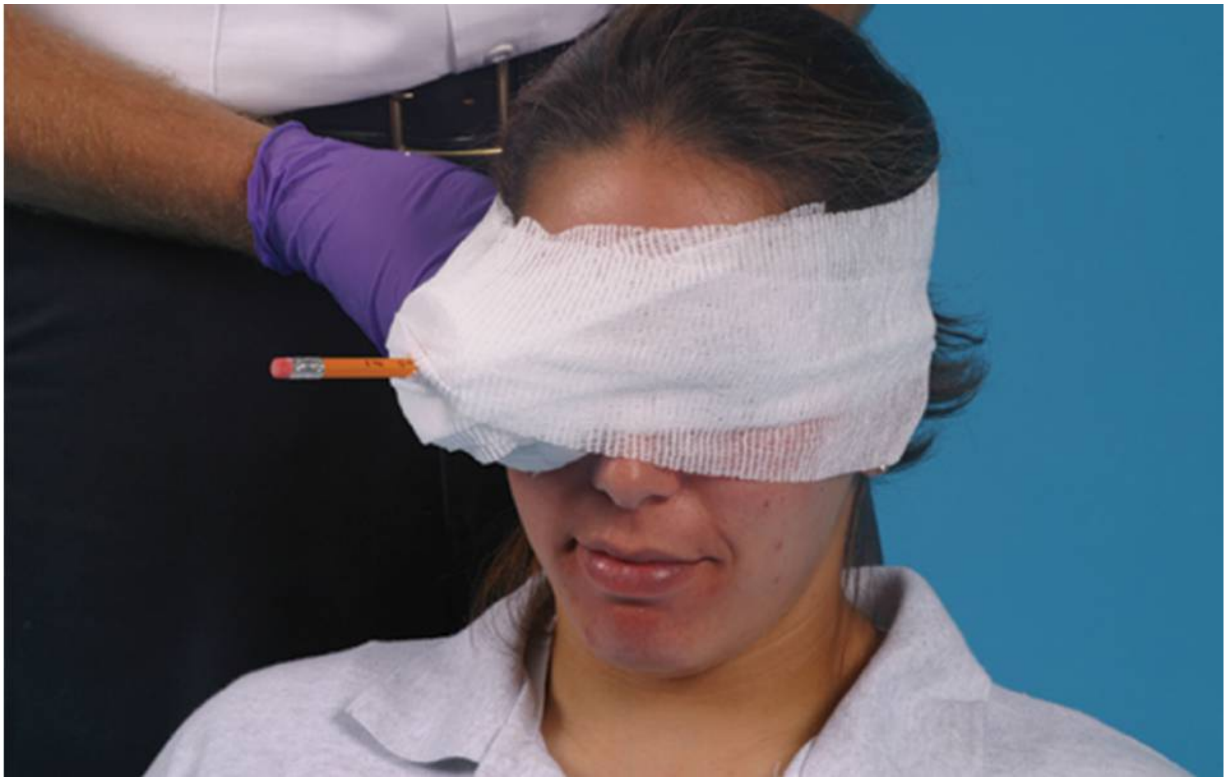


FIGURE 11-25 An impaled object is secured with a protective barrier and a bulky dressing.

© Jones & Bartlett Learning.

Hyphema

A **hyphema** is a collection of blood in the anterior chamber of the eye **FIGURE 11-26**. It may result from blunt trauma to the eye or a medical cause. A hyphema may also be a marker of damage to other structures of the eye and, therefore, requires a full ophthalmologic examination. One concern that arises with this condition is blood clotting in the canal connecting the anterior chamber of the eye to the posterior chamber, causing an acute rise in intraocular pressure. The patient will complain of reduced vision directly proportional to the size of the hyphema. Often the blood is visible unaided, but shining a penlight obliquely at the globe may help to visualize the blood, which will pool with gravity.

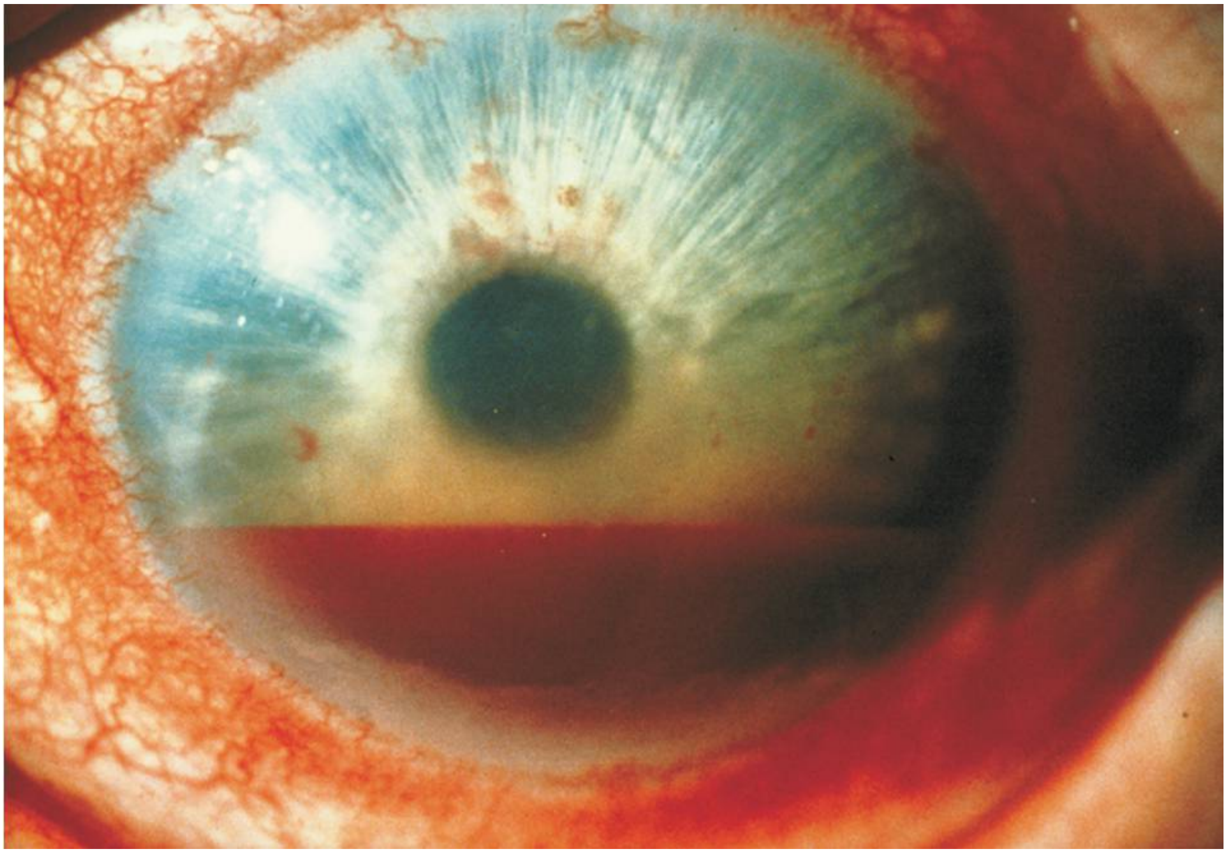

FIGURE 11-26 A hyphema.

© American Academy of Orthopaedic Surgeons.

Grading of hyphemas is based on four categories:

- Grade 1: Layered blood occupying less than one-third of the anterior chamber
- Grade 2: Blood filling one-third to one-half of the anterior chamber
- Grade 3: Layered blood filling one-half to less than the total anterior chamber
- Grade 4: Total clotted blood, often called a blackball or 8-ball hyphema

If there are no other contraindications, transport should occur with the patient sitting as upright as possible and with eye patches applied per protocols or local medical direction. Pain should be managed with acetaminophen; medications with antiplatelet effects (eg, aspirin) should be avoided. An anxiolytic may facilitate transport.

Signs and Symptoms

Hyphema

- Patient complaint of reduced vision (directly proportional to the size of the hyphema)
- Pool of blood in the eye; may be visualized either directly or by shining a penlight obliquely at the globe

Transport Management

Hyphema

- Patch both eyes (controversial).
- Transport the patient sitting as upright as possible.
- Administer analgesics; avoid antiplatelet agents.
- Administer an anxiolytic if necessary to facilitate transport.

Ocular Globe Rupture

Rupture of the globe with ensuing leak of the vitreous humor may be the result of penetration with a foreign body or blunt trauma. Signs of an open globe include penetrating lid injury, bullous conjunctival hemorrhage, blood in the anterior chamber (hyphema), peaked or deformed pupil, lens dislocation, vitreous hemorrhage, and decreased visual acuity. Management for transport includes protecting the affected eye with a rigid eye shield or cup, rather than a soft patch. Antiemetics and pain medication should be given for transport. Sometimes antitussives are also used to prevent any increase in intraocular pressure as the result of coughing.

Signs and Symptoms

Ocular Globe Rupture

- Penetrating lid injury
- Bullous conjunctival hemorrhage
- Blood in the anterior chamber (hyphema)
- Peaked or deformed pupil
- Lens dislocation
- Vitreous hemorrhage
- Decreased visual acuity

Transport Management

Ocular Globe Rupture

- Protect the affected eye with a rigid eye shield or cup.
- Administer antiemetics and pain medication.
- If necessary, administer an antitussive to prevent increased intraocular pressure as the result of coughing.

Ocular Avulsion

Enucleation of the eyeball from the eye socket is possible from a trauma **FIGURE 11-27**. Multiple facial fractures may increase the chance of this injury. The globe may actually be hanging from the optic nerve. Despite the dramatic presentation, loss of vision is not inevitable. Proper care includes protecting the eye from further trauma in transit by using a protective cup or other rigid protective device with moistened gauze padding.

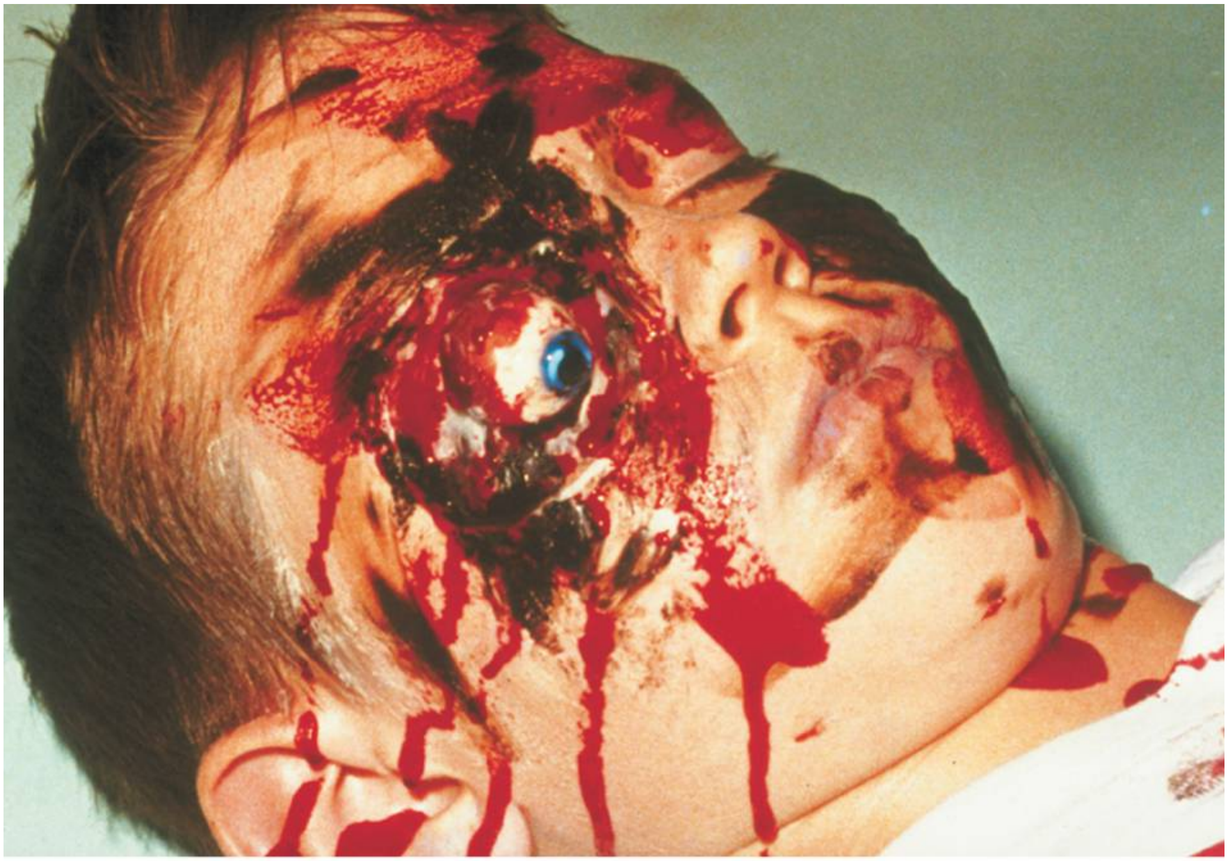

FIGURE 11-27 Ocular avulsion.

© American Academy of Orthopaedic Surgeons.

Transport Management

Ocular Avulsion

- Protect the eye from further trauma with a protective cup or other rigid protective device with moistened gauze padding.

Traumatic Retinal Detachment

Retinal detachment refers to separation of the inner layers of the retina from the pigmented epithelium. It may be caused by several other conditions besides trauma, including diabetic retinopathy and sickle cell disease.

Initially, the patient complains of the sensation of flashing light, often accompanied by a shower of floaters and vision loss. The vision loss may be described as filmy, cloudy, irregular, curtain like, or wavy. Patients may also complain of black spots, especially in the center of the visual field, or spiderweb-like vision.

When retinal detachment is suspected, it is imperative to avoid pressure to the globe. A rigid metal eye shield, rather than a soft patch, should be used to protect the eye. Although some types of retinal detachment are treated medically, most require surgery within 24 hours. In the past, retinal detachment uniformly led to blindness. Today, however, rapid diagnosis and surgery may be truly sight saving.

Signs and Symptoms

Traumatic Retinal Detachment

- Sensation of flashing light, often accompanied by a shower of floaters and vision loss
- Black spots, especially in the center of the visual field
- Spiderweb-like vision

Transport Management

Traumatic Retinal Detachment

- Avoid pressure to the globe.
- Protect the eye with a rigid metal eye shield.

Mandibular Fracture and Dislocation

The mandible is the only movable bone in the skull and makes up the lower third of the face. Because of its U shape, single blows to this bone can cause multiple fractures anywhere around its length. The mandible can also become anteriorly dislocated, causing the mouth to be locked in an open position. Signs of fracture include crepitus, trismus, swelling, and patient complaints that the jaw does not feel right or close normally (malocclusion).

Treatment is usually not necessary on a scene call, but transfers to rehabilitation facilities or tertiary centers may involve a patient with a jaw wired shut in maxillomandibular fixation. Provision must be made for inserting an emergency airway during such transfers. This may involve having wire cutters available to open the jaw, using nasotracheal intubation skills and equipment, and being prepared to obtain emergency surgical access.

Signs and Symptoms

Mandibular Fracture or Dislocation

- Crepitus
- Trismus
- Swelling
- Patient complains the jaw does not feel right or close normally (malocclusion)

Transport Management

Mandibular Fracture or Dislocation

- If the patient's jaw is wired shut, have wire cutters available to open the jaw in case an emergency airway is needed.
- Have nasotracheal intubation skills and equipment available.
- Be prepared to make emergency surgical access.

Dental Avulsion

Avulsed teeth have a good chance of successful reimplantation if replaced within 1 hour. Until that time, the tooth or teeth must be handled carefully.

The American Dental Association has developed the following guidelines for managing dental avulsion:

- Never place an avulsed tooth in anything that can dry or crush the outside of the tooth.
- Do not handle the tooth roughly. Do not rinse it off or rub, scrape, or disinfect the outside of the tooth.
- Place the tooth in a soft transport device, preferably in Hank's solution (a pH-balanced, isotonic, glucose/calcium/magnesium solution). Do not use tap water. Some recommendations suggest whole milk as a second-best solution to Hank's solution. A third choice is saline, but only for less than 1 hour.

Neck Injuries

The critical structures running through the neck are relatively unprotected and, therefore, are susceptible to many types of injuries. In addition to damage to critical airway and vascular structures, the possibility of an unstable cervical spine and spinal cord injury must be considered in a trauma patient. For scene calls, use of selective spinal motion restriction criteria has become standard practice. If a patient has a cervical collar in place at the sending facility and the sending physician has not cleared the cervical spine, the cervical collar should be kept in place. The CCTP can achieve an acceptable degree of additional spinal motion restriction by properly securing the patient to the transport stretcher. Use of rigid backboards and spinal motion restriction devices for prolonged periods (ie, several hours), as is common with CCT, is fraught with potential complications.

Always consider patients with neck injuries as potentially having a “difficult airway.” Deterioration of the patient’s airway in the back of a transport vehicle with limited space and personnel can be disastrous; thus, airway insertion should be completed prior to transport whenever there is a high index of suspicion that an artificial airway will be needed. Special airway considerations in the presence of neck injuries include bleeding into the airway field, expanding hematomas, and tracheal disruption.

The CCTP should immediately attempt to achieve hemorrhage control in any patient with signs of a major vascular, airway, or digestive tract injury. In case of an air leak or expanding hematoma, the CCTP should also attempt to achieve definitive airway control. Following these attempts, the patient should be taken directly to the operating room for surgical exploration.

For the purposes of assessment and management, the neck is typically divided into three zones, each with unique hemorrhage control and surgical limitations **FIGURE 11-28**:

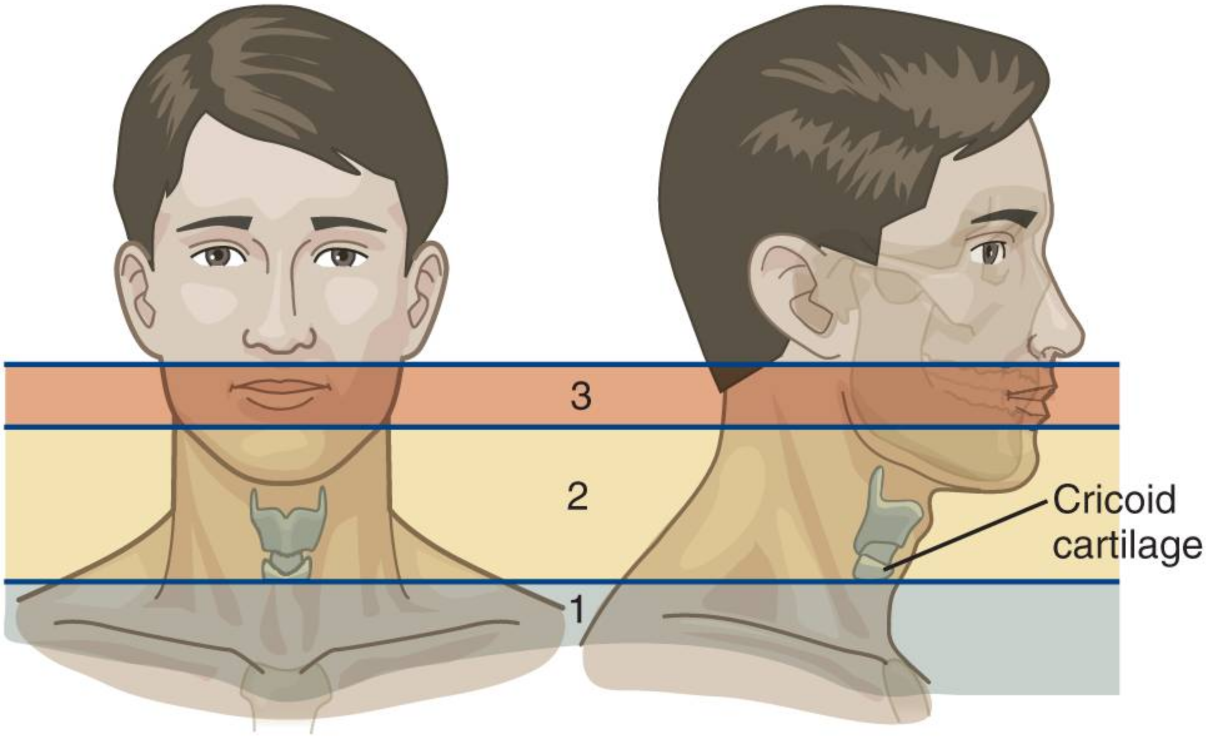

FIGURE 11-28 Neck zones.

© Jones & Bartlett Learning.

Description

- Zone 1—the most inferior—is defined by the clavicle and sternal notch inferiorly and the horizontal plane dissecting the cricoid cartilage superiorly. Structures in zone 1 include the proximal common carotid arteries; the vertebral and subclavian arteries; the subclavian, innominate, and jugular veins; the trachea; the recurrent laryngeal and vagus nerves; the esophagus; and the thoracic duct.
- Zone 2 is defined by the cricoid cartilage inferiorly and the angle of the mandible superiorly. It includes the carotid arteries, jugular and vertebral veins, pharynx, larynx, proximal trachea, recurrent laryngeal and vagus nerves, and spinal cord.
- Zone 3 is defined by the angle of the mandible inferiorly and the base of the skull superiorly. It includes the extracranial carotid

and vertebral arteries, the jugular veins, the spinal cord, cranial nerves IX through XII, and the sympathetic trunk.

Zones 1 and 3 have a higher incidence of vascular injury with penetrating trauma because vessels in these zones are fixed to other structures. There is significant incidence of esophageal injury with penetrating zone 1 injuries; because these injuries are often asymptomatic, they can be missed, often with devastating consequences. Nearly all zone 1 and zone 3 injuries and any asymptomatic zone 2 injuries can usually be evaluated with CT angiography (CTA) or other dedicated vascular imaging. If an injury in any zone requires surgical repair, the patient should be taken to the operating room without delay. Patients with symptomatic zone 2 injuries should go directly to surgery upon arrival at the hospital.

For neck trauma resulting in hoarseness accompanied by skin lacerations, ecchymosis, tenderness, subcutaneous emphysema, or stridor, an immediate otolaryngology consult is recommended. Indeed, this consultation may be the reason for the patient's transport to a larger hospital. Humidified oxygen, inhaled corticosteroids, and nebulized epinephrine may be ordered for patients with these types of neck injuries. If concern for airway compromise exists, a secure airway should be established before initiating transport.

The thyroid is located mainly in zone 1 of the neck, inferior to the cricoid cartilage, with some extension of the superior poles into zone 2. The thyroid is very vascular, and direct trauma to the front of the neck that affects this endocrine gland can cause hematomas of sufficient size to impinge on the airway. If surgical airway management is required, the entry location may need to be inferior to the usual site and inferior to the thyroid gland. Scattered reports of **thyrotoxicosis**, or thyroid storm, after thyroid trauma have been noted. The treatment is the same as that of thyroid storm due to other causes. See Chapter 18, *Endocrine Emergencies*, for more information.

Neck wounds may need to be dressed with occlusive dressings. If the wound affects the lower neck or clavicular area, vascular access in the lower extremity should be considered as the result of compromised drainage from the arms.

Laryngotracheal Injuries

Laryngotracheal injuries account for fewer than 1% of all traumatic injuries. Most occur in the area of the cervical trachea, and direct blunt trauma is the most common cause. Examples include contact with a steering wheel to the extended throat, hanging, strangulation, and “clothesline” injury during sports such as mountain biking or snowmobiling. Penetrating laryngotracheal injuries represent 10% of all penetrating neck injuries.

Bubbling from a neck wound and subcutaneous air, along with dysphonia, dyspnea, stridor, visible wounds, and swelling, are all signs of laryngotracheal injury. These injuries can appear stable for a time, only to be followed by rapid and catastrophic deterioration.

The most severe cases involve laryngotracheal disruptions. It is vital that paralytics and muscle relaxants not be used in patients with such injuries, because the only support for the trachea may be the surrounding musculature. If the patient is paralyzed, the trachea may retract into the chest, making it impossible to ventilate the patient. If the trachea is visible through the neck wall, the endotracheal tube should simply be passed through the neck into the trachea.

Signs and Symptoms

Laryngotracheal Injury

- Bubbling from a neck wound
- Subcutaneous air
- Dysphonia
- Dyspnea
- Stridor
- Visible wounds
- Swelling

Transport Management

Laryngotracheal Injury

- Airway management with careful endotracheal intubation
- Occlusive dressing for open neck wounds, especially if bubbling is present
- Spinal precautions
- Transport to a trauma center

Vascular Neck Injuries

Injury to the carotid, subclavian, and vertebral arteries and external and internal jugular veins can produce rapid exsanguination, hematoma formation, or embolization of air. One-fourth of all penetrating neck trauma cases involve vascular neck injuries. Mortality may be as high as one-half of these patients. If there is concern for an expanding hematoma from an injured vessel in the neck, securing the airway as soon as possible is crucial to patient survival. If delays occur, the airway may become unsalvageable without surgical intervention.

Many of the complications of vascular neck injuries do not appear until days to weeks after the trauma and involve thromboemboli causing neurologic problems. Because of the possibility of venous air embolism, direct pressure with an occlusive dressing should be applied to open vascular neck injuries while the patient is kept in the Trendelenburg position. Keep in mind that the Trendelenburg position may lead to respiratory compromise and that ventilatory assistance may be needed.

Accidental or improper removal of a central venous line or catheter can also readily lead to significant air embolism. Should a central catheter become dislodged during transport, the CCTP should act quickly to apply pressure with an occlusive dressing. Maintain a high index of suspicion when symptoms appear in a patient who recently had a central catheter discontinued prior to transport. When removing a central catheter, the patient should be placed in a Trendelenburg position prior to discontinuing the line.

Transport Management

Vascular Neck Injury

- Secure the airway early.
- Apply direct pressure to the injury with an occlusive dressing.
- Keep the patient in the Trendelenburg position.

Abdominal Trauma

Traumatic injuries to the abdomen are some of the most difficult injuries for the CCTP to recognize. Whether providing care at a trauma scene or transferring a critical patient from the ED to a trauma center, it is important to document an accurate history and physical exam for later comparison. At the sending facility, it is usually worthwhile to interview the crew who brought the patient from the field. Knowing the extrication time, scene details, and trends in patient condition is important in caring for trauma patients. With interfacility critical care transport calls, always try to review all studies that have been done, including lab tests, radiography, ultrasonography (FAST exam), and CT imaging, as well as any procedures that have been performed.

Considerations in Blunt Versus Penetrating Abdominal Trauma

As with other injuries, abdominal trauma can be classified into two categories: blunt and penetrating.

Blunt abdominal trauma occurs when an external force is placed on the abdominal cavity, such as during a fall, MVC, or motorcycle crash. One of the most commonly missed culprits in blunt abdominal trauma is the seat belt, which can act as a force vector of injury. Approximately 40% of lumbar spine fractures in MVCs are associated with intra-abdominal injury, as the seat belt causes the spine to flex/extend and compresses intra-abdominal contents. Use of seat belts has significantly decreased the incidence of morbidity and mortality related to MVCs, but these restraining devices continue to cause less noticeable abdominal injuries.

Penetrating abdominal trauma can involve many different objects, such as knives, guns, tree limbs, or metal rods. Such injuries will be very difficult for the CCTP to assess because detailed information on the object involved is often not available (eg, the size of the knife, the length of the blade, and whether it had a jagged or straight edge). In many instances, even if this information is available, it will still be very difficult to rapidly identify which structures inside the abdominal cavity were injured without the assistance of diagnostic imaging studies. Penetrating injuries usually require operative exploration to assess the extent of injury, and transport should not be delayed to perform additional imaging.

Challenges in Diagnosing Abdominal Trauma

The abdominal cavity is an extremely large space that houses many different vital organs. In many instances, the patient may experience either blunt or penetrating trauma to the abdominal cavity, yet signs or symptoms of injury may remain very subtle until shock becomes obvious. Because of the size of the abdominal cavity, a significant amount of blood can collect within this area and go unnoticed. Unlike other vital organs in the body, those in the abdominal cavity have very little protection, which makes them that much more susceptible to injury.

The following organs, structures, and vessels are located within the abdomen, and, if injured, can cause potential harm to the patient:

- Spleen
- Liver
- Kidneys
- Aorta
- Urinary bladder
- Gallbladder
- Small and large intestines
- Pancreas
- Stomach

Blunt or penetrating trauma to many of these organs can cause a life-threatening hemorrhage and serious organ damage. It is important for the CCTP to focus attention on the mechanism of injury, instead of becoming unduly distracted by the outward signs of trauma found on assessment. Injuries to any of the previously listed organs may not readily present with outward signs and symptoms—a fact that makes it that much more important for the CCTP to perform a detailed assessment and a thorough ongoing assessment during the transport, looking for subtle changes that might indicate a progressing condition. If a significant abdominal injury is suspected or confirmed, the most important treatment that the CCTP can provide is rapid transport to the trauma center for definitive care.

Once the CCTP recognizes the need for immediate transport to the trauma center, their job is to stabilize and maintain the patient's hemodynamic status as efficiently as possible until arrival at the trauma center. This task will be difficult and may require the administration of a crystalloid solution, blood products, or even vasoactive medications in more severe cases. Grey Turner sign **FIGURE 11-29** and Cullen sign **FIGURE 11-30** are indications of internal abdominal bleeding.

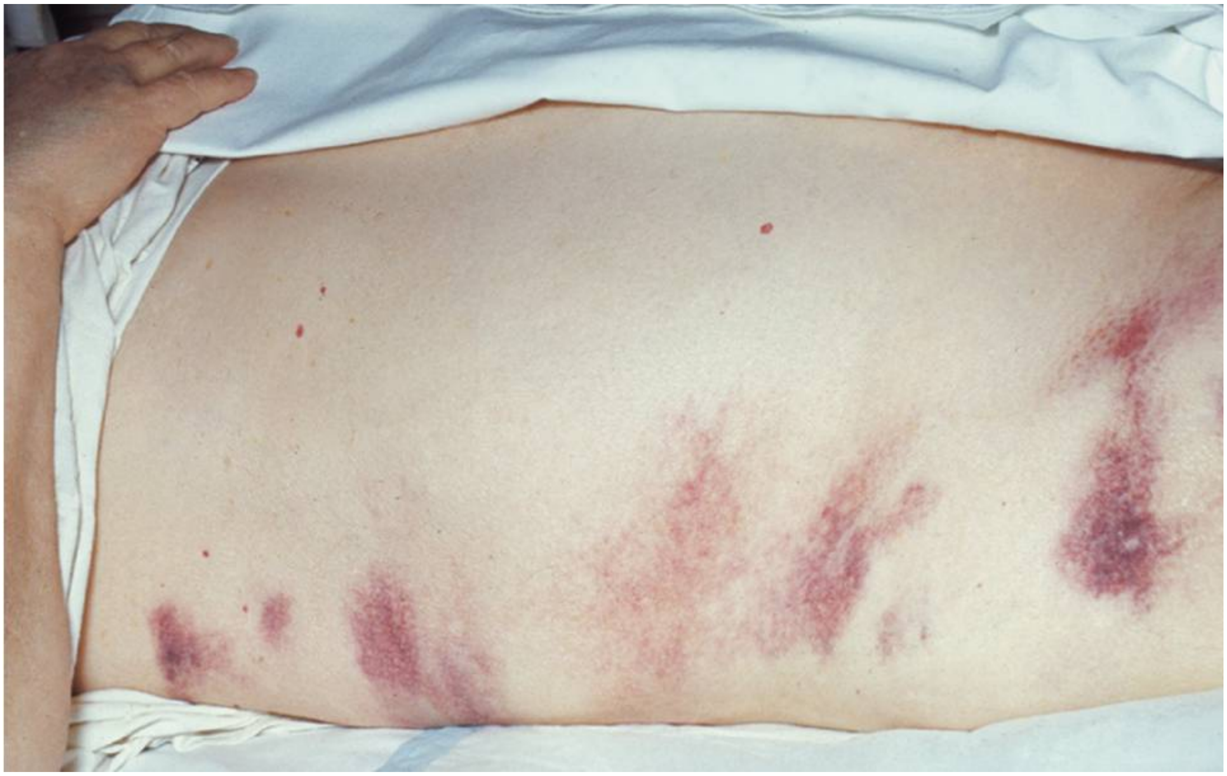

FIGURE 11-29 Grey Turner sign.

“Images of Memorable Cases - 50 years at the bedside” by Herbert L. Fred, MD and Hendrik A. van Dijk.

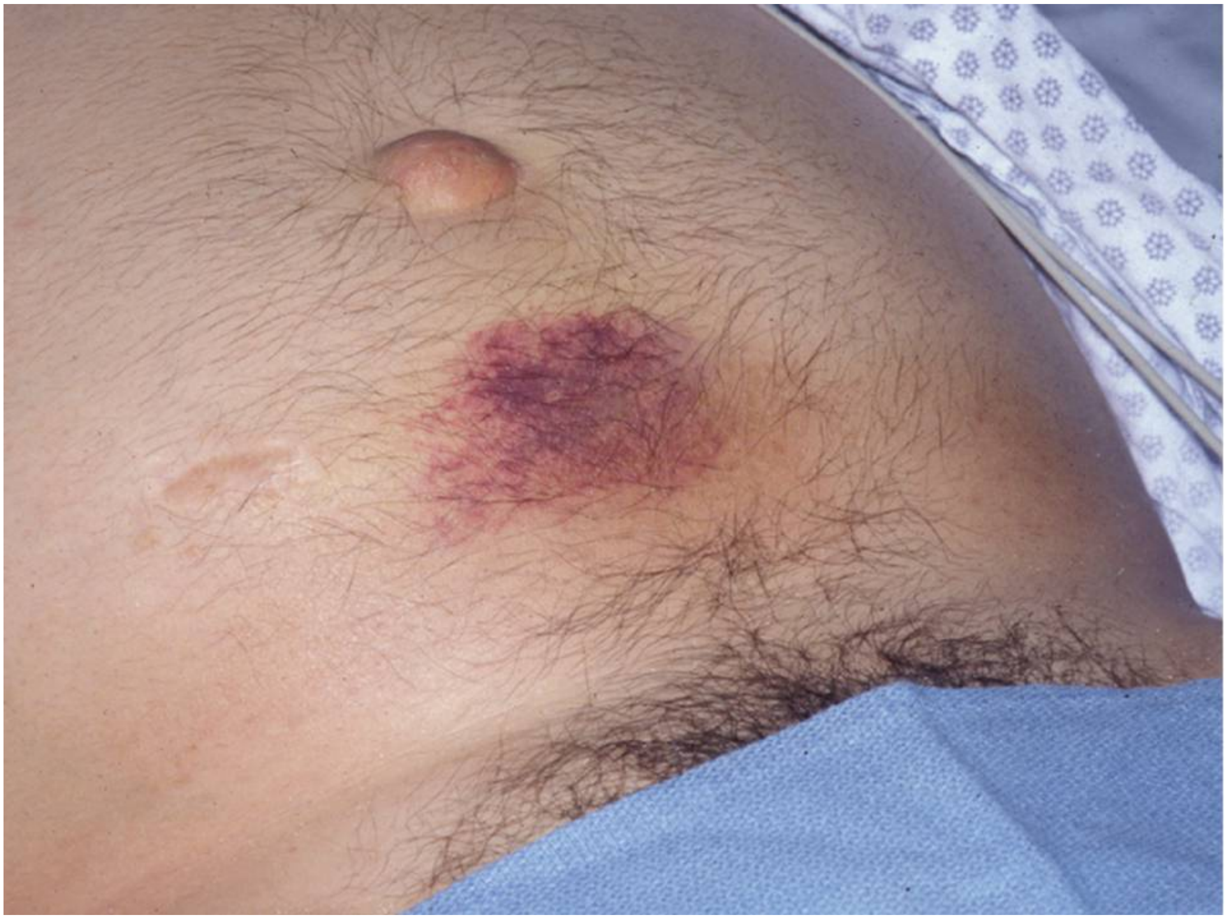

FIGURE 11-30 Cullen sign.

“Images of Memorable Cases - 50 years at the bedside” by Herbert L. Fred, MD and Hendrik A. van Dijk.

Assessment

When beginning the physical assessment of the patient with abdominal trauma, the CCTP should try to ascertain as many details about the events leading up to the injury as possible. Gathering more information will make diagnosing and treating the problem that much quicker and oftentimes simpler. The initial physical exam to rapidly identify blood loss is the most important task. When performing this exam, remember to always inspect, auscultate, and palpate—in that order. The primary assessment needs to be completed at the bedside, before beginning transport, as it will be very difficult to obtain an accurate assessment in the back of a moving helicopter or ambulance. This assessment must be repeated frequently during the transport, with the CCTP being ready to provide immediate interventions if necessary. In particular, the CCTP will need to monitor the patient's level of consciousness, heart rate, and blood pressure, watching for changes that would indicate a progressively worsening condition. Additionally, changes in the abdominal exam should be documented. Special note should be made if the abdomen becomes tense or if pain increases with palpation or becomes worse when palpation is removed from the abdomen.

Patients who experience massive amounts of blood loss may compensate initially but will eventually begin to present with signs of shock. Signs and symptoms for which the CCTP should be wary include the following:

- Altered mental status
- Tachycardia
- Absence of palpable pulses
- Skin that is paler than baseline, moist, and mottled
- Poor peripheral perfusion
- Hypotension

Although the assessment should not be limited to these symptoms, they are some of the most common warning signals of hypovolemic shock.

Management

Regardless of the findings obtained during the initial assessment, all patients suspected of having abdominal injuries should be transported with appropriate supplemental oxygen and fluid administration. A minimum of two IV lines (as with most CCT patients) should be established, and central lines may need to be considered. Placing CVP and arterial pressure lines is a very good idea because noninvasive blood pressure monitoring performed in transit can yield inaccurate results, especially in patients with hypotension. However, permissive hypotension should also be considered, especially if an aneurysm of a great vessel is suspected. The patient's blood pressure should be maintained at 80 to 90 mm Hg systolic or 60 to 65 mm Hg MAP.

Boluses of crystalloids should be given in 250-mL to 500-mL amounts titrated to blood pressure, MAP, or CVP until blood is available. Patients with more severe abdominal injuries may need aggressive airway management and blood administration; most transport programs carry packed red blood cells (O negative) for such emergency situations. Some EMS units carry whole blood, which is preferred to packed red blood cells. To prevent hemodilution, protocols should allow the administration of human blood if a large volume of fluids is deemed necessary. Research into many new fluids with oxygen-carrying capacity continues, and many of these products are expected to eventually reach the market.

Except in cases of suspected urethral injury, all patients with serious abdominal trauma should, in addition to the vascular access, have an indwelling urinary catheter placed prior to transport. Completing this step prior to transport will help the CCTP evaluate shock by quantifying the amount of urine output. In addition, the presence of frank blood in the urinary catheter indicates renal system damage. Patients should be kept warm, and open abdominal wounds should be covered first with a sterile dressing and then with an occlusive dressing to prevent evaporative cooling.

Signs and Symptoms

Abdominal Injury

- Altered mental status
- Tachycardia
- Absence of palpable pulses

- Tense or rigid abdomen
- Skin that is paler than baseline, moist, and mottled
- Poor peripheral perfusion
- Hypotension

Transport Management

Abdominal Injury

- Administer appropriate oxygen therapy, fluids, or blood.
- Establish large-bore vascular access; consider placement of a central line.
- Keep the patient’s blood pressure at 80 to 90 mm Hg systolic or 60 to 65 mm Hg MAP.
- Administer boluses of crystalloids in 250- to 500-mL amounts titrated to blood pressure, MAP, or CVP.
- If necessary, secure the airway.
- If necessary, administer blood products.
- Except in cases of suspected urethral injury, insert an indwelling catheter prior to transport.
- Keep the patient warm (prevent hypothermia/hyperthermia).
- Cover open abdominal wounds first with a sterile dressing and then with an occlusive dressing to prevent evaporative cooling.

Resuscitative Endovascular Balloon Occlusion of the Aorta

Resuscitative endovascular balloon occlusion of the aorta (REBOA) is a treatment that is increasingly being used for resuscitation of patients in hemorrhagic shock who have sustained a massive blood loss. First described during the Korean War as a technique for controlling intra-abdominal hemorrhage, REBOA has gained traction in trauma surgery and emergency medicine as a temporizing measure for refractory hemorrhagic shock, blunt or penetrating abdominal trauma, pelvic fractures with significant hemorrhage, and ruptured abdominal aortic aneurysms. It may also be applied as a temporizing measure in outlying hospitals prior to transferring a trauma patient to a higher-level trauma center. Importantly, REBOA has not yet been proved safe for aeromedical transfer, and ongoing research is examining the effects of altitude on the occlusion balloon. Consultation with both the sending and the receiving facilities is paramount for ensuring patient safety in the event of interfacility transfer with a REBOA in place.

The REBOA procedure involves insertion of a small balloon catheter through a femoral artery into the proximal aorta **FIGURE 11-31**. The insertion depth depends on the goal of treatment and the anatomic location of bleeding. Once inserted to the appropriate depth, the balloon is inflated. This occludes the aorta, preventing additional bleeding below the level of the balloon and increasing cardiac afterload above the level of the balloon.

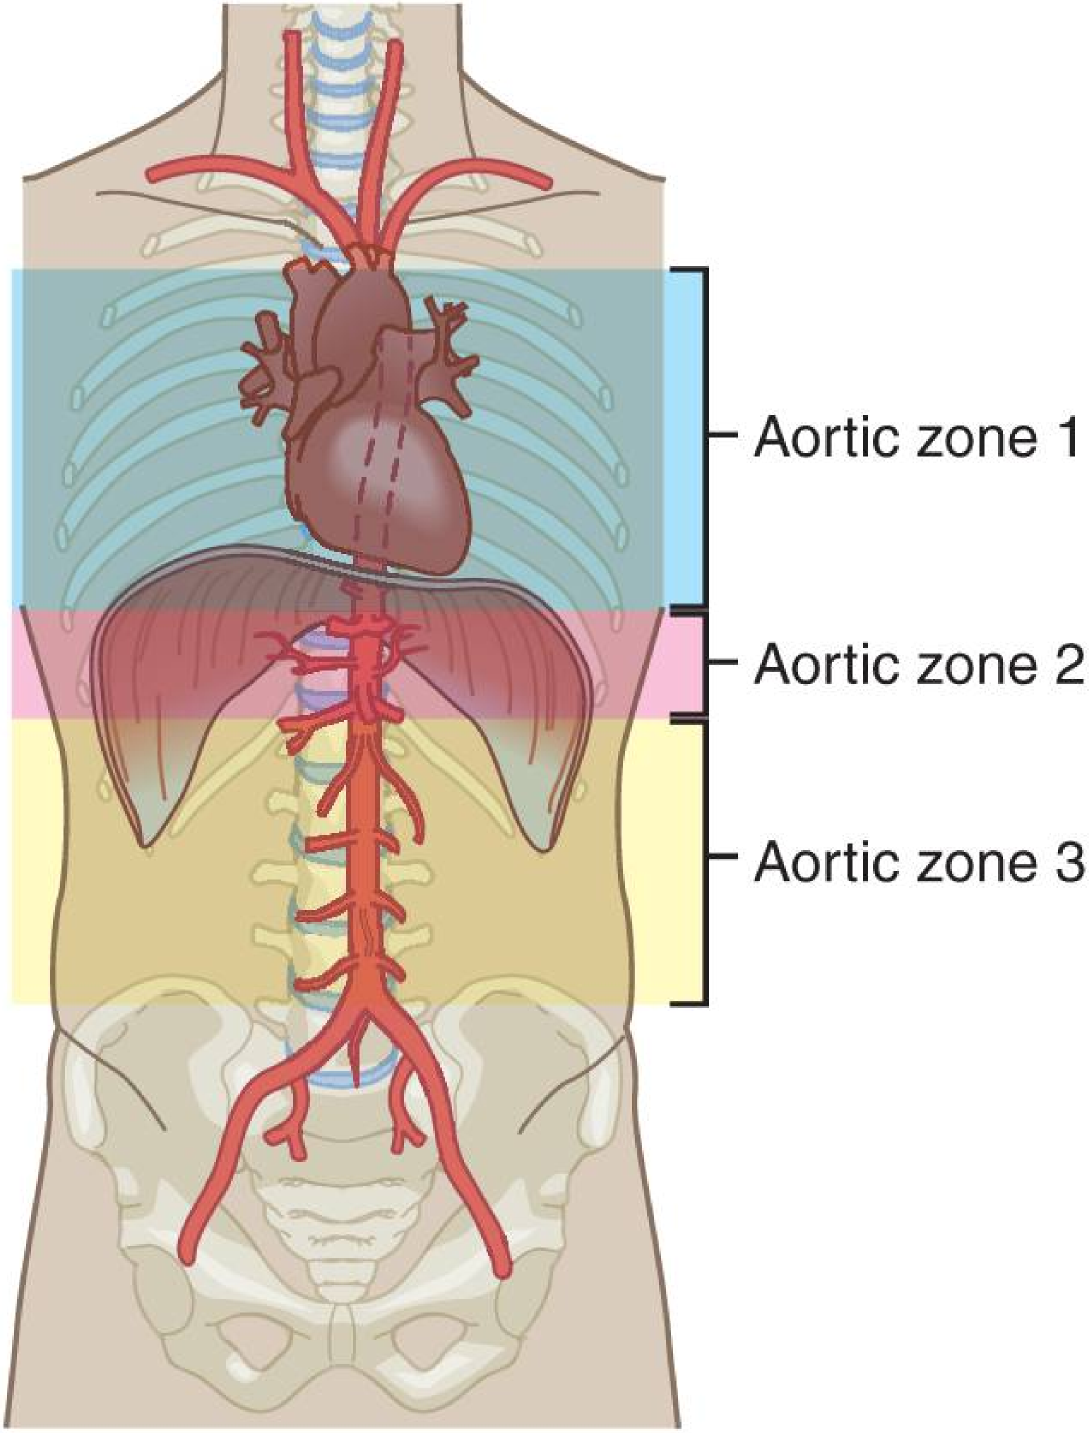
As part of the REBOA approach, the aorta is divided into three zones **FIGURE 11-32**:

- Zone 1 spans from the origin of the left subclavian artery to the celiac trunk.
- Zone 2 extends from the celiac trunk to the lowest renal artery.
- Zone 3 extends from the lowest renal artery to the bifurcation of the femoral arteries.



Aortic zone 1
Aortic zone 2
Aortic zone 3

FIGURE 11-32 Aortic zones.

Data from Stannard A, Eliason JL, Rasmussen TE. Resuscitative endovascular balloon occlusion of the aorta (REBOA) as an adjunct for hemorrhagic shock. *J Trauma*. 2011;71(6):1871. doi:10.1097/ta.0b013e31823fe90c.

Indications for zone 1 placement include temporary control of severe intra-abdominal hemorrhage, severe retroperitoneal hemorrhage, and traumatic arrest with suspected infradiaphragmatic injury as the source of hemorrhage. Indications for zone 3 placement include patients with severe pelvic, junctional (groin/perineum), or proximal lower extremity hemorrhage that cannot be controlled by other methods. Zone 2, the smallest area of the aorta, is typically used intraoperatively only in selected vascular or aortic procedures.

While placement of a REBOA catheter is not currently within the CCTP's scope of practice, familiarity with the placement procedure is important in understanding the function and maintenance of the device. These catheters should be placed in a sterile environment. As shown in **FIGURE 11-33**, the REBOA catheter has a flexible, transducing tip for pressure monitoring, a balloon with radio-opaque markers at either side, and markings to measure the insertion depth over the length of the tubing. The REBOA catheter also features two sets of bold markings that indicate the average insertion depth for zone 1 (45 to 49 cm) and zone 3 (26 to 29 cm). There are two ports: one for the balloon (clear; marked BAL) and one for arterial access (red; marked ART). Finally, at the most proximal end of each catheter is a paper tab that has spaces to record the insertion depth, balloon inflation volume, time of inflation, and blood pressure change following the balloon's inflation. Each of these measurements is critical to the stability and safety of the procedure.

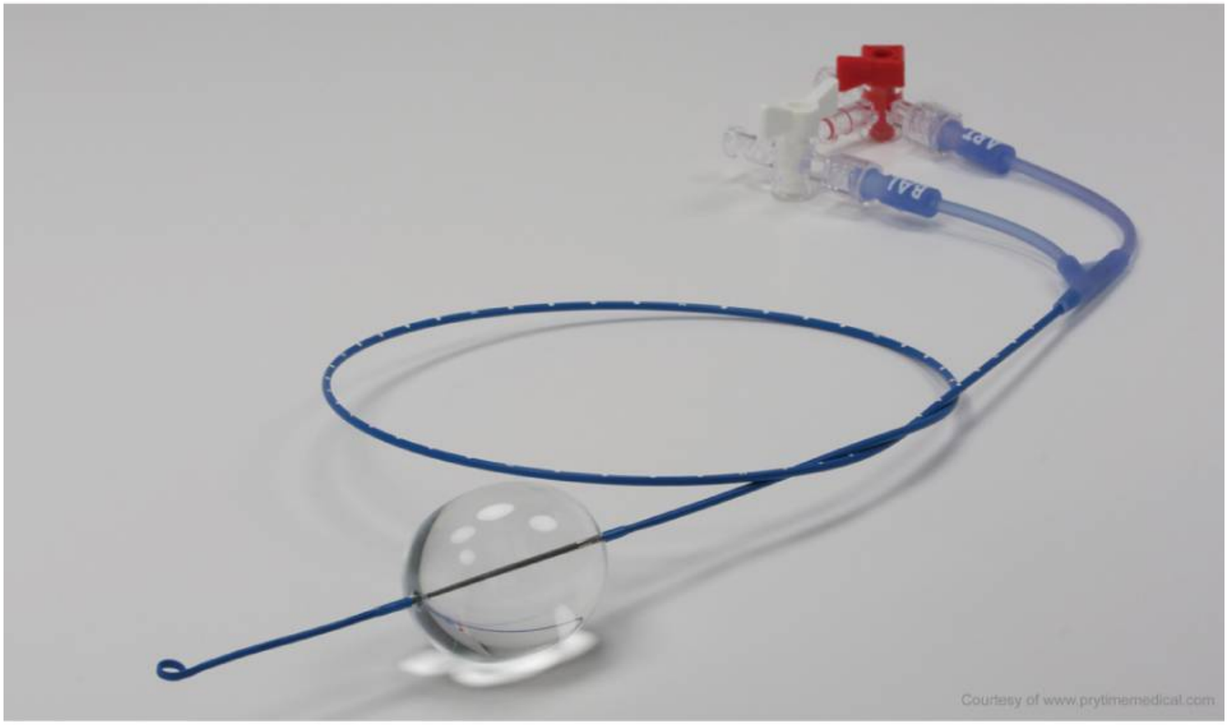


FIGURE 11-33 A catheter designed for resuscitative endovascular balloon occlusion of the aorta.

Courtesy of Prytime Medical Devices, Inc. www.prytimemedical.com.

Prior to placing the REBOA catheter, the provider must obtain femoral arterial access. Unlike traditional arterial lines, REBOA catheters require at least a 7-French arterial sheath, larger than that typically used for pressure monitoring. Once the 7-French arterial sheath is in place, the REBOA catheter should be prepared. If the average depth markings are not used, the depth of insertion for zone 1 can be measured from the sternal notch to the femoral access site, and the depth of insertion for zone 3 can be measured from the xiphoid process to the femoral access site. Next, the provider flushes the arterial port and catheter with sterile saline and ensures that any air has been removed from the balloon by gently inflating it with about 2 to 3 mL of sterile saline and then withdrawing the fluid immediately. The orange peel-away sheath is used to extend the flexible distal tip of the REBOA catheter just before inserting it through the 7-French arterial line. To place the REBOA catheter into the femoral artery, the provider manipulates the orange peel-away catheter to guide the straightened flexible tip into the arterial line and advance it to 15 cm. Catheter advancement should be smooth. The next steps are to advance the catheter to the predetermined depth, and if available, obtain a radiograph or ultrasonographic image to ensure the catheter is at the appropriate level. Once confirmed, the provider can inflate the balloon starting with 2 mL of sterile saline in zone 3, where the aorta is relatively smaller, or 8 mL of sterile saline in zone 1, where the aorta is wider.

After initial inflation of the balloon, an arterial blood pressure tracing should be obtained. Additional sterile saline should be slowly infused into the balloon until a sudden increase in the blood pressure tracing is observed. This sudden increase indicates occlusion of the aorta. Distal pulses should not be palpable in the lower extremities. The provider can then secure the femoral arterial catheter and REBOA catheter in place with sutures and dressings. Finally, imaging should be performed to confirm correct placement and balloon inflation. The insertion depth, time of balloon inflation, amount of saline in the balloon, and blood pressure change should be recorded.

For CCTPs, several important considerations arise when approaching patients with REBOA catheters in place. First, the arterial line tracing should be noted, and if the waveform or range changes, medical control or the receiving facility should be notified immediately. The REBOA catheter should not be repositioned or removed without first fully deflating the balloon. Ongoing research is investigating how long the balloon on the REBOA catheter can be kept inflated. General recommendations are that zone 1 should not be occluded for more than 60 minutes, ideally less than 30 minutes, and zone 3 should not be occluded for more than 90 minutes, ideally less than 60 minutes.

Removal of the REBOA catheter involves first deflating the balloon, which will drop the cardiac afterload and cause a precipitous drop in blood pressure and mean arterial pressure. Whenever the REBOA catheter is manipulated, providers should be prepared to treat a sudden decrease in the patient’s blood pressure, and the balloon should be deflated slowly.

While potentially lifesaving, aortic occlusion poses significant risks, such as femoral artery or aortic injury and long-term damage from ischemia to abdominal organs and lower extremities. REBOA use indicates the patient is in imminent danger of cardiovascular collapse and death, so transport to definitive care should not be delayed under any circumstances. As more experience is gained with use of REBOA, its indications and practice will undoubtedly evolve, along with the implications for transport by CCTPs. Clearly, use of REBOA creates a time-sensitive and urgent need for definitive care.

Hollow Versus Solid-Organ Injury

Hollow organs primarily leak their contents when injured, whereas solid organs bleed. Treatment of injury to either type of organ should be oriented toward treating shock and expeditious transport.

Solid organs include the liver (in the upper right quadrant), the spleen (in the upper left quadrant), and the pancreas and kidneys (in the retroperitoneal space). Solid-organ injuries are increasingly being managed nonoperatively with observation or in an interventional radiology suite, where imaging can be used to identify the injured vessel(s) and catheter-deployed treatments provided. Management with interventional radiology is a common option. The primary concern with any solid-organ injury is hemorrhage resulting in hypovolemic shock.

The hollow organs consist of the digestive tract including the stomach (in the upper left quadrant), the small and large intestines (throughout all quadrants), and the gallbladder (under the liver in the upper right quadrant). Additionally, hollow organs in the midline include the urinary bladder and ureters, the uterus, and the great vessels of the descending (abdominal) aorta and the inferior vena cava. The primary concern with hollow-organ injury is peritonitis resulting in distributive shock.

Spleen

The spleen is a bean-shaped organ in the left upper quadrant that serves as a site for maturation of white blood cells and filtration of senescent (old) red blood cells. This organ gets a direct vascular supply from the aorta, and its drainage goes directly to the inferior vena cava. Approximately 5% of circulating blood filters through the spleen every minute. Given this volume, injury to the spleen can produce massive hemorrhage very quickly.

The spleen is the most commonly injured organ in the abdominal cavity. It can even be injured by what seems to be minor trauma.

Young adults and patients with sickle cell disease or mononucleosis are at particular risk of such injuries, as a result of their spleens being relatively larger.

Located in the upper left quadrant of the abdomen, the spleen is partially protected by the lower rib cage, but lacks a strong exterior capsule. Injuries that do not disrupt the structure of this organ will likely produce only minimal bleeding. In contrast, more significant bleeding may occur if the exterior capsule is damaged.

The presence of normal vital signs does not rule out an injury to the spleen. The patient may simply complain of pain on the primary assessment, with symptoms of shock developing later. In some cases, symptoms may arise as late as 2 to 3 weeks after the original injury. This understanding is especially important in patients who have a history of splenic trauma but present with sudden decompensation. Delayed splenic rupture can occur when splenic injury is managed nonoperatively but the splenic capsule weakens and eventually ruptures.

A helpful tool for recognizing a splenic injury through referred pain is the **Kehr sign**. This sign presents as pain in the shoulder as a result of the presence of blood or other irritants along the diaphragm and superior peritoneum. Pain in the left shoulder is considered a classic symptom of a ruptured spleen, but may also result from any free blood irritating the diaphragm. The same phenomenon also occurs on the right side with irritation to the liver or gallbladder.

Failure to recognize, understand, and treat the signs and symptoms of hypovolemic shock related to internal hemorrhage will rapidly lead to the patient’s death. Nevertheless, many spleen injuries can be managed through bed rest and careful observation, because this organ sometimes heals over time and invasive interventions are not always needed. Embolization of the spleen is another increasingly common nonoperative management technique and may be employed in circumstances where surgery needs to be avoided but the patient has signs and symptoms of ongoing hypovolemia.

Signs and Symptoms

Spleen Injury

- Pain in the area of the spleen
- Kehr sign: pain in the shoulder despite no evident injury to the shoulder

Transport Management

Spleen Injury

- Provide oxygen and monitor ABCs as indicated.
- Treat the patient for signs and symptoms of hypovolemic shock.

Liver

The largest organ in the abdominal cavity, the liver is also the most vascular organ and receives 25% of the total cardiac output. The liver has a little more protection than the spleen does, because it is surrounded by many different structures of the thorax, including ligaments that stabilize the organ to the diaphragm and abdominal wall, reducing the risk of impact. However, the ligament in front of the liver (ligamentum teres) can injure the liver in the case of a sudden deceleration. Additionally, the liver's close proximity to the lower rib cage makes it susceptible to injury after a rib fracture occurs. Liver injuries will cause pain in the right upper quadrant, along with pain in the right shoulder as blood accumulates around the diaphragm.

In the past, the majority of liver injuries were surgically repaired. Studies have since shown that many less severe liver injuries can tolerate 1 or 2 days of observation before making a decision to surgically repair them. In most instances, simple observation is the only intervention needed, because the liver heals over time and invasive interventions are not always necessary. Angioembolization, an interventional radiology technique, is also growing in popularity as a hemorrhage control method, as long as the bleed is confined to one side of the liver. However, in severe liver injuries, surgery may be the only means to prevent exsanguination.

Stomach

Damage to the stomach from trauma is rare. Blunt trauma to this organ most commonly occurs during MVCs when a full stomach is caught against the steering wheel. The stomach can also be damaged in penetrating injuries. In trauma patients who are intubated, placing a nasogastric or orogastric tube can help decompress the stomach.

Large and Small Intestines

The intestines are hollow organs that occupy much of the space within the abdominal cavity. Penetrating trauma is the most common cause of injury to the intestines because they lie very close to the surface of the abdomen. When objects such as knives or bullets penetrate the abdominal wall, injury to the intestines is likely.

Although penetrating trauma is the most common source of injury to these organs, blunt trauma to the abdominal wall—especially from a seat belt—can also damage the small bowel. The lap portion of the seat belt lies along the lower quadrants of the abdominal cavity. The patient with such an injury would likely present with an ecchymotic area across the lower portion of the abdomen (seat belt sign), which should prompt an assessment for internal injuries **FIGURE 11-34**.

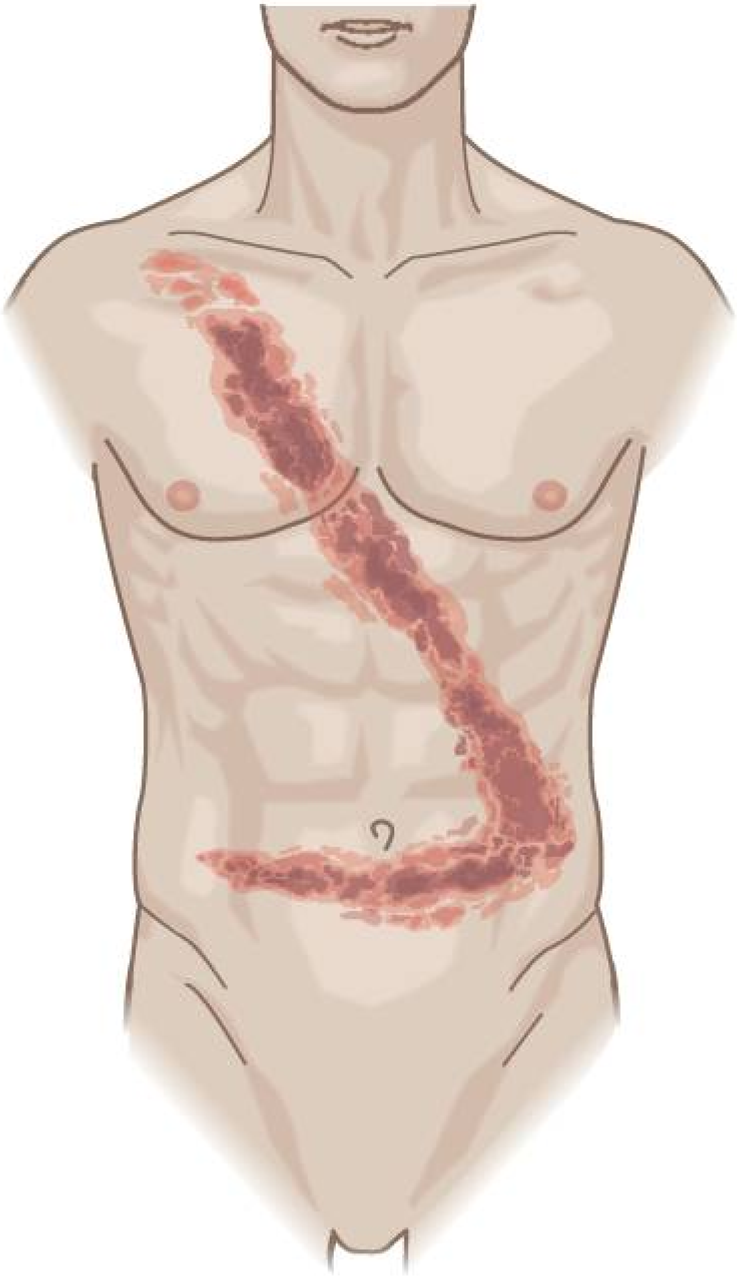

FIGURE 11-34 Seat belt sign.

© Jones & Bartlett Learning.

Injuries to the wall of the small or large intestine can cause digestive material to leak out of the lumen, leading to both peritonitis and pain. The bowel mesentery is the fatty sheet containing the blood vessels that supply the bowel wall **FIGURE 11-35**. It is often a source of hemorrhage in blunt and penetrating trauma patients; injury to the mesentery usually requires surgical repair. Approximately 80% of gunshot wounds to the abdomen and 30% of stab wounds penetrate the small or large bowel. Because the jejunum and ileum are anchored to the abdominal wall via the ligament of Trietz, the mesentery and its vasculature often are torn with such injuries, causing hemorrhage.

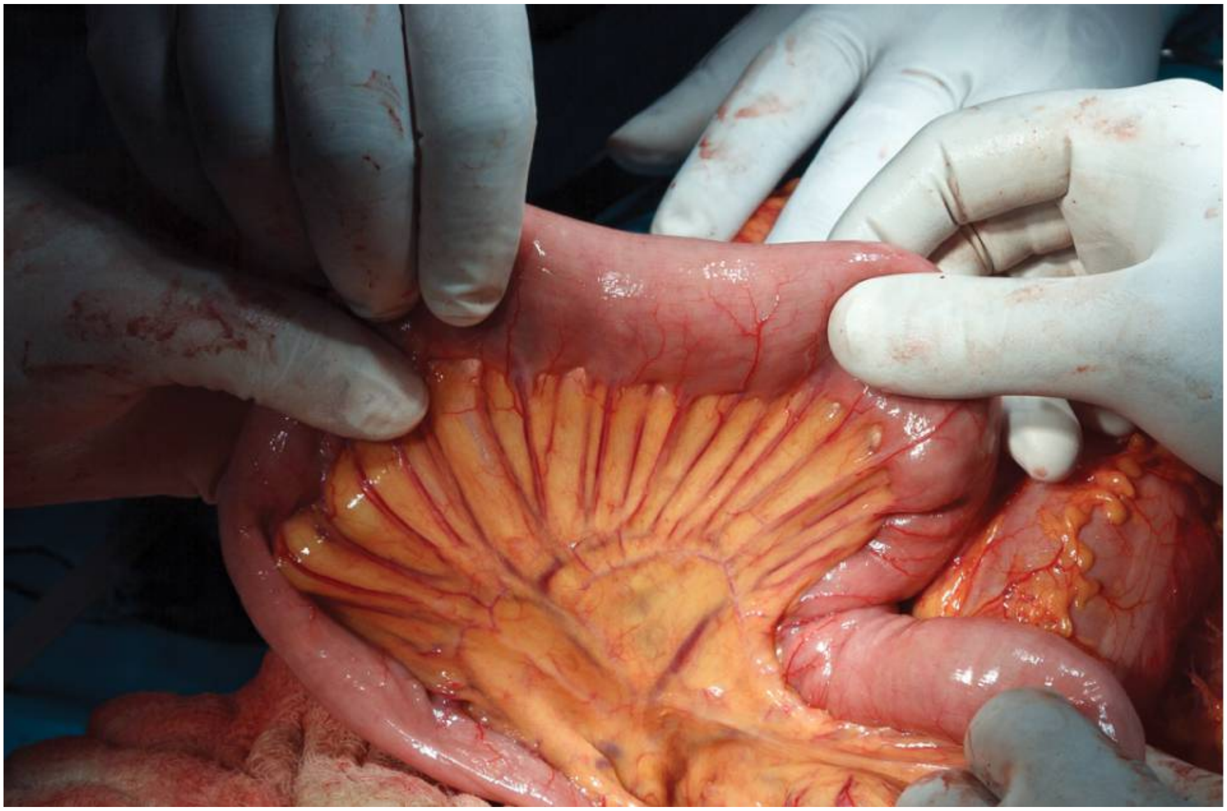

FIGURE 11-35 Bowel mesentery.

A lack of visible injury should not be used as a rationale for ruling out internal injury. Instead, CCTPs must rely on their assessment skills to detect abnormalities. In some cases, the presence of pain with palpation to the abdomen might be the only indicator of injury. In addition to the pain with palpation, other indicators, such as guarding, abdominal distention, rebound tenderness, and vomiting, may be present.

The large intestine or colon is the organ most frequently injured by penetrating trauma. Such an injury was found in 96% of penetrating trauma cases in one study, with gunshots accounting for more than 90% of the injuries. Ruptures of the colon or rectum are particularly susceptible to sepsis and peritonitis.

Signs and Symptoms

Intestinal Injury

- Ecchymotic area across the lower portion of the abdomen (seat belt sign)
- Presence of pain with palpation to the abdomen
- Guarding
- Abdominal distention
- Rebound tenderness
- Vomiting

Transport Management

Intestinal Injury

- Maintain a high index of suspicion for occult injury.
- Establish large-bore IV access.
- Consider other injuries, such as chest, neck, and lumbar spine injuries.
- Provide rapid transport.

Duodenum

The duodenum deserves special note because it is a retroperitoneal organ and, therefore, is well protected. If ruptured, because of its retroperitoneal location, it may not produce symptoms. Nevertheless, because of its close proximity to the stomach, liver, pancreas, gallbladder, bile ducts, aorta, and inferior vena cava, the duodenum is never the only organ injured. An injury to the duodenum should be suspected with high-velocity blunt trauma to the midabdomen, such as when a child is thrown off a bicycle and the abdomen strikes the handlebars.

Vascular Injuries

Unfortunately, injuries that occur to the vessels of the abdomen are usually life threatening. The abdominal aorta is a large vessel that carries blood away from the heart, supplies all the abdominal organs, and continues its distribution of blood and oxygen to the toes. Severe blunt trauma may disrupt these vessels, although the most common cause of vascular injury is, once again, penetrating trauma. In instances of blunt trauma, the shearing force at impact causes the vessels to break away from their branches, allowing blood to flow freely into the abdominal cavity. The following major blood vessels in the abdomen can be injured in trauma events:

- Aorta
- Inferior vena cava
- Left or right renal artery
- Superior or inferior mesenteric artery
- Left or right iliac artery

Bleeding from an injury to any of the major abdominal vessels may occur rapidly, and signs of shock may not be noticed as blood accumulates in the abdomen. Aggressive treatment of patients with such injuries is required but may not prove very helpful, because arterial injuries will cause exsanguination unless immediate surgery is available. Therefore, rapid transport to a hospital capable of immediate surgery may be the best possible treatment. The abdominal cavity is also home to several large veins whose rupture will cause the body to lose large amounts of blood, albeit not at the rapid pace of an arterial rupture. Bleeding into the abdominal cavity may slowly occur without obvious signs or symptoms.

The treatment of vascular injuries is similar to the treatment of the other abdominal injuries. Airway patency is the key concern, because patients who are experiencing massive blood loss are likely to demonstrate an altered mental status. Immediate steps should be taken to perform endotracheal intubation to secure the patient's airway if necessary. The CCTP should focus on treating the hypovolemic shock and transporting the patient to a center capable of trauma surgery. REBOA may be indicated depending on the level of injury, availability of femoral arterial access, and provider training. In the initial treatment of such a patient, aggressive fluid resuscitation is necessary to maintain a systolic blood pressure of at least 80 mm Hg but not higher than 90 mm Hg, with progression toward blood products as soon as possible.

If the patient survives the transport, the surgical team needs to intervene as soon as possible and attempt to surgically repair the disturbed vessel. Even if the patient survives to surgery, several serious complications can occur afterward—for example, disseminated intravascular coagulation (DIC), continued bleeding, and thrombosis formation. All are life threatening, and will be treated as such by the team caring for the patient.

Signs and Symptoms

Abdominal Vascular Injury

- Potentially none
- Altered mental status
- Hypovolemic shock

Transport Management

Abdominal Vascular Injury

- Maintain airway patency; ensure adequate ventilation.
- Administer judicious fluid resuscitation; ensure adequate tissue perfusion.
- Transport the patient immediately to a center capable of trauma or vascular surgery.

Pelvic Trauma

Pelvic Fracture

Pelvic fractures typically result from trauma due to MVCs (approximately 60% to 70% of all cases), pedestrian–versus–motor vehicle incidents (12% to 18%), motorcycle crashes (5% to 10%), and falls (up to 10%). Because of the significant force involved, the presence of a pelvic fracture should alert the CCTP to the potential for other injuries in the abdomen and pelvis. In one study, mortality from blunt pelvic fractures was as high as 50%. Most of the threat to life from these injuries comes from internal hemorrhage from the associated vasculature within the pelvis.

The pelvis is made of three paired bones—the ilium, the ischium, and the pubis—that are collectively called the innominate bones. The innominate bones are connected posteriorly by the sacrum and coccyx. Their very rich blood supply comes from the left and right iliac arteries. The veins in the pelvis lack valves and adhere to the pelvic wall. Because these blood vessels have thin walls, they are easily torn, and fractures to the pelvis can result in catastrophic hemorrhage.

The pelvis also houses the reproductive organs and the urinary bladder. When full, the bladder can rise above the pelvic rim and rupture as part of a seat belt injury. The uterus, ovaries, and fallopian tubes are well protected in the nonpregnant patient. Injuries to these organs are usually found after the patient is transported to the trauma center, when the patient is assessed using CT.

Subjective assessment of potential pelvic fracture includes a good history of the mechanism of injury, location, and radiation of pain, as well as an assessment of the presence of hematuria and the possibility of pregnancy. Objective examination includes observing for the rotation or uneven height of the iliac crests and uneven length of the legs. Palpation of the posterior aspect of the pelvic ring should not elicit tenderness. Gentle lateral compression posteriorly and inward compression medially at the iliac crests should not result in pain, crepitus, or movement. This test should be done one time, carefully, and stopped and not repeated if any instability is felt.

Management of pelvic injury depends on the type of fracture. Field treatment consists of splinting and treatment for shock. Soft-tissue damage to the genitalia can be managed like any other soft-tissue injury. Packaging for transport of suspected or confirmed pelvic fracture entails immobilization of the pelvis with a pelvic binder **FIGURE 11-36**. The patient should be moved on a scoop stretcher or backboard to minimize pelvic movement.

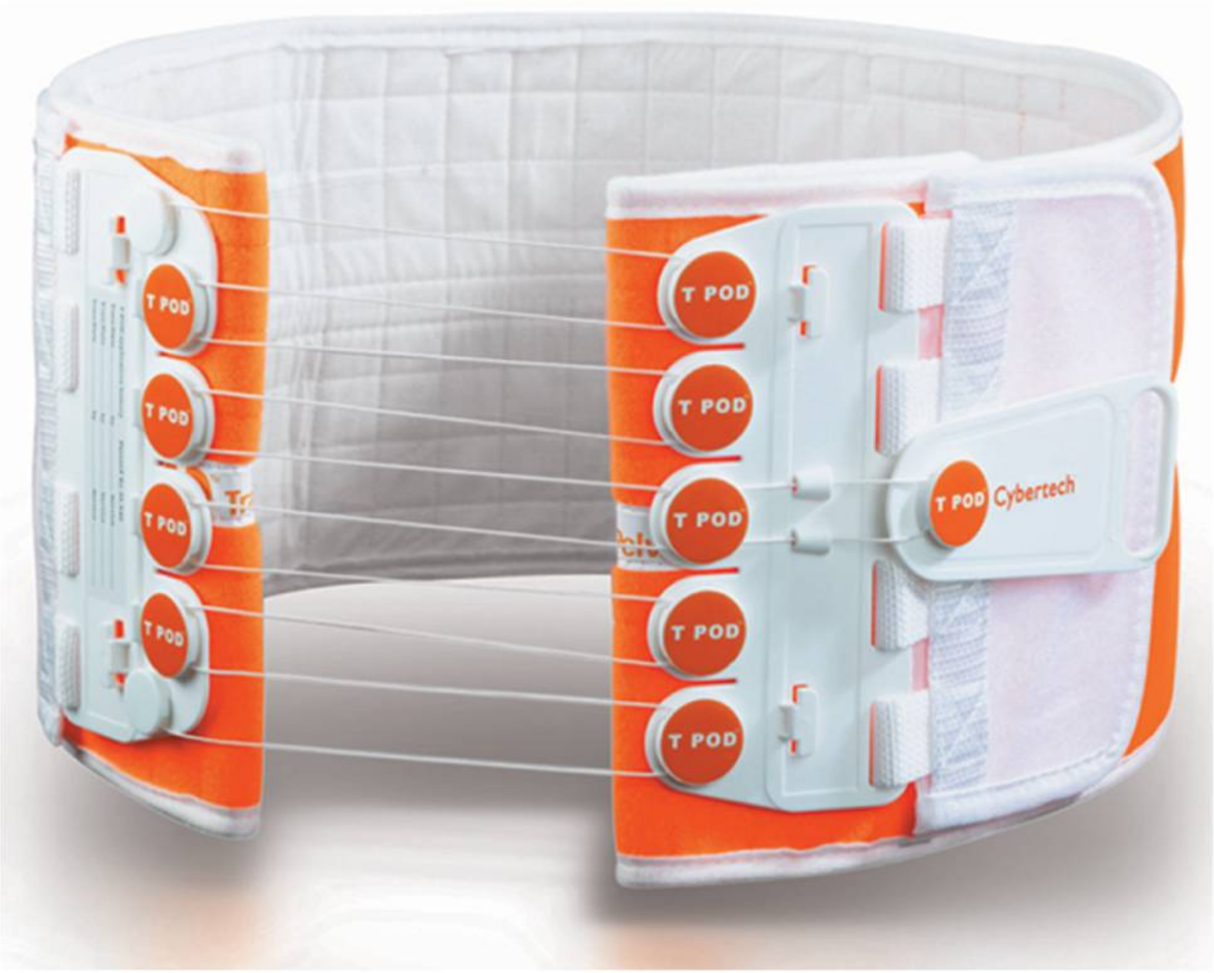

FIGURE 11-36 A pelvic binder.

Courtesy of Pyng Medical Corp.

Open-Book Fractures

Open-book fractures, a subset of pelvic fractures, account for approximately 15% of pelvic fractures and involve the loss of stability of the pelvic ring. They result from anterior-posterior compression forces that separate the pelvis at the symphysis pubis. The greatest danger with this injury is from hemorrhage. Reduction of these fractures decreases the bleeding.

Assessment and treatment of an open-book fracture are the same as for any pelvic fracture, and patients should be transported on a well-padded backboard or scoop. Pelvic binders or even pneumatic antishock garments have also been used successfully to manage these injuries during transport.

Signs and Symptoms

Pelvic or Open-Book Fracture

- Rotation or uneven height of the iliac crests
- Uneven length of the legs
- Tenderness upon palpation of the posterior aspect of the pelvic ring
- Pain, crepitus, or movement upon gentle lateral compression posteriorly and inward medial compression

Transport Management

Pelvic or Open-Book Fracture

- Splint the fracture by restricting movement and stabilizing the pelvis.
- Treat the patient for signs and symptoms of shock.
- Manage any soft-tissue damage to the genitalia.
- Package the patient for transport using motion restriction measures on a scoop stretcher or similar transfer device; alternatively, use a pelvic binder.

Extremity Trauma

Musculoskeletal Injuries

Musculoskeletal injuries are rarely life threatening. They include fractures, sprains, strains, dislocations, muscular contusions, and compartment and crush syndromes. Often dramatic, they may suggest the amount of energy transferred to the body and the likelihood of additional injury. However, the CCTP must not let the dramatic picture presented by these fractures distract from a proper primary and secondary assessment.

Initial motion restriction on the scene can be accomplished by using a backboard as a whole-body splint to decrease on-scene time for patients who have experienced multiple trauma. During interfacility transports, there is usually time to make sure individual fractures are properly splinted. In both cases, adequate pain control should be used. All musculoskeletal injuries should be assessed for the six Ps—pain, pallor, pulselessness, paresthesia, paralysis, and pressure—before and after any manipulation. These findings should be documented on the patient's chart, and pulse locations should be marked with a felt-tip or skin marker on the patient to speed rechecking during transport.

Fractures

A **fracture** is a break in the continuity of a bone. It may be either open or closed. With any fracture, the CCTP's priorities are prevention of further injury due to movement and pain assessment and management. The CCTP should use appropriate analgesic medications as permitted by the system's protocols to reduce the patient's pain and upset.

In a closed fracture, the skin over the bone remains intact, reducing the risk of infection. However, closed fractures can be as dangerous as open fractures due to bleeding into the surrounding tissues.

Depending on the anatomic area where a closed fracture occurs, a large amount of blood could be lost before enough pressure is achieved internally to tamponade the bleeding. For example, a closed fracture of one femur could easily result in the loss of 1 L of blood, whereas bilateral femur fractures could result in the loss of 2 L of blood **TABLE 11-6**. Multiple fractures of trauma patients can cause massive internal hemorrhage and even death, despite no external bleeding being noted.

TABLE 11-6 Estimated Blood Loss by Fracture Type

Estimated Potential Blood Loss (mL)	Fracture Type
125 each	Rib
250–500	Radius or ulna
500–750	Humerus
500–1,000	Tibia or fibula
1,000–2,000	Femur
1,000 to massive	Pelvis

© Jones & Bartlett Learning.

In an open fracture, the skin over the bone is broken, introducing the additional risk of infection, which could lead to sepsis and increases the risk of mortality. Open fractures typically result from high-energy injuries, so they have the potential for more blood loss and concomitant injuries than closed fractures do.

Clinical signs and symptoms of fractures include pain, swelling, deformity, rigidity, limb shortening, ecchymosis, guarding, and crepitus. The patient could have either one of these signs and symptoms or a combination of them.

Management of isolated fractures is as follows:

- Maintain an open airway and apply appropriate oxygen therapy.
- Assess pulses and motor and sensory function distal to the fracture site.
- Control bleeding with direct pressure and pressure dressings; if that is not effective, use a tourniquet. Apply a sterile dressing to any exposed bone or tissue.
- Initiate IV fluids to maintain peripheral perfusion.
- Consider administering analgesic medication titrated to the patient's pain level prior to manipulating the fracture if the patient is hemodynamically stable.
- Splint the fracture site in a normal anatomic position with an appropriate splint while maintaining circulation.
- Reassess pulses and motor and sensory function distal to the fracture site after application or manipulation of a splint.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.
- Use traction splints for immobilization of femur fractures, if appropriate, to help reduce muscle spasms and control hemorrhage. Local protocols should guide the assessment of the risks versus the benefits of traction splinting.

Signs and Symptoms

Extremity Fractures

- Pain
- Swelling
- Deformity
- Rigidity
- Shortening
- Ecchymosis
- Guarding
- Crepitus

Differential Diagnosis

Extremity Fractures

- Fracture
- Sprain
- Contusion
- Compartment syndrome

Transport Management

Extremity Fractures

- Maintain an open airway; apply appropriate oxygen therapy.
- Assess pulses and motor and sensory function distal to the fracture site.
- Control bleeding with direct pressure and pressure dressings; if that is not effective, apply a tourniquet.
- Apply a sterile dressing to any exposed bone or tissue.
- Initiate IV fluids.
- Consider administering analgesic medication.
- Splint the extremity in its normal anatomic position with an appropriate splint while maintaining circulation.
- Reassess pulses and motor and sensory function distal to the fracture site after application or manipulation of the splint.
- Monitor oxygen saturation, vital signs, and the cardiac monitor.

Femur Fracture

The femur is the largest bone in the body and is surrounded by some of the body’s most powerful muscles. When the femur is broken, the muscles contract, causing sharp bone ends to override each other, damaging soft tissue and increasing the rate of blood loss. More importantly, the slack muscle can provide a large space for the collection of blood. Generally, femur fractures lead to a loss of at least 1 L of blood from circulation.

The traction splint was theorized to pull the slack muscles taut again, tamponading the bleeding. When first invented during the Crimean War in the 1850s, this intervention reduced mortality from femur fractures secondary to gunshot wounds from 80% to 20%. Nevertheless, a number of contraindications and dangers arise with use of traction splints. The contraindications include hip and pelvic fractures, knee injury, and ankle damage. The dangers include damage or worsening damage to the neurovascular bundle of the thigh; this includes the sciatic and femoral nerves and the vasculature of the area. Local protocols should include a risk-versus-benefit assessment when traction splinting is being considered.

Spinal Injury

Patients being transported from one facility to another who have not definitively had their spines cleared should be transported with motion restriction in place. The CCTP should apply an appropriately fitted cervical collar and firmly secure the patient to the transport stretcher. It is not necessary to place patients with motion restriction in a recumbent position, but care should be taken to keep the spine in line and minimize flexion or extension. Advance planning for airway management and prevention of aspiration, especially in small aircraft, must be undertaken prior to transport.

Thoracic Fracture

Thoracic fractures can lead to a loss of innervation of the intercostal muscles, which then contributes to respiratory insufficiency. Sympathetic nervous control arises from the thoracic and high lumbar spinal cord. Although it is rare, a condition called spinal shock can affect the thoracic area or higher. In this type of shock, hypotension is accompanied by bradycardia, instead of tachycardia. Pulse pressure will be normal or widened, instead of narrowed as in hypovolemia. The area above the fracture will be pale and cool, but the area below it will be warm. Treatment should consist of fluids and vasopressors to maintain the patient’s MAP in the range of 80 to 90 mm Hg.

Lumbar Spine Fracture

The lumbar vertebrae are the largest vertebrae. Because they are not supported—as the thoracic vertebrae are—by the ribs, they are susceptible to injury. Jackknifing, such as over a seat belt, is frequently the mechanism of injury in lumbar spine fracture and is associated with intra-abdominal injury in as many as 40% of these fractures. Motion restriction for transport is the appropriate treatment.

Rib Fracture

Single rib fractures are rarely life threatening. They may cause pneumothorax, and torn intercostal arteries can lead to significant blood loss or hemothorax. Multiple rib fractures will negatively impact respiratory excursion, even without a flail segment.

The goal of treatment for rib fractures is analgesia to improve inspiration. The CCTP should provide sufficient pain medication so that the patient is less inclined to self-splint, which can interfere with respiration. In rare cases, multiple rib fractures may require ventilatory assistance; however, adequate analgesia should be achieved prior to airway intervention.

Extremity Fracture

Casting

With fractures of the extremities in trauma patients, casts made of fiberglass or plaster are applied by an orthopaedic surgeon after acute swelling has gone down. Casting usually takes place at least 24 hours after the injury occurs. Swelling under a cast can cause compartment syndrome.

Any patient with a cast who is transported by a CCTP should be evaluated for neurovascular function distal to the cast prior to transport and periodically during transport. It is recommended that the location where pulses are found be marked on the skin and documented in the patient care record.

Reduction/Realignment

Typically, reduction and realignment of a fractured extremity is not a priority of care in the critical patient—instead, resuscitation of cardiovascular status must always take priority. Usually, reductions are done by an orthopaedic surgeon as part of the resuscitation team or soon thereafter. Realignment becomes a priority if the neurovascular function distal to the injury is compromised. This is accomplished by applying gentle traction in the anatomic direction of the bone distal to the fracture while stabilizing the bone proximal to the break. The bone is then brought into alignment or to a position in which the maximal pulse is felt, and is splinted in that direction.

External Fixation

External fixation of fractures has become more common, especially in critically ill patients. Placed by an orthopaedic surgeon, external fixation uses external rods held to the bone with plates and screws. The apparatus is placed surgically. The external joints are then adjusted over time as needed by the orthopaedist. Occasionally, CCTPs will transport patients with this device in place. Adequate padding and comfortable positioning are required for such transports.

Internal Fixation

Internal fixation is the placement of rods with plates and screws in the operating room to hold fractures in place for healing. The rods may be removed later, or they may be left in place permanently. Occasionally, the rods work themselves out of position and may need surgical revision. Generally, this equipment is not of concern during transport.

Compartment Syndrome

In compartment syndrome, bleeding or swelling occurs within the nonstretchable fascia that surrounds different muscle groups and divides each extremity into compartments. Because the compartments can accommodate only a small amount of bleeding or swelling, this condition increases the pressure within the compartment, which eventually compresses arteries and veins, prevents adequate perfusion of the muscle, and causes pain. Although the anatomic locations where compartment syndrome most commonly occurs are the lower legs and the forearms, this condition can develop in any extremity and the buttocks. In one study, 69% of compartment syndrome cases were associated with fracture (one-half of the fractures were to the tibia), but burns, external compression from splints or bandages, and crushing injury were also noted to lead to this complication. In the same study, 31% of patients with compartment syndrome had soft-tissue injuries without a fracture. Compartment syndrome usually develops over a period of hours, so frequent assessments are imperative.

Clinical signs and symptoms of this condition initially present as pain out of proportion to the evident injury, sometimes described as burning and paresthesia over the compartment site. Additional signs include tension of a muscle when not in use, loss of distal sensation or pulses, and extreme pain on extension or voluntary movement. The presence of pulses or Doppler blood flow does not rule out compartment syndrome, as pulselessness is typically the last symptom to appear. The signs are commonly referred to as the six Ps—pain, pallor, pulselessness, paresthesia, paralysis, and pressure. Sometimes a seventh P is added, **poikilothermia**, or a coldness of the affected extremity relative to the contralateral side.

Management of compartment syndrome is as follows:

1. Maintain an open airway and apply oxygen therapy as necessary.
2. Assess pulses, motor, and sensory function.
3. Elevate the extremity above the heart.
4. Place ice packs over the extremity.
5. Initiate IV fluids to maintain peripheral perfusion.
6. Consider loosening any constrictive splint material and/or clothing.
7. Administer pain medication.
8. Monitor carefully for signs of, and be prepared to treat, rhabdomyolysis, hyperkalemia, and myoglobinuria.

For interfacility transport, several methods may be used to monitor actual compartment pressures invasively. In a noncontracting muscle, the normal mean interstitial tissue pressure is close to 0 mm Hg. If this pressure becomes elevated to 30 mm Hg or more, small vessels in the tissue can become compressed, resulting in reduced blood flow, ischemia, and pain. Pay close attention to both compartment pressure and diastolic blood pressure **FIGURE 11-37**. It is considered an emergency if the diastolic blood pressure drops to less than 30 mm Hg over the compartment pressure. When compartment pressure exceeds diastolic pressure, the blood flow in the extremity stops.

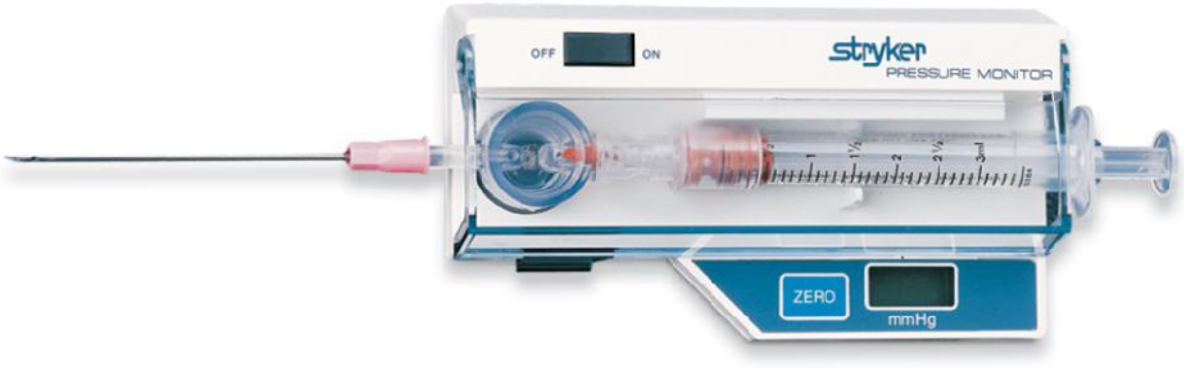

FIGURE 11-37 Compartment pressure monitoring device.

Courtesy of Stryker.

Untreated compartment syndrome–mediated ischemia of the muscles and nerves will lead to eventual irreversible damage and death of the tissues within the compartment. Definitive treatment involves fasciotomy—that is, cutting the fascia and opening the compartment to release the pressure. This procedure is typically performed in the operating room under general anesthesia. The compartment is then left open until bleeding is controlled and swelling is resolved.

Signs and Symptoms

Compartment Syndrome

- Pain
- Pallor
- Pulselessness
- Paresthesia
- Paralysis
- Pressure
- Poikilothermia (affected extremities may be colder on the affected side)

Transport Management

Compartment Syndrome

- Maintain an open airway; apply oxygen therapy as necessary.
- Assess pulses and motor and sensory function frequently.
- Elevate the extremity above the heart.
- Place ice packs over the extremity.
- Initiate IV fluids to maintain peripheral perfusion.
- Consider loosening any constrictive splint material and/or clothing.
- Administer pain medication.
- Monitor carefully for signs of, and be prepared to treat, rhabdomyolysis, hyperkalemia, and myoglobinuria.

Rhabdomyolysis and Crush Syndrome

Rhabdomyolysis is damage to the sarcolemma (muscle membrane) from any cause. This damage allows an influx of calcium and sodium, followed by water, into the cells. When these cells then rupture, they release myoglobin, aspartate transaminase, lactate, creatine kinase, potassium, uric acid, and phosphorus into the surrounding tissues. These substances are then absorbed into the circulation. The membrane damage also results in extracellular hypocalcemia and hyperkalemia; hyperkalemia leads to cardiac arrhythmias. The release of myoglobin combined with hypovolemia and acidosis leads to the blockage of renal tubules, causing acute renal failure.

Rhabdomyolysis has multiple etiologies, both traumatic and medically induced. The leading causes are exercise, alcohol, drugs, infections, trauma, compression, and seizures. This condition may also stem from metabolic myopathies, drugs and toxins (including cocaine and hallucinogens such as phencyclidine hydrochloride [PCP] and 3,4-methylenedioxymethamphetamine [MDMA]), infections, electrolyte abnormalities (including hypokalemia, hypophosphatemia, and both hypernatremia and hyponatremia), electrical current injuries, hypoxia (including carbon monoxide poisoning and sickle cell crisis), hyperthermia (including heat stroke, neuroleptic malignant syndrome, and malignant hyperthermia), and idiopathic causes.

Assessment

Assessment must start with a high index of suspicion, given the many causes of rhabdomyolysis. Any patient who lies in one position without being able to move for several hours is at risk. Physical examination may reveal motor weakness, obvious evidence of trauma or compression, and sensory loss. All of these symptoms may be accompanied by evidence of dehydration and dark or brown urine. The urine on a dipstick will show blood, with only a few red blood cells apparent on microscopic urine analysis, and a blood test will reveal significant creatine kinase levels of five times normal or higher. The upper normal level of creatine kinase is 150 U/L, but several hundred thousand units per liter may be present in rhabdomyolysis.

Electrolyte analysis will demonstrate the presence of hyperkalemia (potassium level greater than 5.5 mEq/L), with the expected ECG changes of tall, pointed T waves with a narrow base that widens as the potassium level increases, and then a flattening P wave. Hypocalcemia may also be present; it is defined as a calcium level lower than 8.2 mg/dL (2.05 mmol/L) or, in the case of ionized calcium, a concentration of less than 4.6 mg/dL (less than 1.15 mmol/L). In addition, a prolonged QT interval may be evident on ECG.

Management

When a CCTP is called to a scene that involves prolonged (longer than 2 hours) entrapment of a large muscle area of the patient, it is imperative that evaluation and treatment be started prior to the release of the entrapped patient. **Crush syndrome** is known as the smiling death—a sobriquet attributable to the pattern of extricated patients being happy and smiling until the released potassium reaches their heart, at which point sudden death ensues. Immediately prior to rescue, 2 L or more of saline (not potassium-containing lactated Ringer solution) should be infused and 1 mEq/kg of sodium bicarbonate given. It has been theorized—and now demonstrated in at least one published case report—that application of a tourniquet to the proximal, unentrapped portion of a pinned extremity (or extremities) delays release of hyperkalemic and acidotic blood back into circulation for the duration of time that the tourniquet is in place. Such a practice may allow for stabilization of other injuries; the tourniquet can then be released in the more controlled in-hospital setting or operating room.

The entrapped patient should be placed on a heart monitor when released. If the patient develops signs suggestive of an elevated potassium level, then calcium gluconate should be given as often as every 5 minutes as a slow IV push. Once an indwelling urinary catheter is placed, fluids should be given to maintain output of 300 mL/h. Bicarbonate should be given to keep urine pH at or greater than 7.65. This can be done by adding 3 ampules of bicarbonate to 1 L of 5% dextrose in water to maintain an isotonic solution. Mannitol is the diuretic of choice: It is both an osmotic diuretic, reducing swelling of the damaged muscle, and an intravascular volume expander. Mannitol also dilates and flushes the renal tubules. As a free radical scavenger, this agent reduces direct damage from these ions. Loop diuretics (eg, furosemide) should be avoided in patients with suspected rhabdomyolysis or crush syndrome, because they acidify the urine.

During interfacility transfers, the CCTP should follow the patient's electrolyte levels carefully and use them to guide therapeutic interventions. This includes an electrolyte analysis completed immediately prior to transfer and, if available, use of bedside electrolyte monitoring during transport, such as with an i-STAT device **FIGURE 11-38**.

Signs and Symptoms

Rhabdomyolysis

- Motor weakness
- Obvious evidence of trauma or compression
- Sensory loss
- Dehydration
- Dark or brown urine
- Blood with only a few red blood cells on microscopic urine analysis
- Significant elevations of creatine kinase (5 times normal or higher)
- Hyperkalemia (>5.5 mEq/L), plus ECG changes of tall, pointed T waves with a narrow base that widens as potassium increases, and then a flattening P wave
- Hypocalcemia (<8.2 mg/dL [<2.05 mmol/L] or <4.6 mg/dL [<1.15 mmol/L ionized]), plus a prolonged QT interval on ECG

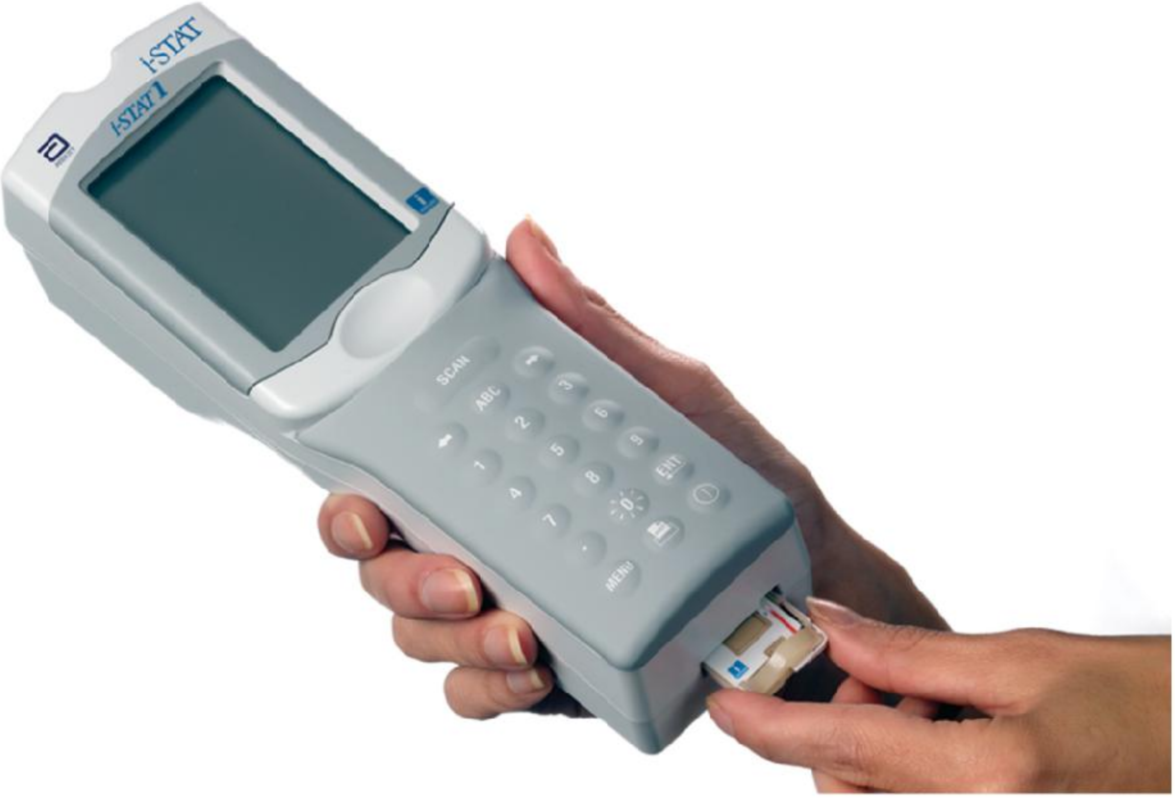

FIGURE 11-38 An i-STAT bedside electrolyte monitoring device for use during transport.

Courtesy of Abbott Laboratories.

Transport Management

Rhabdomyolysis

- Administer 2 L (or more) of saline.
- Administer 1 mEq/kg of sodium bicarbonate.
- Place the patient on a heart monitor.
- If signs of elevated potassium develop, give calcium as often as every 5 minutes as a slow IV push. Discontinue if severe bradycardia develops.
- Insert an indwelling urinary catheter, and give enough fluids to maintain output of 300 mL/h.
- Give enough bicarbonate to keep urine pH equal to or greater than 7.65, by adding 3 ampules per 1 L of D_5W (5% dextrose in water) given.
- Administer mannitol if the patient is producing urine.
- During interfacility transfers, monitor electrolytes.

Pulseless Extremity

Although a traumatized pulseless extremity may be repositioned successfully to reestablish circulation, this maneuver carries inherent dangers. Such repositioning should be done with manual traction in anatomic alignment with the long bone. Traction should reduce—not cause—pain if it is done in the correct anatomic direction. If the injury involves a dislocation rather than a fracture, analgesia and benzodiazepines may help relax the muscles to facilitate the repositioning. Position the extremity to maximize the strength of the pulse and splint it in this position. Mark the skin where pulses are obtained to make reassessment faster.

Trauma to Special Populations

Geriatric trauma and trauma to pregnant patients are covered here. Pediatric trauma is covered in Chapter 24, *Pediatric Emergencies*.

Geriatric Trauma

Some 54 million Americans (16.5%) were older than 65 years in 2019, a number expected to increase to 98 million by 2060. Geriatric refers to patients age 65 years and older; regarding trauma, mortality rates start to climb after the age of 30 years. The incidence of complicating comorbid conditions also increases after age 30 years. These coexisting medical conditions may cause lesser traumas to have a higher mortality due to increased physiologic stress.

Although patients older than 65 years account for only 11% of pedestrian incidents, they make up 25% of the fatalities in such incidents. A driver older than 65 years is five times more likely to be fatally injured in an MVC than a younger driver is. In another example of the greater vulnerability of older adults, the 1-year mortality rate for hip fractures in the over-65 population is 20% and the 2-year rate is 33%. One in five burn center admissions is a patient older than 65 years (approximately 1,500 people per year), and these older patients have a fatality rate seven times that of younger patients.

Some special considerations are necessary when dealing with geriatric patients who have experienced trauma. For example, assessment of the airway needs to include the presence of dentures or other dental devices that may have become dislodged. Removing dentures may make intubation easier, but without having them in place, achieving a satisfactory mask seal becomes more difficult. Broken teeth are at an increased risk of becoming a foreign body obstruction in older patients.

Kyphosis in geriatric patients can cause problems in terms of both motion restriction and airway management. Extra padding to fill the void under the patient’s head and additional personnel to assist with motion restriction may be necessary. Geriatric patients also have reduced subcutaneous fat, so extra padding should be used between any applied splints and the skin.

Because of a reduced cough reflex and an increased risk of aspiration, additional attention to suctioning may be necessary in older adults. Their nasal tissues are more fragile and, if the patient is on anticoagulants, the risk of bleeding may render the use of both basic and advanced nasal airways problematic. Respiratory assessment must take into account reduced vital capacity and decreased ability for chest excursion, even prior to injury. Reduced tidal volume and lower minute volume can lead to a significant reduction in oxygen and carbon dioxide exchange as a baseline. Progressive hypoxia can result from even minor chest injury. Increased PIP may be necessary as a result of chest wall stiffness. Older patients are often more dependent on diaphragmatic excursion, and any restriction of the abdomen may interfere with this respiratory movement.

In addition, assessment for shock and perfusion may be difficult in older adults. Capillary refill may be normally delayed in these patients. Furthermore, cardiovascular assessment of the geriatric patient may be complicated by the ongoing use of medications such as beta blockers or other antihypertensive agents. These medications may interfere with compensatory mechanisms of shock, keeping the heart rate artificially low in the face of hypovolemia. Likewise, patients with pacemakers may be unable to compensate by raising their heart rate. Preexisting hypertension means that decompensated shock may present as what appears to be a normal blood pressure to the observer. A slow or absent vasoactive response means that the patient is more dependent on preload for maintaining an adequate circulation.

Fluid resuscitation remains the mainstay of traumatic shock resuscitation in older patients. Nevertheless, caution must be exercised to prevent fluid overload owing to the inability of the older person’s cardiovascular system to adjust to rapid changes in fluid volumes.

Slow responses to questions or a lack of orientation to a location or date may not be a sign of head trauma in the geriatric patient, but rather part of the patient's baseline. Therefore, if the patient is conscious, history taking may require more patience when waiting for answers. The use of open-ended questions is recommended. If a family member is available, obtaining a sense of the geriatric patient's baseline mental status can assist in identifying changes or deficits.

Trauma During Pregnancy

Abdominal Injuries to Pregnant Patients

Injuries to pregnant patients are complicated by the multiple physiologic changes experienced by the pregnant woman and the fact that the CCTP is responsible for two lives. The primary cause of fetal demise in a mother who experiences trauma is maternal shock and death. Therefore, the best treatment for the fetus is to resuscitate the mother. Trauma occurs in 7% of pregnancies and is the leading cause of nonobstetric death in pregnancy, accounting for 7% of all maternal deaths and 80% of fetal deaths. The most common cause of trauma during pregnancy is MVCs, followed by assault. Approximately 8% of women between ages 15 and 40 years who present to trauma centers do not even know they are pregnant. Chapter 22, *Obstetric and Gynecologic Emergencies*, describes the physiologic changes in pregnancy in more detail.

Some of the changes associated with pregnancy can mimic shock. For example, in the first trimester, the woman's systolic blood pressure drops about 5 mm Hg and diastolic blood pressure drops 15 mm Hg. The pregnant patient's heart rate also increases as much as 20 beats/min. Other changes may hide shock as well. Blood volume increases by about 50% in midpregnancy, and a relative anemia results from hemodilution. Consequently, the pregnant trauma patient may lose as much as 40% of her blood volume before the signs of shock become obvious. Because of the increased levels of coagulation factors and fibrinogen associated with pregnancy, the risk of deep vein thrombosis, pulmonary embolus, and DIC increases, especially in patients with multisystem trauma. Because of the increase in blood flow to the uterus to more than 0.5 L/min during pregnancy, along with venous congestion of the pelvic vessels, the risk of massive blood loss is considerably increased with trauma to the bony pelvis of a pregnant patient.

Any pregnant patient who sustains a pelvic injury or fracture is at very high risk for a bladder and/or uterine injury. At term, the uterus/placenta is perfused with approximately 600 to 800 mL of blood *per minute*. There should be a high rate of suspicion for these injuries, because these patients may exsanguinate rapidly.

Abruptio Placentae

In pregnant women who experience blunt trauma, as many as 70% of fetal deaths are the result of abruptio placentae. Sudden deformation of the uterine wall can shear the placenta from the site of implantation, without any external signs of this injury. Signs of abruption include vaginal bleeding (seen in only 37% of cases), abdominal cramping, and symptoms of maternal hypovolemia. The most important sign is fetal distress. Ultrasonograms are less than 50% accurate in finding an abruption. Women with an abruption are at an extremely high risk for DIC as a result of release of thromboplastin from the placenta.

Management

Fetal resuscitation focuses on maternal resuscitation, and maternal resuscitation starts with the ABCs. Given a higher risk of aspiration and the increase in gastric acidity in pregnant patients, isolating and monitoring the airway is of vital importance. Because of their increased oxygen consumption and reduced reserve, all pregnant patients should have their oxygenation maximally optimized. Hypoxia alone can cause a 30% reduction in uterine blood flow. Increased tidal volume and respiratory alkalosis as a baseline must be taken into account when using ventilators and end-tidal carbon dioxide ($ETCO_2$) monitoring. The target for $ETCO_2$ should be 30 mm Hg, rather than the usual 40 mm Hg. Early IV access with judicious fluid resuscitation should be initiated before signs of shock appear.

Beyond 20 weeks' gestation, the patient should be tilted left laterally to at least a 15° angle to prevent inferior vena cava compression. CVP is helpful in guiding fluid administration, but remember that CVP normally trends down to as low as 3 mm Hg as pregnancy progresses.

Signs and Symptoms

Abruptio Placentae

- Vaginal bleeding
- Abdominal pain
- Back pain
- Uterine tenderness
- Signs of shock
- Lack of fetal heart sounds

Differential Diagnosis

Abruptio Placentae

- Ectopic pregnancy
- Placenta previa
- Preterm labor
- Spontaneous abortion

Transport Management

Abruptio Placentae

- If the patient is beyond 20 weeks' gestation, tilt her laterally to the left, to at least a 15° angle, to prevent vena cava compression.
- Provide bleeding control.
- Maintain the patient's airway; provide appropriate oxygen therapy.
- Initiate early IV access and implement judicious fluid resuscitation (eg, with lactated Ringer solution).

- Provide rapid transport.

Flight Considerations

The principles presented in this chapter apply to both ground and air critical care transport. Given the critical nature of their injuries, however, patients with severe trauma are more likely to be transported by air, especially in situations in which ground transport time could take considerably longer than air.

Summary

Caring for patients with traumatic injuries requires the CCTP to have a solid understanding of the trauma system used in the United States. Knowledge and application of commonly used trauma scoring systems are essential parts of the CCTP's scope of practice. The CCTP must apply this knowledge and the appropriate assessment skills to assess, triage, and treat patients with traumatic injuries, and to transport them to the most appropriate facility. It is imperative that the CCTP be competent in clinical skills, understand why certain injuries occur, and have knowledge of which emergency procedures need to be performed to decrease morbidity and mortality. By mastering these skills, the CCTP becomes an integral part of the overall trauma care and management process, which in turn maximizes the patient's acute care, rehabilitation, and recovery.

CASE STUDY

You are working the day shift with a nurse-medic–staffed helicopter. You have been dispatched to a scene. You receive a report from your communications center stating that you are going to a farm site where an older man has been kicked by a bull. The patient is currently alert and his vital signs are stable, as reported by the paramedics on the scene. The closest Level I trauma center from the scene is a 30-minute flight.

Upon landing, you and your partner approach the scene, which is in the pasture of a beef cattle farm. You survey the scene to ensure your safety. You receive a report from the local paramedics. The patient, a 68-year-old man, was assisting in feeding cattle when one of the bulls attacked him, first striking him in the chest with his head (horns removed) and then kicking him in the chest. The medic states that the patient is complaining of shortness of breath and severe chest pain, but otherwise he is alert and oriented and his vital signs remain stable.

Your assessment reveals a well-developed man who appears to be extremely short of breath. He is wearing a nonrebreathing mask and is receiving oxygen at 15 L/min; his oxygen saturation is 90%. In looking at his chest wall, you see a significant defect on the left side of the chest, with paradoxical chest wall motion. The patient is alert and oriented, with a GCS score of 15. The ground medics report that his breaths are becoming progressively shorter. The patient has two large-bore IV lines in place and has already received 1,000 mL of normal saline. His vital signs include a blood pressure of 110/70 mm

Hg, a pulse rate of 118 beats/min, a respiratory rate of 32 breaths/min, and an oxygen saturation of 90%.

You and your partner discuss the patient's need for pain medication. You administer 2 µg/kg of IV fentanyl. The patient's heart rate slows down to approximately 100 beats/min, but his respiratory status does not improve. You and your partner discuss managing this patient's airway/ventilator status and elect to intubate the patient orally before leaving the scene. Using your local protocol, you administer etomidate, 0.3 mg/kg IV, and succinylcholine, 2.0 mg/kg IV. The intubation is performed without difficulty. After intubation, you hear bilateral breath sounds but crackles in the left base. You apply capnography and monitor the patient's $ETCO_2$. His initial reading after intubation was 60 mm Hg, so you increase the ventilator minute volume. You finish packaging the patient and begin transport.

In flight, you administer long-term paralytics and additional sedation agents, and continue to treat the patient's pain. His vital signs remain stable, with a blood pressure of 98/70 mm Hg, a pulse rate of 90 beats/min, and ventilations at 16 breaths/min with 97% saturation. His $ETCO_2$ reading is 40 mm Hg, which shows that he is adequately ventilated. You and your partner discuss IV flow rates and elect to keep both IV lines open. The patient is admitted to the Level I trauma center and a report is given to the attending staff.

1. Why did you elect to intubate this person when the standard of care for flail chest is to keep the patient off mechanical ventilation if it all possible?
2. Why did you decide to continue the patient's fluids in fight?

Analysis

In cases of flail chest, the patient's pain is treated aggressively. With the pain under control, many times the patient is then able to ventilate adequately on their own. In this patient, two issues needed to be considered. First, the patient was dyspneic and was not breathing adequately, as shown by his poor oxygen saturation despite appropriate oxygen therapy. Even after his pain was treated and his heart rate slowed down, his oxygen saturation was borderline at best. Second, the patient faced the prospect of a 30-minute flight, and the chance that his condition would continue to deteriorate seemed high. In the treatment of flail chest, mechanical ventilation should be reserved for patients who have persistent respiratory insufficiency or failure, after adequate pain control. This patient met that standard; therefore, intubation is appropriate, and rapid sequence intubation should be performed. Follow the local protocol for appropriate medication use. In this patient, it is imperative that you continue to treat his pain after administering long-term paralytics and sedation. Patient monitoring after intubation must include continuous waveform capnography; a capnography reading is an excellent indicator of respiratory rate and adequate ventilation in flight.

Many services now carry continuous positive airway pressure devices on the helicopter. This patient would have been a candidate for continuous positive airway pressure in flight, thereby avoiding mechanical ventilation. The CCTP would have to be astute in ongoing pulmonary assessment to realize when the patient's condition is failing and would need to provide mechanical ventilation if necessary.

When chest trauma is significant enough to break multiple ribs, there is a higher associated risk of underlying parenchymal injury to the lung. Aggressive fluid resuscitation only worsens the interstitial fluid leak, which leads to ventilation-perfusion mismatch and, in turn, worsening pulmonary contusion. This patient had already received 1,000 mL of fluid, which probably worsened his lung condition.

The patient's mean arterial pressure (MAP) should be maintained at or above 65 mm Hg. His current reading is approximately 79 mm Hg, which is adequate for end-organ perfusion. This patient's IV fluids should be slowed. If his blood pressure dictates, titrate the patient's fluids according to his MAP.

PREP KIT

Ready for Review

- A paradigm shift in the care of critically injured trauma patients has resulted in an emphasis on rapidly identifying and treating those patients who need immediate transport to an appropriate trauma center.
- The ability of the CCTP to rapidly identify life-threatening injuries while recognizing the need for transport to a trauma center can help decrease the incidence of morbidity and mortality related to these traumatic injuries.
- CCTPs may encounter trauma patients during a scene call, when they are called to back up field BLS or ALS providers. In these cases, the CCTP will be working in more austere and less controlled conditions with less sophisticated assessment tools than are available in an interfacility transport.
- CCTPs may also aid in transferring critical patients with trauma, usually from smaller facilities to higher-level trauma centers. In this situation, the CCTP may have access to the results of any assessment findings identified prior to transport and may be able to enlist the aid of the sending physician or other house staff to help with stabilization efforts prior to transport.
- The balance of treatment before transport versus what can be done en route should always be a top priority in the CCTP’s decision-making process.
- Trauma is the leading cause of death in children and adults younger than 45 years in the United States.
- Many people survive an MVC, only to sustain a debilitating injury that leaves them incapacitated. Providers must appreciate the importance of avoiding secondary injury caused by improper handling of these patients.

- Understanding Newton's first law of motion—"A body in motion remains in motion in a straight line unless acted upon by an outside force"—enables the CCTP to predict patterns of injuries in trauma incidents and deliver the appropriate standard of care.
- Traumatic injuries are generally classified into one of two categories: blunt or penetrating.
- Blunt injuries result from energy exchange between an object and the body, without intrusion through the skin—for example, rapid forward decelerations (crashes), rapid vertical decelerations (falls), and energy transferred from blunt instruments (assault).
- Penetrating injuries refer to injuries caused by external forces in which the tissue is penetrated by an object—for example, injuries caused by projectiles such as bullets, knives, fragments from explosions, and falls upon fixed objects.
- Deceleration injuries are caused by a sudden stop of the body's forward motion. Because they may not be visible to the CCTP, an excellent understanding of the types of mechanisms of injury and effective assessment skills are imperative for detecting them.
- External force injuries occur when forces violate the tissues of the body. Their severity depends on the anatomic area involved as well as the mass, size, and the velocity of the foreign object that enters the body.
- The CCTP must not develop tunnel vision; that is, the CCTP must not focus on a visible injury, which may or may not be life threatening, while paying little or no attention to other, genuinely life-threatening injuries.
- Maintaining a calm, professional demeanor and using a systematic approach allows the CCTP to maintain a high index of suspicion and attention to detail.
- Trauma scoring systems are used in the CCT environment to provide assessment information, to report quality outcomes, and as indicators of patient survivability.
- The Glasgow Coma Scale (GCS) is a neurologic assessment tool that assigns a numerical value to the patient's condition based on

three body functions: best eye-opening response, best verbal response, and best motor response.

- The GCS should be used regardless of the cause of central nervous system alteration. It is predominantly applied and the score reported during the care of critically ill and injured patients when their current level of consciousness is pertinent to their acuity level.
- Patients who present with GCS scores of less than 8 typically require intubation or another form of advanced airway intervention.
- The trauma score takes into account the GCS score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill rate. This score, which ranges from 1 to 16 (the best possible score), reflects the likelihood of patient survival.
- The revised trauma score measures three physiologic parameters: respiratory rate, systolic blood pressure, and GCS score. The total score ranges from 0 (the most severely debilitated patient) to 13 or, when a weighted system is used, from 1.0 to 7.8408.
- The revised trauma score is considered flawed because it measures the body’s physiologic response to the injury and fails to identify a small percentage of severely injured trauma patients.
- The Abbreviated Injury Scale (AIS) is an anatomic scoring system that provides a reasonably accurate means of ranking the severity of an injury by categorizing injuries into six body regions. Scores for each region range from 1 (minor injury) to 6 (unsurvivable), but do not take into account multisystem injuries.
- The Injury Severity Score (ISS) is an anatomic scoring system that provides an overall score for patients with multiple injuries. Scores range from 1 (minor injury) to 75 (high mortality).
- A patient with an ISS of greater than 15 is frequently considered to have major trauma and requires immediate attention and, in most cases, transfer to a Level I facility.
- The trauma injury severity score is used to determine the survival probability of the critically ill and/or injured patient. It takes into

account the ISS, the revised trauma score, and the patient's age, which collectively summarize the patient's physiologic and anatomic indicators.

- Trauma centers are classified into Levels I through IV. Level I centers (regional centers that provide every aspect of trauma care) have the most resources, followed by Level II centers (facilities that provide initial definitive care), Level III centers (facilities that provide assessment, resuscitation, emergency medical care, and stabilization, and then transfer patients to higher-level centers), and Level IV centers (clinics that provide ATLS prior to patient transfer).
- Patients with severe trauma (Level I patients) are more likely to be transported by air, especially in situations in which ground transport time could take longer than air transport.
- Interfacility care for trauma patients will often involve patients who are very ill and in need of close assessment and continued monitoring. Management after these patients' arrival at a hospital should follow ATLS guidelines.
- As in the prehospital setting, immediate attention during interfacility transport is directed at the ABCs. It is also imperative to assess the patient from head to toe for external injuries.
- The CCTP must be prepared to detect and treat complications of the initial evaluation and treatment, including fluid overload, transfusion reactions, contrast-induced renal issues, abdominal compartment syndrome, bleeding, and shock.
- Hypothermia, acidosis, and coagulopathy are the lethal triad of trauma. Every effort should be made to avoid these pathologies in caring for trauma patients.
- The incidence of hypothermia in trauma patients can be as high as 50%, and mortality rates can approach 100%. Treatment should focus on prevention or reduction of hypothermia in these patients.
- Hypothermia can lead to acidosis, as can administration of large volumes of acidic crystalloid solutions like normal saline, which has a pH of 5.5 and a very high level of chloride.

- Coagulopathy can be precipitated not only by hypothermia and acidosis, but also by acute blood loss. Aggressively managing hemorrhage and ensuring early replacement of clotting factors through transfusion of blood products are important interventions to reverse or prevent progressive coagulopathy.
- Obtaining and understanding imaging studies related to trauma is an integral component of the trauma care paradigm for the CCTP.
- Standard radiographs are part of the initial assessment of the patient with multisystem trauma; they can provide confirmation of endotracheal tube placement, lead to identification of fractures, and suggest the need for further intervention prior to initiation of transport.
- In trauma patients, computed tomography scanning is typically used to identify head injury, bleeding, and complex fractures. Typical studies will scan the head, chest, and abdominal-pelvic regions.
- Focused assessment with sonography for trauma (FAST) ultrasonography is used to identify the presence of free intraperitoneal or pericardial fluids, and has replaced diagnostic peritoneal lavage and laparotomy for this indication.
- Critical care clinicians may also use focused-exam imaging modalities such as transthoracic and transesophageal echocardiography.
- Magnetic resonance imaging provides much better resolution that can help identify abnormalities in trauma patients, but requires substantial amounts of time to obtain. It is infrequently used in the initial care for trauma patients.
- Intra-abdominal pressure (IAP) is the static pressure inside the abdominal compartment. Deleterious effects of intra-abdominal hypertension (IAH) can lead to abdominal compartment syndrome (ACS) and death if untreated. Definitive treatment is surgical decompression, but many interventions can be implemented to help prevent IAH and ACS. The CCTP may be asked to obtain IAP measurements during transport.

- When transporting trauma patients, CCTPs should always ask for and ensure that all copies of any imaging studies are included as part of the patient care record.
- Approximately 25% of all trauma deaths are directly associated with thoracic injuries.
- The primary function of the thorax is to support adequate oxygenation and circulation. Therefore, injuries to the chest must be found and managed promptly.
- Care must be taken in trauma patients to ensure adequate positive-pressure ventilations without allowing intrathoracic pressure to rise too high; this may become an issue during flight.
- Pneumothorax injuries cause air to be drawn into the thoracic cavity with each breath. A collapse as small as 10% can be life threatening if the patient has other comorbid issues.
- Sealing a sucking chest wound can cause a tension pneumothorax if air is still able to enter the pleural cavity from the lung side of the wound and builds up, or if the seal is ineffective. Monitoring the airway and breathing in these patients is critical.
- A simple pneumothorax is most often associated with a closed chest injury, such as from a fractured rib being driven inward into the lung or from a medical cause that leads to collapse of the lung.
- A tension pneumothorax is a life-threatening injury that results from a continual influx of air into the pleural space. It may occur secondary to a closed simple pneumothorax or after sealing an open pneumothorax.
- Management of a tension pneumothorax consists of immediate needle decompression.
- Hemothorax can be caused by blunt or penetrating trauma, as well as a tumor eroding through the great vessels. It may potentially lead to hypovolemic shock or, if a large amount of blood accumulates in the pleural cavity, respiratory distress.

- Patients with a pneumothorax, hemothorax, hemopneumothorax, or empyema ultimately may need a chest tube inserted. In addition, CCTPs routinely care for and transport patients with chest tubes in place.
- Because of the potential for massive hemorrhage from thoracic trauma, the CCTP must be familiar with the administration of blood and blood products.
- Recent studies comparing the effectiveness of pigtail versus larger conventional chest drainage tubes show no significant differences in resolution of pneumothoraces, hemothoraces, empyemas, and effusions.
- A flail chest (flail segment) consists of a fracture in two or more places to two or more adjacent ribs. Bruises to the underlying tissue causing a pulmonary or myocardial contusion are the most dangerous sequelae of a flail chest.
- Flail segments pose a threat to the patient’s ability to breathe, increase the risk for developing a hemothorax or pneumothorax, and require immediate treatment.
- The gold-standard treatment for flail chest is mechanical ventilation with a sedate, paralyzed patient who has been adequately treated for pain. Some patients may be managed conservatively with pain medications and oxygen supplementation alone.
- Pericardial tamponade is a life-threatening condition that requires immediate treatment. It occurs in 2% of penetrating injuries to the chest and upper abdomen, and is more common in stab wounds to the heart than in gunshot wounds.
- Most often, prehospital management of pericardial tamponade is only supportive; sometimes, however, the CCTP may need to perform or assist in an emergency pericardiocentesis.
- A pericardial window procedure involves removing a section of the pericardium to create a window, allowing fluid that has accumulated in the pericardium to drain, and leaving a drain in

place. Monitoring drain output and frequent cardiovascular assessments can prevent recurrence of cardiac tamponade.

- Traumatic aortic rupture is the most common cause of immediate death in MVCs.
- Tears in the ascending aorta are almost uniformly immediately fatal, but patients with tears on the descending side have a 15% chance of making it to the operating room. Even so, there is a 30% mortality rate among those patients who do survive until arrival at the hospital.
- The ligamentum arteriosum is the most common cause of aortic dissection in trauma patients.
- Myocardial contusion (bruise to the myocardium) is primarily the result of blunt trauma to the anterior chest wall, such as trauma that occurs during MVCs or with other blows to the front of the chest (eg, gunshot to a bulletproof vest).
- With myocardial contusion, damage to small blood vessels may cause local bleeding and direct trauma to cells. Because the areas downstream from the damaged vessels are no longer perfused, the damage may resemble that associated with myocardial infarction.
- If blunt compression of the abdomen occurs (eg, from blunt or penetrating trauma), it may cause diaphragmatic rupture and herniation of abdominal organs into the thoracic cavity. This impairs lung expansion and decreases venous return, resulting in decreased ventilatory and cardiac output.
- Tracheobronchial injuries are rare, but often life threatening. The leakage of air that occurs with such damage may cause a tension pneumothorax or tension pneumomediastinum, which will act like a cardiac tamponade.
- Management of tracheobronchial disruption includes judicious use of ventilatory support.
- Lacerations and bruising of the lung tissue (pulmonary contusion) can cause bleeding and leakage of plasma into the alveoli and

interstitial space. This damage interferes with gas exchange and can lead to severe hypoxemia.

- Patients with pulmonary contusion may be managed with noninvasive, continuous positive airway pressure, adequate analgesia, and resuscitation fluids as needed.
- Esophageal perforations are most often caused by penetrating injuries, such as from projectiles, or by caustic ingestion, but can also be caused by an underlying medical issue, such as cancer, gastroesophageal reflux disease erosions, or excessive vomiting.
- Traumatic asphyxia—a severe sudden crushing injury to the chest and abdomen—is not a form of asphyxia, nor is it by itself fatal. Associated injuries, if present, tend to be far more serious.
- Facial trauma can be life threatening as a result of airway compromise and the threat to the patient’s ability to get sensory information through sight and hearing; it also has many social and self-image implications for the patient and can be distracting for caregivers.
- A punctured eardrum may cause vertigo and nausea, which the CCTP may need to control with medication. The patient should be protected from aircraft noise.
- Blood or fluid coming from the auditory canal indicates a more serious injury and should be assessed with the halo test.
- A ruptured tympanic membrane is not life threatening, but should raise the suspicion for other, much more serious overpressure injuries.
- Eye injuries, although often dramatic, are not life threatening. Care typically consists of protecting the eye from further injury and transporting the patient to the ophthalmology service.
- In patients who have chemical burns to the eye, adequate washing is essential and should be performed for at least 10 minutes prior to transport for acid burns and at least 20 minutes for alkali burns.

- If an object is impaled in the eye, both the eye and the object should be prevented from movement, if possible, during transport.
- Hyphema—a collection of blood in the anterior chamber of the eye—may be a marker of damage to other structures of the eye and requires a full ophthalmologic examination.
- Rupture of the ocular globe with leak of vitreous humor may be the result of penetration by a foreign body or blunt trauma.
- Despite the dramatic presentation of enucleation of the eyeball from the eye socket, loss of vision is not inevitable with such an injury. Proper care includes protecting the eye from further trauma in transit by using a protective cup or other rigid protective device with gauze padding.
- Retinal detachment—that is, separation of the inner layers of the retina from the pigmented epithelium—may be caused by trauma, diabetic retinopathy, and sickle cell disease. With rapid diagnosis and surgery, blindness may sometimes be avoided in such cases.
- Treatment is usually not necessary on a scene call for mandibular fracture or dislocation, but provision must be made for inserting an emergency airway during the transfer of any patient whose jaw is wired shut.
- Avulsed teeth have a good chance of successful reimplantation if replaced within 1 hour.
- The critical airway and vascular structures running through the neck are relatively unprotected during trauma events. In addition, the possibility of unstable cervical spine and cord injury must always be considered.
- Securing the airway with endotracheal intubation should be considered prior to transporting any patient with a neck injury. Deterioration of the patient’s airway in the back of a transport vehicle with limited space and few personnel available to manage this condition can be disastrous.
- Most laryngotracheal injuries occur in the area of the cervical trachea and are often caused by direct blunt trauma. These

injuries can appear stable for a time, only to then be followed by rapid and catastrophic deterioration.

- In case of laryngotracheal disruptions, paralytics and muscle relaxants are absolutely contraindicated.
- Direct trauma to the front of the neck (including the thyroid gland) can cause hematomas of sufficient size to impinge on the airway. Thyrotoxicosis (thyroid storm) has a 20% to 30% mortality rate and has been rarely seen following thyroid trauma.
- Injury to the carotid, subclavian, and vertebral arteries, and to the external and internal jugular veins, can produce rapid exsanguination, hematoma formation, or embolization of air, usually resulting in mortality.
- Widespread use of seat belts has significantly decreased the incidence of morbidity and mortality related to MVCs, but these devices can cause less obvious abdominal injuries.
- Penetrating injuries may be very difficult for the CCTP to assess because detailed information about the penetrating object is often not available. Even when this information can be obtained, it is difficult to rapidly identify which structures inside the abdominal cavity were injured without the assistance of imaging studies.
- If the patient has experienced blunt or penetrating trauma to the abdominal cavity, signs or symptoms of injury may be very difficult to identify until shock becomes obvious. Because of the size of the abdominal cavity, a significant amount of blood can collect within this space and go unnoticed.
- With abdominal injuries, it is important for the CCTP to focus attention on the mechanism of injury, instead of the outward signs of trauma found on assessment.
- If a significant abdominal injury is suspected or confirmed, the most definitive treatment that the CCTP can provide is rapid transport to the trauma center, while stabilizing and maintaining the patient’s hemodynamic status as effectively as possible, so that surgical intervention can be performed if needed.

- In case of abdominal injury, performing a physical exam to rapidly identify the presence of blood loss is the most important task for the CCTP.
- The primary assessment of a patient with abdominal injury should be completed before beginning transport, and repeated frequently during transport, watching for changes that require immediate intervention.
- All patients suspected of having abdominal injuries should be transported on appropriate oxygen therapy with fluid administration. More severe cases may need aggressive airway management and blood administration.
- Resuscitative endovascular balloon occlusion of the aorta (REBOA) has recently gained traction in trauma surgery and emergency medicine as a temporizing measure for refractory hemorrhagic shock, blunt or penetrating abdominal trauma, pelvic fractures with significant hemorrhage, and ruptured abdominal aortic aneurysms.
- Before a REBOA catheter can be placed, femoral arterial access must be obtained. Continuous arterial waveform monitoring should be used to monitor blood pressure and ensure correct placement of the REBOA catheter.
- Indications for zone 1 placement of a REBOA catheter include temporary control of severe intra-abdominal hemorrhage, severe retroperitoneal hemorrhage, and traumatic arrest with suspected infradiaphragmatic injury as the source of hemorrhage.
- Indications for zone 3 placement of a REBOA catheter include severe pelvic, junctional (groin/perineum), or proximal lower extremity hemorrhage that cannot be controlled by other methods.
- The insertion depth, time of balloon inflation, amount of saline in the balloon, and blood pressure change should be recorded after insertion of the REBOA catheter.
- Ongoing research is examining the safety of REBOA catheters in transport.

- The primary concern with hollow-organ injury is the potential for peritonitis and shock to develop.
- The spleen is the most commonly injured organ in the abdominal cavity. Young adults and patients with sickle cell disease are at particular risk for spleen injury.
- Failure to recognize, understand, and treat the signs and symptoms of hypovolemic shock related to internal hemorrhage will rapidly lead to the patient's death.
- The falciform ligament in front of the liver can slice the liver in a sudden deceleration. The liver's close proximity to the lower rib cage also makes it susceptible to injury after a rib fracture occurs.
- Although penetrating trauma is the most common source of injury to the intestines, blunt trauma to the abdominal wall—often caused by a seat belt—can also damage the small bowel.
- Approximately 80% of gunshot wounds to the abdomen and 30% of stab wounds lacerate the jejunum and ileum.
- Injuries that occur to the vessels of the abdomen are usually life threatening. Although severe blunt trauma may disrupt these vessels, the most common cause of vascular injury is penetrating trauma.
- Rapid transport of patients with an injury to any of the major abdominal vessels to a hospital capable of immediate surgery is the best possible treatment.
- The presence of a pelvic fracture should alert the CCTP to the possible existence of other injuries, given the force that must be exerted to cause pelvic fracture; the potential for (possibly fatal) internal hemorrhage is high in such cases.
- Subjective assessment for pelvic fracture includes identification of the mechanism of injury, location and radiation of pain, presence of hematuria, and possibility of pregnancy. Objective examination should include observing for the rotation or uneven height of the iliac crests and uneven length of the legs, palpating the posterior aspect of the pelvic ring, and exerting gentle lateral compression posteriorly and inward medial compression once.

- Musculoskeletal injuries, although often dramatic, may distract the CCTP from more serious injuries. Nevertheless, their presence may be an indicator of the amount of energy transferred to the body and suggest the likelihood of additional injury.
- All musculoskeletal injuries should be assessed for the six Ps—pain, pallor, pulselessness, paresthesia, paralysis, and pressure—before and after any manipulation.
- Regardless of whether a fracture is open or closed, the CCTP must prioritize prevention of further injury as a result of movement, along with pain assessment and management.
- Closed fractures can be as dangerous as open fractures because of their potential to cause internal bleeding into the tissues involved.
- In an open fracture, the skin over the bone is broken, adding the potential danger of infection, which could lead to sepsis and death.
- Femur fractures can lead to a loss of at least 1 L of blood from circulation.
- Patients being transported from one facility to another who have not definitively had their spines cleared should be transported with motion restriction in place. The CCTP should apply an appropriately fitted cervical collar and firmly secure the patient to the transport stretcher.
- Planning for airway management and prevention of aspiration (especially in small aircraft) must be undertaken prior to transport of any patient with a spinal injury.
- Thoracic fractures can lead to a loss of innervation of the intercostal muscles, which then leads to respiratory insufficiency. Spinal shock, in which hypotension is accompanied by bradycardia instead of tachycardia, can affect the thoracic area or higher.
- Any patient with a cast who is transported by a CCTP should be evaluated for neurovascular function distal to the cast both prior to transport and periodically during transport. It is recommended that

the locations where pulses are found be marked on the skin and documented in the patient care record.

- External fixation of fractures using external rods held to the bone with plates and screws has become common. Adequate padding and comfortable positioning are required when transporting patients with these devices.
- Swelling under a cast can cause compartment syndrome. The most common anatomic locations for compartment syndrome are the forearms and legs, but this condition can develop in any extremity and the buttocks.
- If the diastolic blood pressure drops below 30 mm Hg over the compartment pressure, it is considered an emergency. When the compartment pressure exceeds the diastolic pressure, the blood flow in the extremity stops.
- Rhabdomyolysis, which is characterized by hyperkalemia, hypocalcemia, and myoglobinuria, initiates a cascade of events that ultimately results in cardiac arrhythmias and acute renal failure. The leading causes of rhabdomyolysis are exercise, alcohol, drugs, infections, trauma, compression, and seizures.
- When a CCTP is called to a scene involving a patient with prolonged entrapment of a large muscle area, it is imperative to start evaluation and treatment (IV fluids and sodium bicarbonate) prior to the release of the entrapped patient to avoid the mortality associated with crush syndrome.
- Although a traumatized, pulseless extremity may be repositioned successfully to reestablish circulation, doing so carries some risks. If attempted, repositioning should be done with manual traction in anatomic alignment with the long bone.
- Considerations when treating geriatric patients with trauma include several aging-related issues: presence of dentures or other dental devices, kyphosis, reduced cough reflex and increased risk of aspiration, fragility of the nasal tissues, increased risk for bleeding and use of antiplatelet or anticoagulant medications, reduced vital capacity and decreased ability for chest excursion, chest wall

stiffness, difficulty of assessing for shock and perfusion, preexisting cardiovascular abnormalities or use of cardiovascular medications, tendency toward fluid overload, slower mental processing, and difficulties in thermoregulation.

- The primary cause of fetal demise in the pregnant patient who experiences trauma is maternal shock and death. Therefore, the best treatment for the fetus is to resuscitate the mother.
- Some of the normal changes in pregnancy can mimic shock, which makes it difficult to diagnose true shock in a pregnant trauma patient.
- The risk of massive blood loss is considerably increased with trauma to the bony pelvis of a pregnant patient. Any pregnant patient who sustains a pelvic injury most certainly has a bladder and/or uterine injury.
- Fetal resuscitation centers on maternal resuscitation, and maternal resuscitation starts with the ABCs.

Vital Vocabulary

Abbreviated Injury Scale (AIS) A trauma scoring system that ranks injury severity by assigning an individual injury score of 1 to 6 to six body regions, with 1 being a minor injury and 6 being an injury with a high mortality rate; does not account for multisystem injuries.

abdominal compartment syndrome (ACS) A condition that can result from intra-abdominal hypertension, including decreased end-organ perfusion with evidence of failure; if untreated, it can lead to death.

anechoic Free from echo.

Beck triad The combination of a narrowed pulse pressure, muffled heart tones, and jugular venous distention associated with cardiac tamponade; usually resulting from penetrating chest trauma.

crush syndrome The combination of shock and renal failure after a crush injury; it may lead to the death of an entrapped person after the patient is freed from the entrapment.

diagnostic peritoneal lavage (DPL) A surgical procedure to assess for bleeding or intestinal perforation in the abdomen. Classically, a liter of crystalloid is infused into the abdomen and then drawn out to examine for the presence of blood or intestinal contents.

empyema An accumulation of pus in the pleural space.

exploratory laparotomy Surgical exploration of the abdomen.

flail chest A fracture in two or more places to two or more adjacent ribs.

focused assessment with sonography for trauma (FAST) An ultrasonographic examination directed at identifying the presence of free intraperitoneal or pericardial fluids, performed by transducing four distinct areas of the abdomen.

fracture A break in the continuity of a bone.

Glasgow Coma Scale (GCS) An evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response, which are then totaled; effective in helping predict patient outcomes.

hemothorax An accumulation of blood in the pleural space.

hyphema A collection of blood in the anterior chamber of the eye.

Injury Severity Score (ISS) A trauma scoring system that adds the squares of the three highest abbreviated injury scale scores to create a score between 1 and 75 that accounts for multiple injuries, with 1 being a minor injury and 75 being an injury with a high mortality rate.

intra-abdominal hypertension (IAH) Sustained increased abdominal pressure of more than 12 mm Hg.

intra-abdominal pressure (IAP) The static pressure inside the abdominal compartment; normally 5 mm Hg, with variations caused by respirations.

Kehr sign Left shoulder pain that may indicate a ruptured spleen. (Right shoulder pain may indicate trauma to the liver.) This referred pain stems from diaphragm irritation by intra-abdominal bleeding.

morbidity The number of nonfatally injured or disabled people. Usually expressed as a rate, meaning the number of nonfatal injuries in a certain population in a given time period divided by the size of the population.

mortality Deaths caused by injury and disease. Usually expressed as a rate, meaning the number of deaths in a certain population in a given time period divided by the size of the population.

open pneumothorax A communicating chest wound, in which air enters the pleural space from the environment; also called a sucking chest wound.

paracentesis A procedure used to drain free fluid from the abdominal cavity.

pericardial tamponade Impairment of diastolic filling of the right ventricle as a result of significant amounts of fluid in the pericardial sac surrounding the heart, leading to a decrease in the cardiac output.

pericardiocentesis A procedure in which a needle or angiocatheter is introduced into the pericardial sac to relieve cardiac tamponade.

pneumothorax An accumulation of gas or fluid in the pleural space that causes the lung to become detached from the chest wall.

poikilothermia Inability to regulate temperature in an extremity due to lack of perfusion, which may result in abnormally cold extremities.

resuscitative endovascular balloon occlusion of the aorta (REBOA) A surgical procedure in which arterial access is gained through a femoral approach, a balloon catheter is floated into the aorta, and the balloon is inflated to occlude flow; a temporizing measure for refractory hemorrhagic shock, blunt or penetrating abdominal trauma, pelvic fractures with significant hemorrhage, and ruptured abdominal aortic aneurysms, and possibly for outlying hospitals prior to transfer of a trauma patient to a higher-level trauma center.

retinal detachment Separation of the inner layers of the retina from the pigmented epithelium.

revised trauma score A trauma scoring system that rates injury severity by comparing the Glasgow Coma Scale score, the systolic blood pressure, and the respiratory rate and assigning a score ranging from 0 to 13 based on these three values; in some cases the parameters are weighted, resulting in a score ranging from 1.0 to 7.8408.

rhabdomyolysis Damage to the sarcolemma (muscle membrane) from any cause, leading to a release of potassium and myoglobin.

tension pneumothorax A pneumothorax in which an intact chest wall allows air that has entered the thoracic space to progressively accumulate, resulting in catastrophic collapse of pulmonary and cardiac structures in the chest.

thyrotoxicosis An excess of thyroid hormones resulting in a hypermetabolic crisis, including tachycardia greater than 140 beats/min; hyperthermia (sometimes greater than 103.9°F [39.9°C]); coma with agitation, nausea, vomiting, diarrhea, and unexplained jaundice; and pulmonary edema; marked by an elevated thyroxine level. Also called thyroid storm.

tracheal deviation A late sign of a tension pneumothorax in which the trachea is tugged to one side of the neck, usually opposite the side of the pneumothorax.

tracheal tugging Downward traction of the trachea toward the thoracic cavity during inspiration.

trauma injury severity score (TRISS) A scoring system that uses the results of the Injury Severity Score, the revised trauma score, and the patient's age to calculate the survivability rate; rarely used in the transport setting.

trauma score A score ranging from 1 to 16 that takes into account the Glasgow Coma Scale score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill, and relates to the likelihood of patient survival; not accurate for patients with severe head injuries.

traumatic asphyxia A condition resulting from severe, sudden crushing injury to the chest and abdomen, which forces blood backward out of the right side of the heart; engorges the veins of the chest, neck, and head; and gives the chest, neck, and head an extremely cyanotic appearance.

CHAPTER 12

Neurologic Emergencies

Heidi Hutchison, MD

OBJECTIVES

After completing this chapter, you will be able to:

1. Describe the major anatomic structures of the nervous system and their physiology (pp 544–561).
2. Describe how to perform a neurologic assessment, including the following specific assessments: Mini-Mental State Examination; assessment of speech abnormalities, cranial nerves, eyes, motor function, and sensory function; reflex testing; and evaluation of meningeal irritation (pp 561–575).
3. Discuss the pathophysiology of traumatic brain injury, including primary and secondary brain injuries (pp 579–581).
4. Explain the significance of cerebral perfusion pressure and mean arterial pressure (p 580).
5. Discuss the pathophysiology of specific neurologic injuries, including scalp injuries, skull fractures, facial fractures, epidural hematoma, subdural hematoma, and diffuse axonal injury (pp 581–589).
6. Define intracranial pressure (ICP) (p 590).
7. Explain the pathophysiology of increased ICP (pp 592–593).
8. Discuss clinical manifestations of increased ICP (p 593).
9. Discuss the concept of ICP monitoring, including indications, contraindications, complications, methods, and procedures (pp 593–601).
10. Describe the elements of multimodality monitoring (pp 601–603).
11. Discuss management of ICP during transport (p 606).
12. Discuss the pathophysiology of brain herniation (p 606).
13. Describe spinal cord injuries, including primary and secondary spinal cord injuries, complete and incomplete spinal cord injuries, and spinal and neurogenic shock (pp 607–609).
14. Explain the assessment, management, and complications of spinal cord injuries (pp 609–613).
15. Discuss types of stroke, including their assessment and management, and the use of fibrinolytic therapy (pp 613–616).
16. Describe the pathophysiology and management of intracerebral hemorrhage (p 618).

17. Describe the pathophysiology and management of subarachnoid hemorrhage (pp 618–619).
18. Describe the pathophysiology and management of Guillain-Barré syndrome (pp 619–620).
19. Discuss seizures and epilepsy, including their transport management (p 620).
20. Discuss transport considerations for patients with neurologic injuries—prior to transport, on scene, and during interhospital transport (pp 621–622).
21. Discuss considerations for managing neurologic emergencies in flight (p 622).

Introduction

Critical care patients with neurologic complications present a variety of assessment and management challenges during transport for the critical care transport professional (CCTP). The CCTP will find that an understanding of the underlying principles of neurologic structure, function, and dysfunction provides a sound basis for these patients' care. Patients with neurologic illness and injury require skilled care that includes a thorough history and physical examination as well as a variety of specialized interventions. An in-depth understanding of the various types of neurologic injuries, their pathophysiology, and current (evidence-based) management trends is fundamental to ensuring the best possible patient outcomes.

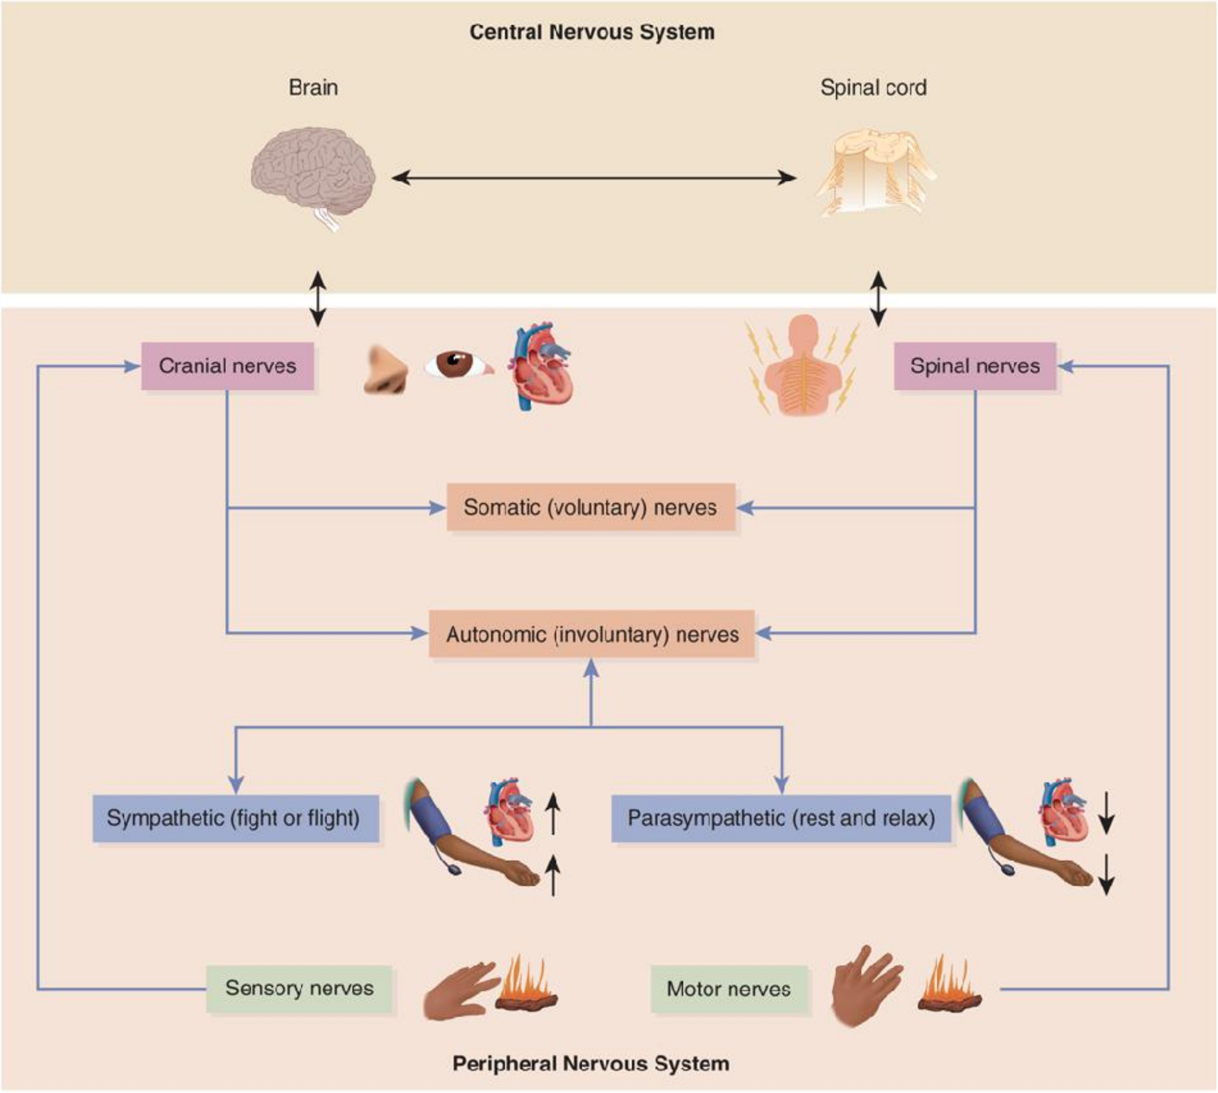
Anatomy and Physiology

The human nervous system is a truly remarkable arrangement of fibers running throughout the body that allows the body to interact with and adapt to differing environments by regulating the activities of virtually every other body system. An intimate understanding of the anatomy and physiology of the nervous system is essential to the delivery of competent medical care—and especially assessment—by the CCTP. This section reviews the structures and functions of the components of the nervous system that are most pertinent to the CCTP's care.

Nervous System Organization

The nervous system is perhaps the most diverse and highly organized organ system in the human body. Its various components are classified in terms of either their location or their function.

When classifying the parts in terms of their location, the nervous system is divided into the central nervous system (CNS), which consists of the brain and spinal cord, and the peripheral nervous system (PNS), which consists of the spinal and **cranial nerves (CN)**. The parts of the PNS are also differentiated on the basis of which information is transmitted via the fibers. Most activities mediated by the nervous system occur as a result of sensory stimulation sensed by special receptors, such as visual, auditory, or tactile receptors. **Afferent pathways** (ascending pathways) carry sensory impulses toward the CNS. **Efferent pathways** (descending pathways) carry impulses away from the CNS to effector organs, such as muscles (smooth and skeletal) or glands **FIGURE 12-1**.



Central Nervous System
Brain
Spinal cord
Cranial nerves
Spinal nerves
Somatic (voluntary) nerves
Autonomic (involuntary) nerves

Description

Physiologically, the nervous system consists of voluntary and involuntary divisions. The **voluntary (somatic) nervous system** is composed of nervous system fibers that connect the structures of the CNS with skeletal muscles and the integument. The **involuntary (autonomic) nervous system** is divided into sympathetic and parasympathetic branches, both of which are composed of nervous system fibers that connect the structures of the CNS with smooth muscle, cardiac muscle, and glands. Using these fibers, the involuntary nervous system regulates the body's internal environment by controlling specific organ systems. For example, the sympathetic nervous system is responsible for sweating, pupil dilation, ejaculation, and temperature regulation, as well as the shunting of blood from the periphery to the core—the flight-or-fight response.

Central Nervous System

The CNS consists of the brain and the spinal cord, both of which are encased in and protected by bone. The brain, located within the cranial cavity, is the largest component of the CNS. It contains billions of neurons that serve a variety of vital functions.

Cranial Anatomy and Physiology

The brain is a very delicate, gelatinous-like substance that requires the protection afforded by the skull. Although the skull primarily serves a protective function, excessive forces can cause a fracture to the adult skull and force bone fragments into vulnerable brain tissue.

The skull, or cranium, consists of the **neurocranium** (brain box) and the **viscerocranium** (the 14 bones that make up the facial skeleton). The neurocranium is the part of the skull that encloses the brain and provides a protective vault for this vital organ **FIGURE 12-2**. It has a domelike roof—the calvaria (skullcap)—and a cranial base. The neurocranium includes eight bones: the frontal bone, paired parietal bones, paired temporal bones, an occipital bone, a sphenoid bone, and an ethmoid bone.

Description Description

When the skull is observed from the inside, the superior surfaces form a smooth inner wall. In contrast, the basilar skull contains many ridges and folds with sharp edges that normally provide structure for the support of many parts of the brain **FIGURE 12-3**. When the head comes into contact with significant forces, the brain may shift over this base and become lacerated or contused by the sharp edges. This mechanism is a culprit in many of the brain injuries encountered by the CCTP.

Description

The base of the skull also contains openings, or foramina, that allow cranial nerves and blood vessels to enter and exit the cranial cavity. These openings also weaken the area, leaving it susceptible to fracture.

Special Populations

Children have extremely pliable skull bones and often have not healed their suture lines or closed their fontanelle before the age of 8 years. Excessive forces can cause a fracture in the adult skull, but in a child they are more likely to result in brain injury without skull fracture.

Meningeal Anatomy and Physiology

The entire CNS is enclosed by a set of three membranes collectively known as the meninges **FIGURE 12-4**. The cranial meninges (internal to the neurocranium) protect the brain and form the supporting framework for arteries, veins, and venous sinuses. The cranial meninges consist of three layers: (1) the **dura mater**, an external thick, dense fibrous membrane; (2) the **arachnoid mater**, an intermediate, delicate membrane; and (3) the **pia mater**, an internal delicate, vascular membrane.

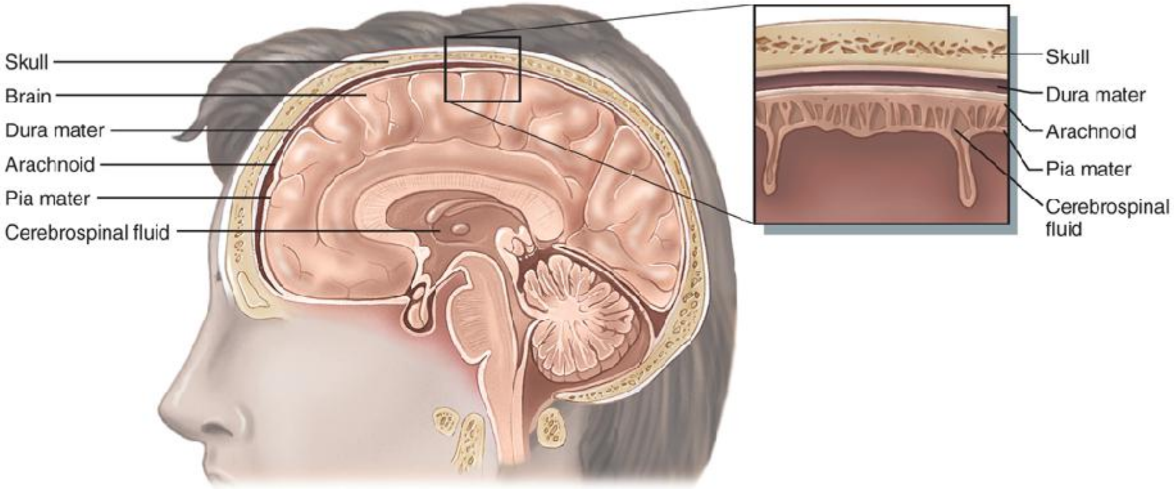

FIGURE 12-4 The meninges.

© Jones & Bartlett Learning.

Description

The dura mater, which adheres to the internal surface of the cranium, is actually a two-layered membrane. The outer layer comprises the periosteum for the cranial bones and is the layer that actually connects to the internal surface of the calvaria. The inner meningeal layer of the dura extends into the cranial space and is continuous at the foramen magnum with the dura covering the spinal cord. Except at those sites where the two dural layers separate to form a dural venous sinus, the two layers are fused. The four extensions or folds of the dura mater are the falx cerebri, the tentorium cerebelli, the falx cerebelli, and the diaphragma sellae.

The **falx cerebri** is a double fold of dura mater that divides the cerebrum into right and left hemispheres by descending vertically into the longitudinal fissure that extends from the frontal lobe to the occipital lobe. This structure is observed to *shift* on computed tomography (CT) scan during times of increased intracranial pressure due to swelling or bleeding. It extends posteriorly by becoming continuous with the tentorium cerebelli.

The falx cerebri attaches to the **tentorium cerebelli** in the midline and holds it up, giving this extension a tent like appearance. The tentorium cerebelli separates the occipital lobes of the cerebrum from the cerebellum and brainstem. This fold of the dura mater divides the brain into an upper compartment (supratentorial) and a lower compartment (infratentorial). The tentorium cerebelli is noted for its role in brain swelling or bleeding; it is the location where the **uncus** (the medially curved anterior part of the hippocampal gyrus) of the temporal lobe slips off of the tentorium and compresses cranial nerve (CN) III, which lies underneath the dural structure. This process causes a unilateral fixed and dilated pupil, characteristic of uncal herniation.

The **falx cerebelli** forms the division between the two lateral lobes of the cerebellum. The final extension of the dura mater, the **diaphragma sellae**, forms a roof over the sella turcica, which contains the pituitary gland.

Further dural separations form the **dural venous sinuses**, which are endothelial cell–lined spaces between the periosteal and meningeal layers of the dura mater. Large veins from the surface of the brain empty into these sinuses, and all blood from the brain ultimately drains through them into the internal jugular veins. These dural sinuses contain arachnoid granulations—tufted prolongations of the arachnoid mater that protrude through the meningeal layer of the dura into the venous sinuses and transfer cerebrospinal fluid (CSF) to the venous system.

The arachnoid mater is an extremely thin and delicate layer that loosely encloses the brain. It is in close contact with the meningeal layer of the dura mater owing to the pressure of the circulating CSF beneath the arachnoid layer. Web like arachnoid trabeculae (small protrusions of connective tissue) pass between the arachnoid and the pia, connecting the two layers and forming the subarachnoid space, which contains CSF and a variety of cerebral arteries and veins. Although it is commonly stated that the brain *floats* in CSF, the brain is actually suspended in the CSF-filled subarachnoid space by the arachnoid trabeculae. In essence, the meninges and CSF form a fluid-filled cushion that protects the brain and spinal cord.

The pia mater is a vascular membrane that adheres to the surface of the brain and follows its contours. It is rich in small blood vessels that supply a large volume of arterial blood to cerebral tissues. In fact, at the point where the cerebral arteries penetrate the cerebral cortex, the pia follows them for a short distance, forming a pial coat and creating a periarterial space. Tufts or folds of the pia mater in the lateral, third, and fourth ventricles form a portion of the choroid plexus, which is responsible for the production of CSF.

Three meningeal spaces are associated with the cranial meninges. The **extradural space** (also known as the epidural space) is normally not an actual space but only a potential one between the cranial bones and the periosteal layer of the dura. It becomes a real space only when blood from torn vessels pushes the periosteum from the cranium and accumulates there. Likewise, the dura-arachnoid junction, also called the **subdural space**, is normally only a potential space but may develop into a real one after a blow to the head causes bleeding into the area. The subarachnoid space between the arachnoid and the pia is an actual space that contains CSF, trabeculae, arteries, and veins.

Ventricular System and Cerebrospinal Fluid

The ventricular system is the central CSF-filled core of the brain. It consists mainly of two lateral ventricles (the largest ventricles) and midline third and fourth ventricles connected by the cerebral aqueduct **FIGURE 12-5**.

FIGURE 12-5 The ventricles of the brain and the cerebral aqueduct.

© Jones & Bartlett Learning.

Description

One lateral ventricle lies in each of the cerebral hemispheres. The lateral ventricles extend from the frontal lobe to the occipital lobe and have horns that extend from the main ventricular chamber. They are named for the respective area of the cerebrum in which they are contained. These ventricles are important structures when **intracranial pressure (ICP)** monitoring, CSF drainage, or placement of a CSF shunt becomes necessary.

The **foramen of Monro** connects the two lateral ventricles with the third ventricle, a central cavity. Situated directly above the midbrain, the third ventricle lies between the structures of the thalamus in the diencephalon.

The **cerebral aqueduct**, the narrowest portion of the ventricular system, provides communication with the fourth ventricle, which lies between the brainstem and the cerebellum. Because of its small size, it is vulnerable to obstruction. At the base of the fourth ventricle, two openings, the **foramen of Luschka** and the **foramen of Magendie**, open the ventricular system into the subarachnoid space and are essential for the normal flow of CSF.

The **choroid plexus** of the lateral ventricles and the third and fourth ventricles produces more than 70% (approximately 500 mL/d) of the CSF by active transport and diffusion. Microscopically, the choroid plexus has the appearance of a delicate sponge, consisting of a collection of blood vessels covered by a thin coating of cells. These surfaces constantly secrete CSF. Other sites within the ventricular system, including the ependymal cells lining the ventricles and blood vessels of the meninges and the blood vessels of the brain and spinal cord, produce the remaining 30% of the CSF.

Cerebrospinal fluid fills the ventricular system and surrounds the brain and spinal cord in the subarachnoid space. It provides some measure of protection for the CNS by acting as a *shock absorber* in minor acceleration and deceleration incidents; it also participates in the removal of waste products from cerebral tissue. CSF is normally clear, colorless, and odorless. The total volume of CSF is approximately 150 mL, of which only 23 mL is found in the ventricles; the remaining 127 mL fills the subarachnoid space surrounding the brain and spinal cord. Under normal conditions, CSF contains very few cells and is low in proteins, glucose, potassium ions, and calcium ions relative to plasma **TABLE 12-1**. In contrast, it is high in magnesium, sodium, and chloride ions as compared to plasma.

TABLE 12-1 Composition of Cerebrospinal Fluid

Property (Substance)	Value (Normal Range)

Property (Substance)	Value (Normal Range)
pH	7.35–7.45
Specific gravity	1.007
Glucose	70–110 mg/dL
Protein	5–8 g/dL
Pressure	7–20 cm (lumbar puncture) 3–15 mm Hg (brain ventricle)
Potassium	3.5–5.0 mEq/L
Sodium	136–142 mEq/L
Chloride	96–106 mEq/L
Calcium	4.60–5.08 mg/dL
Magnesium	1.3–2.1 mEq/L
Carbon dioxide	22–28 mEq/L

© Jones & Bartlett Learning.

Cerebrospinal fluid also has a slightly lower osmolality (289 mOsm/L) compared with serum (290 to 300 mOsm/L). This osmotic gradient is responsible for the transport of small molecules, metabolic products, and drugs from the surrounding brain tissue into the CSF. Likewise, administration of hypertonic solutions promotes diffusion in the opposite direction, removing CSF from the brain and spinal cord.

No feedback mechanisms exist for the regulation of the rate or volume of CSF production. That is, the choroid plexus continues to produce CSF even if the ventricles and subarachnoid spaces are filled and the pressure is high. Consequently, any obstruction to the normal flow of CSF, either in the ventricular system or at the level of the arachnoid granulations, may produce high CSF pressure and lead to brain damage.

Once the CSF is formed in the ventricles, it flows within the closed system. Fluid formed in the two lateral ventricles passes into the third ventricle by way of the two foramina of Monro. The fluid then flows through the cerebral aqueduct into the fourth ventricle. CSF exits the fourth ventricle by taking one of two paths. In the first path, it exits medially through the foramen of Magendie, where it is then directed to the subarachnoid space of the spinal cord. In the second path, CSF exits the fourth ventricle laterally through the two foramina of Luschka, where it is directed to the subarachnoid space surrounding the brain.

On entering the subarachnoid space, CSF moves over the surface of the spinal cord and brain, then ultimately leaves the subarachnoid space and enters the dural venous sinuses via the arachnoid villi. The arachnoid villi are highly permeable one-way valves that allow CSF to exit easily from the subarachnoid space into the venous sinuses, but do not allow blood to enter the subarachnoid space. Blockage of CSF's movement into the dural venous sinuses leads to a condition known as communicating hydrocephalus. If CSF cannot leave the ventricular system, the condition is called noncommunicating hydrocephalus.

Anatomy and Physiology of the Brain

The brain gives humans the ability to reason, function intellectually, express personality and mood, and interact with their environment. This organ weighs approximately 3 pounds (1 kg), a meager 2% of body weight, yet consumes 20% of the total cardiac output. The three major areas of the brain are the cerebrum, the brainstem, and the cerebellum.

Cerebrum

The cerebrum is, by mass, the largest part of the brain, accounting for 80% of its weight. It consists of two cerebral hemispheres that are incompletely separated by the longitudinal cerebral fissure. Both hemispheres are connected at the base of the longitudinal cerebral fissure by the corpus callosum, a large tract of transverse fibers that provides a communication link between the two cerebral hemispheres. The hemispheres are further separated from the underlying brainstem and cerebellum by the transverse cerebral fissure. Both the longitudinal and transverse cerebral fissures contain meninges and thick folds of dura: specifically, the falx cerebri and the tentorium cerebelli.

The surface of the cerebrum is characterized by numerous convolutions called **gyri**. The gyri functionally increase the cortical surface area. Grooves between adjacent gyri are called **sulci**, and the deepest grooves are referred to as **fissures**.

The **cerebral cortex** is the outermost layer of the cerebrum. This layer is 2 to 5 mm thick and contains billions of unmyelinated cell bodies of dendrites and neurons, which are often referred to as gray matter. Underneath the cerebral cortex are the white matter (myelinated) tracts, which communicate impulses from the cerebral cortex to other areas of the brain. Three types of fibers are found in the white matter; they are named for the role they play in communicating information:

- *Commissural* (transverse) fibers are tracts that communicate between corresponding parts of the two hemispheres. The corpus callosum is the largest of these fiber tracts.
- *Projection* fibers communicate between the cerebral cortex and lower portions of the brain and spinal cord.
- *Association* fibers allow communication between various regions of the same hemisphere.

The **cerebral hemispheres** are divided into four paired lobes, based on the divisions demarcated by the fissures: the frontal lobes, the parietal lobes, the temporal lobes, and the occipital lobe **FIGURE 12-6**. In everyday speech, and indeed throughout this chapter, the paired lobes are referred to in the singular form; for example, *the frontal lobe* can be understood to mean the structure comprising both lobes. Another area found deeper inside the cerebrum, the so-called limbic lobe, is also classified as a lobe, although it is technically part of the temporal lobe.

Description

Frontal Lobe

The largest of the four lobes of the cerebral hemispheres is the **frontal lobe**, which accounts for approximately one-third of the total cortical tissue. The frontal lobe lies underneath the frontal bone of the skull; it is separated posteriorly from the parietal lobe by the central fissure and inferiorly from the temporal lobe by the lateral fissure. It is further divided into different areas based on the functions for which those regions are responsible **FIGURE 12-7**.

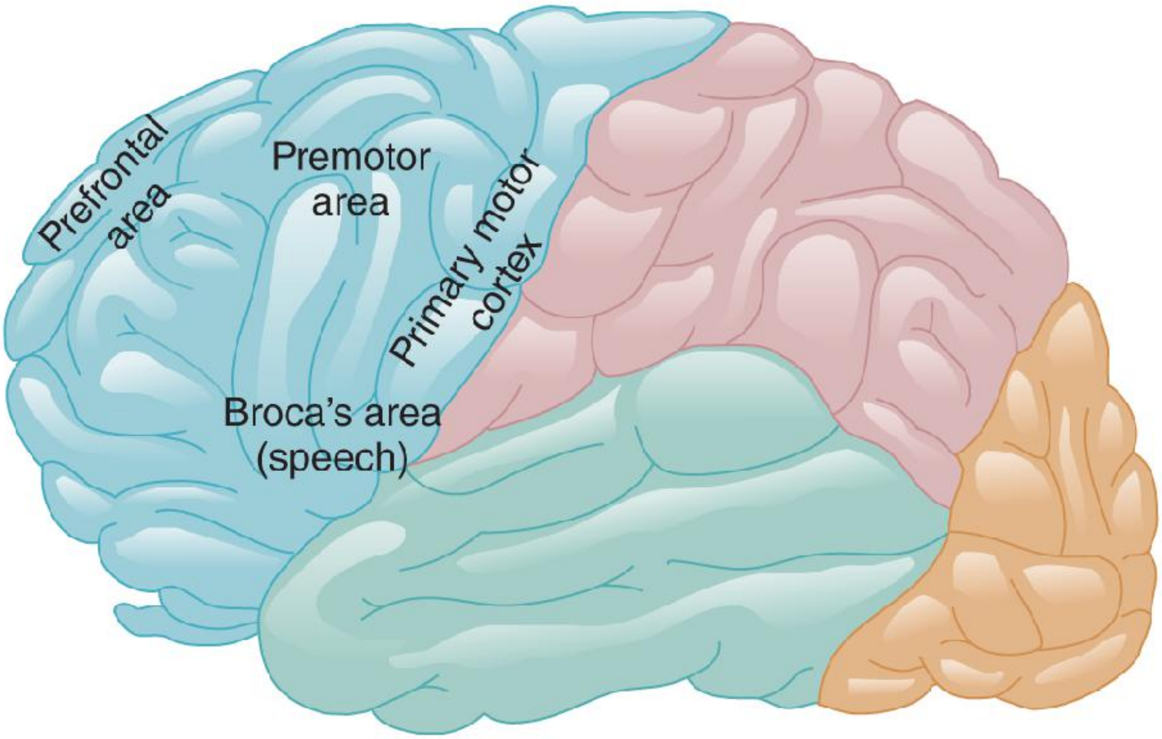

FIGURE 12-7 The frontal lobe of the cerebrum is divided into specific areas based on function.

© Jones & Bartlett Learning.

The **prefrontal area** of the frontal lobe is responsible for a variety of higher functions. This area controls thought, concentration, depth perception, abstract thinking, memory, and autonomic nervous system responses to emotional changes, with help from the thalamus and hypothalamus.

The **premotor area** lies adjacent to the motor area. These areas are connected by cranial nerves III, IV, VI, IX, X, and XII, allowing for coordination of certain movements. For example, stimulation of the lateral portion results in gross generalized movements, such as turning of the eyes and head, turning of the trunk with the head, and coordinated eye movements.

The **motor area** contains pyramidal cells that control voluntary motor function on the opposite side of the body. Body parts that require a great deal of dexterity, such as the thumb and tongue, are allotted a larger motor area than are body parts that do not require much dexterity, such as the shoulder and trunk.

The **Broca area**, located at the inferior frontal gyrus, is an associative area that participates in the formulation of words. Any damage to this area, from either primary injury (direct trauma) or secondary injury (ischemia), results in expressive or nonfluent aphasia.

Parietal Lobe

The **parietal lobe** is situated directly posterior to the frontal lobe and lateral to the central fissure. This lobe is largely responsible for sensory functions, including the integration of sensory information; awareness of body parts; interpretation of touch, pressure, and pain; and recognition of object size, shape, and texture. The parietal lobe consists of a sensory strip that lies adjacent to the motor strip of the frontal lobe. Sensory areas for certain parts of the body are located close to the motor areas for the same body part. Fibers going to the sensory strip carry input associated with cutaneous and deep sensibility sensations, as well as cutaneous sensations of touch, pressure, position, and vibration. Input from the thalamus also reaches the sensory strip.

Associative areas of the parietal lobe interpret sensory input in terms of size, shape, texture, and weight. They enable individuals to localize sensations and define them in terms of pressure, temperature, or vibration. Interpretive aspects of the parietal lobe’s response to stimuli include awareness of body parts, orientation in space, and recognition of environmental spatial relationships.

Occipital Lobe

Occupying the most posterior portion of the cerebrum, the **occipital lobe** is separated from the cerebellum by the tentorium cerebelli. This area of the brain is the primary receptive area for vision, specifically the interpretation of visual stimuli. The primary visual cortex receives impulses from projections of the optic tract; these impulses are then referred to the visual associative areas for interpretation and integration. A person who sustains an injury to the visual associative areas will be able to see objects but will not be able to recognize or identify them (a condition known as visual agnosia).

Temporal Lobe

Located beneath the temporal bone of the cranium, the **temporal lobe** lies in the lateral portion of the cerebrum. It is separated from the frontal and parietal lobes by the lateral fissure. The primary functions of this region relate to hearing, speech, behavior, and memory.

Within the temporal lobe, the primary auditory receptive areas receive sound impulses and assist in determining the sound's source and interpreting its meaning. The auditory associative area is part of the superior temporal gyrus and is known as the **Wernicke area**. Usually the largest part of the dominant hemisphere, it is responsible for comprehension of both written and spoken words. If the Wernicke area becomes damaged, a person may hear sounds, but they will be meaningless (a condition known as receptive aphasia).

In the superior portion of the temporal lobe, at the junction of the frontal, parietal, and temporal lobes, lies the interpretative area. This area is responsible for integrating the auditory, visual, and somatic associative areas to form complex thoughts and memory. It plays a significant role, along with the frontal lobe, in cerebration.

Limbic Lobe

The **limbic lobe** (also called the rhinencephalon) is, strictly speaking, an anatomic part of the temporal lobe, although its function is sometimes discussed separately from the temporal lobe. This area forms the border of the lateral ventricles and contains the hippocampus, uncus, primary olfactory cortex, and amygdaloid nucleus. Functions of the limbic lobe include self-preservation, primitive behavior, moods, the visceral processes associated with emotion, short-term memory, and the interpretation of smell **FIGURE 12-8**.

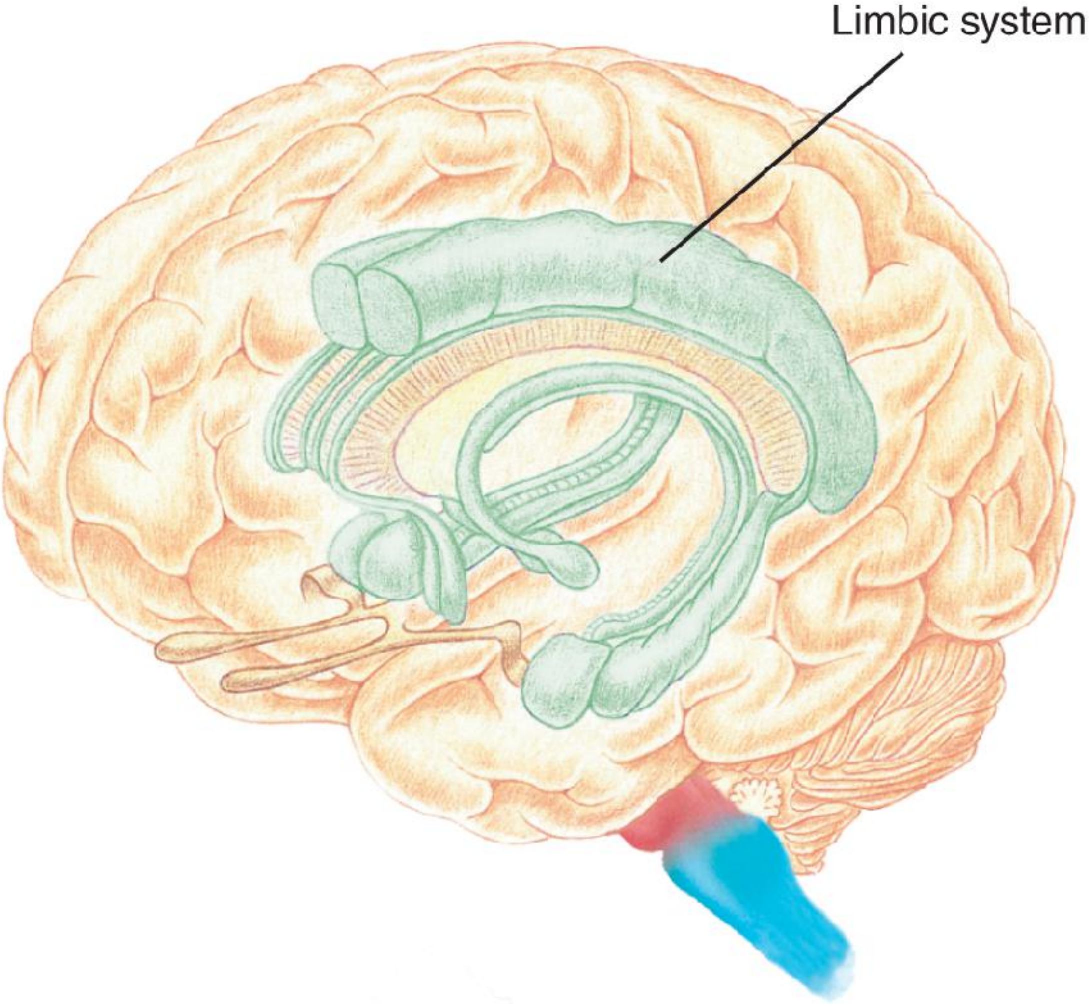

FIGURE 12-8 The limbic system is the seat of emotions, instincts, and other functions.

© Jones & Bartlett Learning.

Diencephalon

The **diencephalon** is a major division of the cerebrum, which itself is divided into four regions: the thalamus, the hypothalamus, the subthalamus, and the epithalamus. The lowest structure of the cerebrum, the diencephalon actually lies on top of the brainstem surrounding the third ventricle. Also found in this region are the pituitary gland and the internal capsule.

The **thalamus**, the largest portion of the diencephalon, consists of a pair of egg-shaped masses of gray matter that form the lateral walls of the third ventricle and are connected to the midbrain. This structure acts as a relay station for motor and sensory activity; basic neuronal activity, such as the processing of brain activity; and memory, thought, emotion, and complex behavior. The relay role performed by the thalamus is a complex function coordinated with the parietal lobe of the cerebrum. All sensory pathways, except for the olfactory pathway, communicate with an area of the thalamus. When sensory impulses reach the thalamus, it sorts and sends each impulse to the appropriate area of the cerebral cortex for final processing. The role of the thalamus in motor activity is to coordinate the cerebrum and cerebellum to produce a smooth, integrated motor response.

Located below the thalamus, the **hypothalamus** forms the floor and the anterior walls of the third ventricle. The pituitary gland lies below the hypothalamus in the sella turcica and is connected to the hypothalamus by the pituitary stalk. The hypothalamus has several functions related to regulating and maintaining the internal body environment (homeostasis) and interacting with the limbic system to generate physical responses to emotions (implementation of behavioral patterns). The hypothalamus exerts its influence through the endocrine system and neuronal pathways **TABLE 12-2**.

TABLE 12-2 Functions of the Hypothalamus

Function	Mechanism
Temperature regulation	Temperature of blood flowing through the hypothalamus is monitored. Impulses are sent to the sweat glands, peripheral vessels, and muscles (shivering).

Function	Mechanism
Regulation of food intake	The hunger center produces the sensation of hunger when stimulated. The satiety center decreases the desire for food when the stomach is full or blood glucose is high.
Regulation of water intake	The hypothalamus monitors serum osmotic pressure; it triggers the release of antidiuretic hormone when osmotic pressure is high and inhibits this hormone’s release when osmotic pressure is low.
Control of pituitary gland secretion	Releasing or inhibiting factors are sent from the hypothalamus to the pituitary gland.
Control of behavioral responses	The hypothalamus mediates visible physical expressions in response to emotions, such as blushing, dryness of mouth, and clammy hands.
Control of the autonomic nervous system	Stimulation responses of the anterior region of the hypothalamus elicit the parasympathetic system response. The posterior region of the hypothalamus mediates the sympathetic system response.

© Jones & Bartlett Learning.

The **epithalamus** is located in the **dorsal** portion of the diencephalon and contains the pineal gland, which is thought to play a role in physical growth and sexual development. The **subthalamus**, which is located below the thalamus, is closely related to the basal ganglia in terms of its function.

Basal Ganglia

The **basal ganglia** comprise several masses of nuclei located deep within the cerebral hemispheres. These structures are primarily associated with fine motor function, particularly of the hands and lower extremities. They provide a pathway between, and assist in processing information from, the cerebral motor cortex and the thalamus. Much of the basal ganglia's function is conducted through the extrapyramidal (involuntary) pathways.

Internal Capsule

As radiation and projection fibers coming from various parts of the cerebral cortex converge at the brainstem, they form the corona radiata. At the point where the fibers enter the thalamus-hypothalamus region, they are collectively called the **internal capsule**. Thus, the capsule is a massive bundle of efferent and afferent fibers connecting the various subdivisions of the brain and spinal cord.

Brainstem

The brainstem acts as a bridge between the cerebral hemispheres and the spinal cord; it is the only structure connecting the cerebellum with the cerebral cortex. All motor and sensory fibers, both those ascending to the cerebral hemispheres and those descending to the spinal cord, travel through the brainstem. The brainstem consists of three parts: the midbrain, the pons, and the medulla oblongata.

The **midbrain** is a small area extending between the diencephalon, the pons, and the third ventricle **FIGURE 12-9**. Several important structures are found in the midbrain, including the cerebral aqueduct (Sylvian, which connects the third and fourth ventricles), the superior colliculi (which controls visual reflexes and the center for upward gaze) and inferior colliculi (auditory system), cranial nerves III (oculomotor) and IV (trochlear), and the reticular activating system (RAS).

FIGURE 12-9 The midbrain.

© Jones & Bartlett Learning.

Description

The midbrain's major function is to relay stimuli involved in voluntary motor movement of the body. The tectospinal and rubrospinal tracts of the extrapyramidal (involuntary) motor system are also found in this region: The **tectospinal tract** controls reflex motor movements in response to visual and auditory stimuli, whereas the **rubrospinal tract** controls the tone of flexor muscles. The **Edinger-Westphal nucleus** is located in the midbrain and is responsible for mediating the autonomic reflex centers that govern pupillary accommodation to light.

Located between the midbrain and the medulla oblongata, the **pons** **FIGURE 12-10** relays information to and from the brain and spinal cord along fiber tracts. Motor tracts for motor movement descend through the pons, and sensory tracts necessary for touch, pressure, proprioception, pain, and temperature ascend through the pons. The **ventral** surface of the pons contains fibers that connect to the cerebellum, which allows for efficient and smooth transmission of information from the cerebellum to the cerebral cortex. Two respiratory control centers are found in the pons: the apneustic center, which is responsible for stimulating and producing sustained respirations, and the pneumotaxic center, which antagonizes the apneustic center, clinically inhibiting inspiration. Both centers of control communicate with the medullary respiratory center. Cranial nerves V (trigeminal), VI (abducens), VII (facial), and VIII (acoustic) originate in the pons.

Description

The **medulla oblongata**, the lowermost portion of the brainstem, connects with the spinal cord at the foramen magnum. Decussation (crossing) of the motor fibers occurs in the caudal aspect of the medulla. Inferior to the point of decussation, stimuli from the left side of the brain control movement on the right side of the body, and vice versa.

The medulla also contains groups of neurons that control involuntary functions such as swallowing, vomiting, coughing, vasoconstriction, and respiration. The respiratory center of the medulla works in conjunction with the apneustic and pneumotaxic centers of the pons to produce controlled respirations.

The medullary respiratory control center is responsible for the basic involuntary rhythm of respiration, but must be stimulated from higher centers to maintain a life-sustaining respiratory pattern. The reticular formation also has its beginnings in the medulla, with cranial nerves IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal) exiting from the medulla.

Cerebellum

The cerebellum is located just superior and posterior to the medulla oblongata and consists of three major parts: (1) the cortex, or gray outer covering; (2) the white matter, which connects the cerebellum to other parts of the CNS; and (3) four pairs of deep cerebellar nuclei, located deep within the white matter. The gross structure of the cerebellum includes two distinct hemispheres and the vermis, or central portion **FIGURE 12-11**.

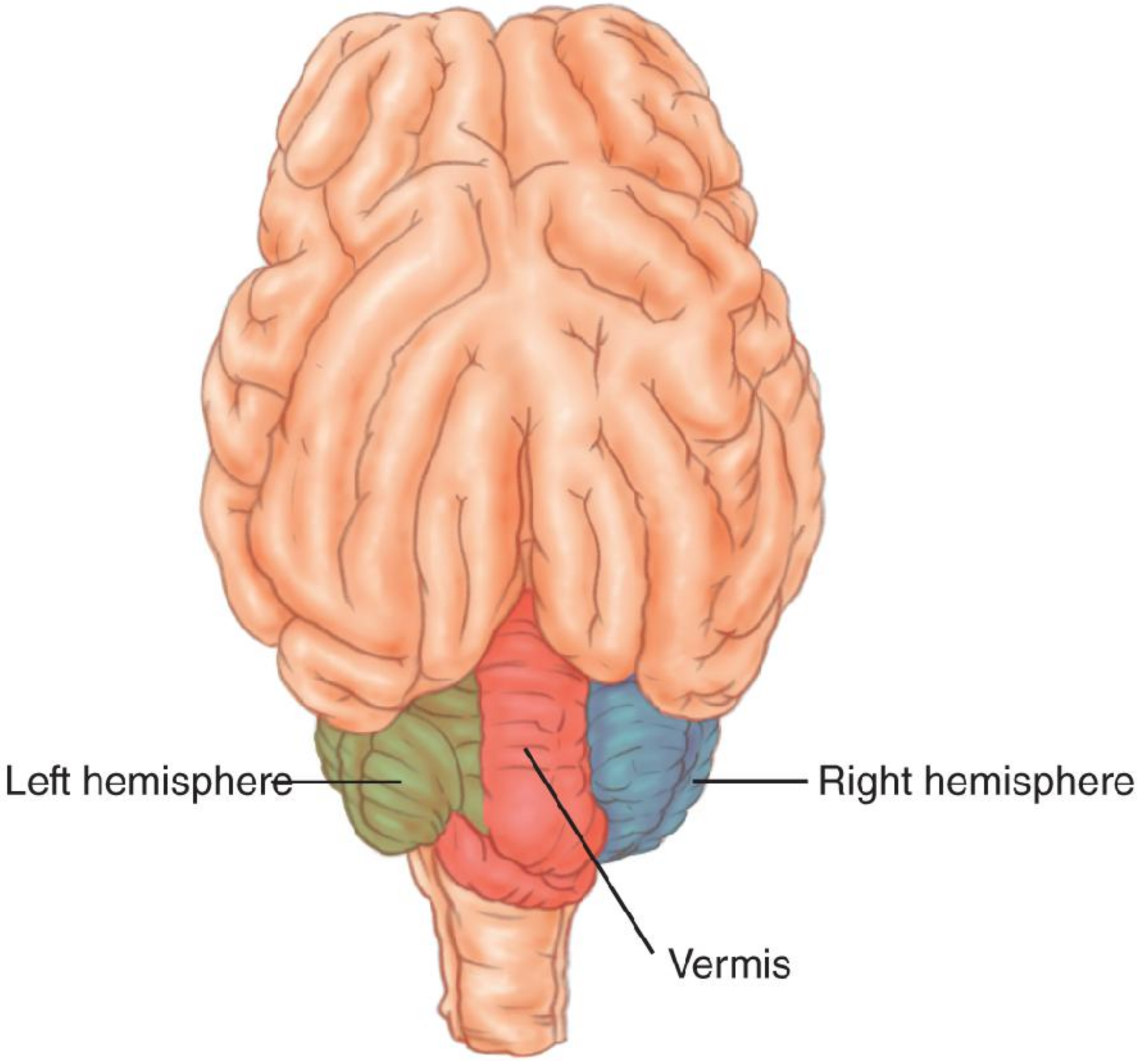

FIGURE 12-11 The vermis and the hemispheres of the cerebellum.

© Jones & Bartlett Learning.

The primary function of the cerebellum is coordination of voluntary movement. The vermis is responsible for trunk control. The three lobes of the hemispheres are responsible for upper and lower extremity control, including control of antigravity muscles, proprioception, tactile impulses, motor tone facilitation, volitional breaks in movement, synergy of movement, and equilibrium. Input is received from sensory pathways of the spinal cord, the brainstem, and the cerebrum; output is transmitted through the descending motor pathways. Cerebellar influences work through continual excitatory and inhibiting stimuli, resulting in smooth motor movements instead of rapid, erratic movements.

Reticular Formation

The **reticular formation (RF)** comprises a set of neurons that extends from the upper level of the spinal cord, through the medulla, pons, and midbrain, and into the thalamus and cerebral cortex. Composed of both motor and sensory tracts, the RF is closely tied to functions of the basal ganglia, thalamus, cerebellum, and cerebral cortex. This bundle of neural fibers has many excitatory and some inhibitory capabilities, and can enhance, suppress, or modify impulse transmission. The main role of the descending RF is to provide a balance between the excitatory and inhibitory stimuli so as to maintain normal muscle tone, which supports the body against gravity. Also located in the RF are centers for blood pressure (BP), respiration, and heart rate function. The ascending RF is essential for arousal, attention, and perceptual association.

Reticular Activating System

The **reticular activating system (RAS)** is a diffuse system—not an actual anatomic structure—that extends from the lower brainstem to the cerebral cortex. Input from multiple sensory pathways is received in the RAS, and signals are transmitted to various areas of the cerebral cortex, providing multiple opportunities for stimulation of the RAS. The lower portion of the RAS, which is rooted in the brainstem, assists with control of sleep-wakefulness cycles and consciousness; the upper portion, which is in the thalamus, facilitates focusing attention on a specific task. When the upper portion of the RAS sustains damage, the person enters a vegetative state, exhibiting sleep-wake cycles and other brainstem functions but no upper levels of cerebration.

Cerebral Circulation

The brain makes huge demands on the other body systems: 15% to 20% of total cardiac output and 40% of the oxygen in the available blood are required to meet normal cerebral metabolic needs. The predominant metabolic process that occurs in the brain is the oxidation of glucose to provide energy. Therefore, the overall goal of cerebral circulation is to provide enough blood to supply oxygen, glucose, and nutrients for this process.

The total amount of blood received by the brain is distributed carefully among those areas with high metabolic demands. Carbon dioxide serves as the primary regulator for blood flow in the CNS. A potent vasodilator, its presence causes more blood to flow to certain areas of the brain. The brain is supplied blood by two pairs of arteries: the two vertebral arteries and the two internal carotid arteries **FIGURE 12-12**.

Description

Circle of Willis

The **circle of Willis** is a collection of arteries located at the base of the skull that is divided into anterior and posterior circulation branches **FIGURE 12-13**. Its physiologic significance derives from the fact that this structure may be able to compensate for reduced blood flow from any one of the major contributors to cerebral circulation. Some individuals, however, may have hypoplastic or missing communicating vessels, which may inhibit this compensatory mechanism.

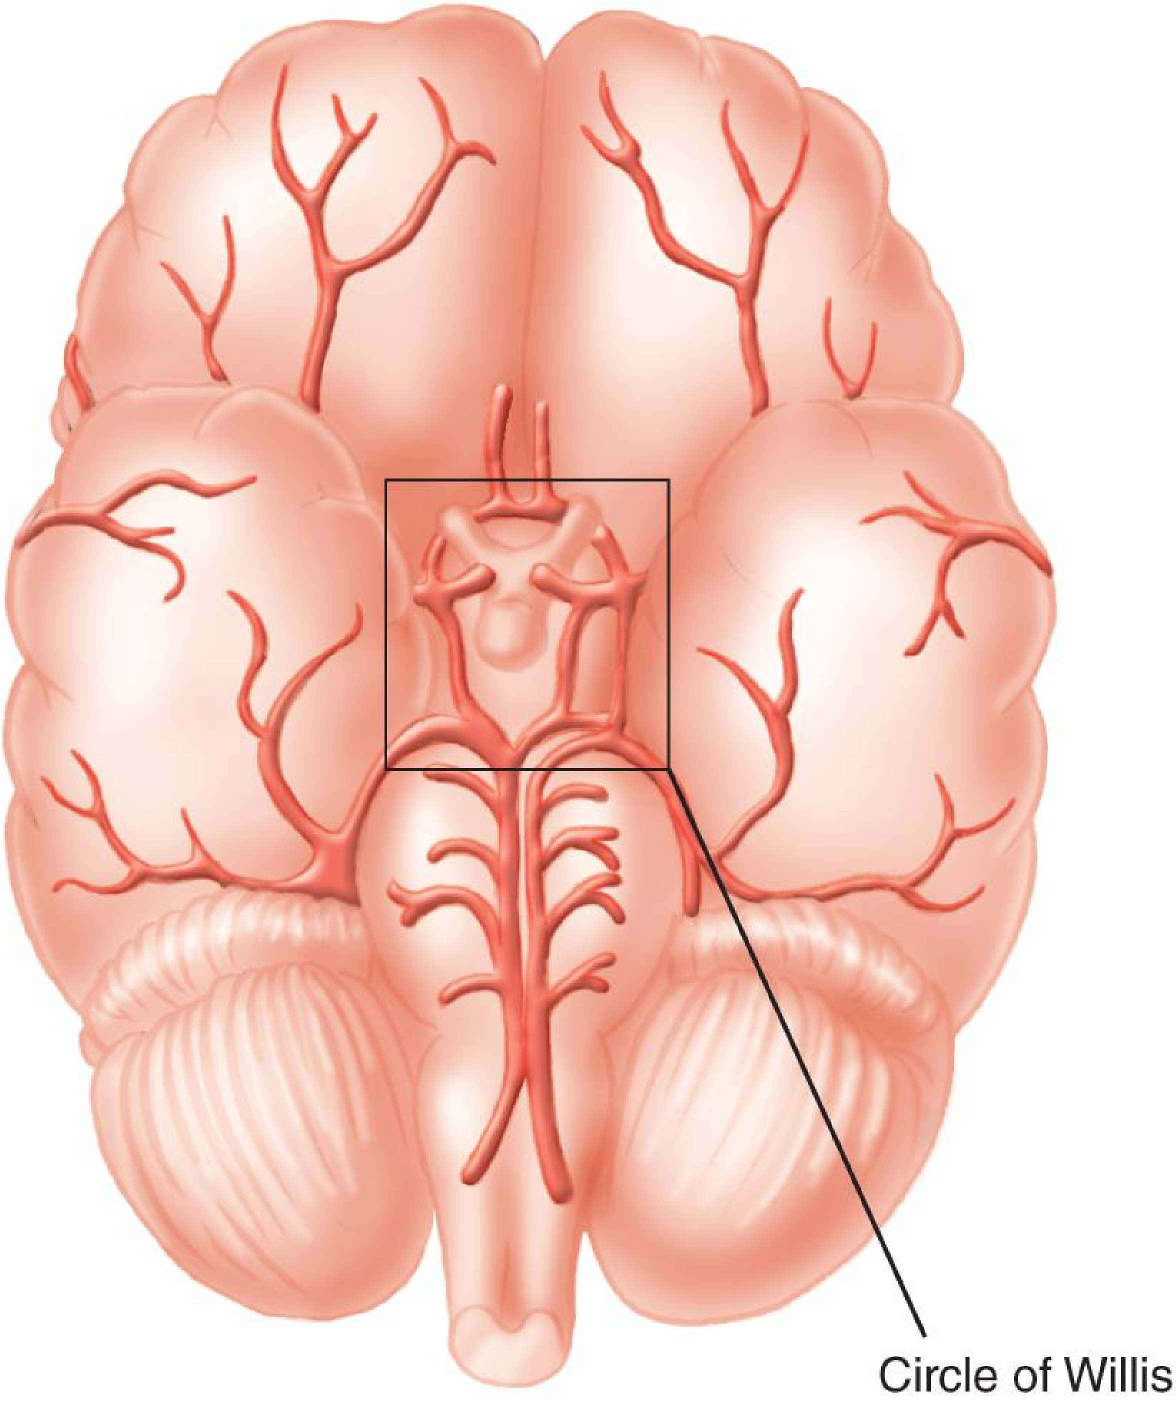

FIGURE 12-13 The circle of Willis.

© Jones & Bartlett Learning.

The circle of Willis is fed by the internal carotid and basilar arteries. The three cerebral arteries (anterior, middle, and posterior) supplying each hemisphere are connected by communicating arteries to form a complete circle. **TABLE 12-3** lists the areas of the brain supplied by the cerebral arteries.

TABLE 12-3 Major Cerebral Arteries

Cerebral Artery Origin	Structures Supplied
Anterior	Basal ganglia, corpus callosum, medial surface of cerebral hemispheres, and superior surface of frontal and parietal lobes
Middle	Frontal lobe, parietal lobe, and cortical surface of temporal lobe
Posterior	Occipital lobes and the medial and lateral aspects of the temporal lobe

© Jones & Bartlett Learning.

Vertebral Arteries

The vertebral arteries, or posterior circulation, arise from the subclavian arteries and enter the skull through the foramen magnum, ventrolateral to the spinal cord. At the level of the pons, the two vertebral arteries join to form the basilar artery. The basilar artery then divides at the level of the midbrain to form paired posterior cerebral arteries. The vertebral arteries and their branches predominantly supply blood to the cerebellum, brainstem, and spinal cord, as well as to some parts of the cerebrum. The basilar artery continues upward into the posterior portion of the circle of Willis and into the two posterior cerebral arteries.

Internal Carotid Arteries

The internal carotid arteries anteriorly supply a proportionately greater amount of blood flow. They originate from the common carotid arteries and enter the cranium through the base of the skull. At the base of the brain, the internal carotid arteries connect to the circle of Willis and then branch into the anterior and middle cerebral arteries, which provide the majority of the anterior circulation.

Venous Drainage

The superficial and deep veins of the brain enter the dural venous sinuses, which subsequently drain into the internal jugular veins. Cerebral veins on the superolateral surfaces of the brain drain into the superior sagittal sinus. Cerebral veins on the posteroinferior aspect drain into the straight, transverse, and superior petrosal sinuses **FIGURE 12-14**.

Blood–Brain Barrier

Several protective mechanisms act together to maintain the delicate balance of the brain's internal environment. Particularly noteworthy in this respect is the **blood–brain barrier**, the network of endothelial cells and astrocytes (neuroglia) that envelops the fragile cerebral capillaries. The blood–brain barrier is found throughout the brain except in small areas of the fourth ventricle, hypothalamus, and pineal gland, where chemoreceptors and osmoreceptors sample the circulating plasma. This barrier regulates the transport of nutrients, ions, water, drugs, and waste products through the process of selective permeability.

From a functional standpoint, the blood–brain barrier features tight junctions between adjacent capillary endothelial cells; in contrast, the capillaries found elsewhere in the body have pores between adjacent endothelial cells. Some molecules are easily transported through the endothelial cells in the blood–brain barrier, whereas this barrier blocks other toxic or harmful compounds so as to protect the fragile neurons.

Passage of substances across the blood–brain barrier depends on the particles' size, lipid solubility, chemical breakdown, and protein-binding potential. This barrier is readily permeable to water, oxygen, carbon dioxide, and glucose. Likewise, most drugs or compounds that are lipid soluble and stable at a physiologic pH rapidly cross the barrier. Uptake of sodium and potassium is slow, however, as is uptake of dyes and other organic and inorganic anions and cations.

Anatomy and Physiology of the Spinal Cord

An understanding of the form and function of spinal anatomy coupled with a high level of suspicion for spinal cord injury (SCI) is required to decipher the often subtle findings associated with a possible SCI.

Spine

The spine usually consists of 33 irregular bones (vertebrae) that articulate to form the vertebral column, which is the major structural component of the axial skeleton **FIGURE 12-15**. Some patients may have 32 or 34 vertebrae. These skeletal components are stabilized by both ligaments and muscles. Together these components support and protect neural elements while allowing for fluid movement and erect stature.

Description

Vertebrae are identified according to their location as cervical, thoracic, lumbar, sacral, or coccyx. Each vertebra is unique in appearance, but collectively they share basic structural characteristics. The **vertebral body**, or anterior weight-bearing structure, is made of bone that provides support and stability. Shared components of most vertebrae include the body, lamina, pedicles, and spinous processes **FIGURE 12-16**.

Description

The inferior border of each pedicle contains a notch forming the **intervertebral foramen**. This space in the middle of the vertebra allows for the exit of a peripheral nerve root and spinal vein as well as the entrance of a spinal artery on both sides at each vertebral junction.
